Using the technique developed by Liang and Pardee (1992), we initiated an extensive display of the genes specifically expressed in the midgut of *Anopheles gambiae* and induced or up-regulated after a blood meal. cDNAs corresponding to mRNAs expressed between 18 to 24 hours after the blood meal are selected and further characterized. The ones having the expected expression pattern will then be used to isolate full-length c-DNA's. We have currently selected 100 of such cDNA fragments. Verification of their expression pattern and determination of their partial sequence is under-way.

Liang, P., & Pardee, A. B. (1992). *Science*, 257 967-971.

DAY-LENGTH DEPENDENT GENE EXPRESSION OF JUVENILE HORMONE ESTERASE IN THE COLORADO POTATO BEETLE

A.M.W. Vermunt, A.B. Koopmanschap, C.A.D. de Kort

Department of Entomology, Wageningen Agricultural University, Wageningen, The Netherlands

In the Colorado potato beetle, juvenile hormone (JH) plays a key role in day-length dependent physiological processes and it is the JH titer which determines whether reproduction or diapause will occur. One of the main factors, besides JH synthesis, which influences the JH titer is enzymatic degradation of JH by a specific esterase. Beetles reared under short-day conditions showed high JH esterase activity after the initial drop in JH titer. If the JH titer decreases to almost zero, the beetles will enter diapause. The JH esterase was isolated from the hemolymph and appeared to be a dimer consisting of 57 kDa subunits. The cDNA encoding JH esterase was cloned and used as probe to follow the expression of the gene in the fatbody. The level of mRNA was higher in short-day beetles than in long-day beetles, which corresponds with the enzyme activity.

09-059

CLONING AND EXPRESSION OF HEAT SHOCK PROTEIN GENE AT THE ONSET OF POST-DIAPAUSE DEVELOPMENT IN *BOMBYX MORI* (LEPIDOPTERA: BOMBICIDAE)E. Kosegawa, W. Hara¹, T. Kikawada, K. Shimizu and T. OkajimaDepartment of Genetics and Breeding, National Institute of Sericultural and Entomological Science, Yamanashi, Japan - ¹ Department of Research Planning and Coordination, National Institute of Sericultural and Entomological Science, Ibaraki, Japan

The silkworm, *Bombyx mori*, enter diapause at the early gastrula stage. The embryonic diapause can be artificially terminated by hot HCl treatment after the chilling for one month. Some proteins were found to be induced at the onset of post-diapause development after the hot HCl treatment (Coulon-Bublex and Dorel, 1991; Kosegawa et al., 1991). These include proteins which resemble typical heat shock protein HSP70 in terms of isoelectric point and molecular weight. Cloning of HSP70 cDNA and Northern analysis detected the HSP70 gene transcription in the artificially activated eggs. On the basis of the results obtained, the role of HSP70 on diapause termination will be discussed.

09-060

EXPRESSION PATTERNS AND CHROMOSOMAL LOCALISATION OF THE LATE TRYPSIN GENE IN *AEDES AEGYPTI*.F.O. Oduol¹, J.M. Crampton¹, D.W. Severson², P. Eggleston³.

¹Wolfson Unit of Molecular Genetics, Liverpool School Of Tropical Medicine, Pembroke Place, Liverpool L3 5QA, UK - ² Department of Animal Health and Biomedical Sciences, University of Wisconsin, Madison, Wisconsin, USA - ³ Department of Genetics and Microbiology, University of Liverpool, Donnan Laboratories, Liverpool L69 3BX, UK.

Currently, there is much interest in the development of transgenic technology to provide novel strategies for vector control through the manipulation of mosquito genomes. Ultimately, the successful exploitation of this approach may require some degree of control over transgene expression. It may, for example, be useful to have promoters which limit expression to certain tissues (such as the mid-gut) or to certain times (perhaps post blood meal). We are investigating the late trypsin gene from the mosquito *Aedes aegypti*, which is a serine protease expressed at high levels after a bloodmeal. Northern blot analysis of temporal expression patterns in the mid-gut reveals that late trypsin mRNA can be detected 8 hours after the bloodmeal, with maximal expression at 24 hours post-bloodmeal. Spatial expression patterns have also been investigated by hybridising histological sections of the mid-gut with late trypsin probes, at various time points after the bloodmeal. The late trypsin gene (*TyAD1*) has been genetically mapped using RFLP multipoint linkage analysis among F2 intercross individuals from a pairwise mating between a Liverpool strain female and a RED strain male. This analysis located *TyAD1* to chromosome 2 with the following linkage associations; *spot-abdomen* [17.3cM] *LF98* [3.7cM] *TyAD1*.

09-061

ORGANIZATION OF GENES CODING FOR MALE SPECIFIC SERUM PROTEINS IN THE MEDFLY *CERATITS CAPITATA*Christophidis G.¹, Thymianou² S., Mauroidis M.², Mintzas A.², and K. Komitopoulou¹¹ Department of Biology, Section of Biochemistry, Molecular and Cellular Biology and Genetics, Athens Greece² Department of Biology, Section of Genetics, Cell Biology and Development, Patras Greece

Nine genomic clones containing genes coding for male specific serum proteins have been isolated by screening a genomic library with an MSSP cDNA clone. Restriction mapping of them has revealed the existence of four MSSP gene copies, which are organized in two pairs, named a (a1 and a2) and b (b1 and b2). Each pair is contained within 8.5 kb and the two copies are tandemly arranged. Moreover an insertion of a mariner-like element has been found 320 bp upstream of the transcription site of a1 and a2 genes.

Subcloning and sequencing of appropriate restriction fragments containing each MSSP copy and its flanking sequences, showed that they have exactly the same organization: each one consists of two exons, one small and one large, separated by an intron 400 long. They have also small untranslated regions, 23 bp at the 5' end and 79 bp at the 3' end.

Comparison of DNA sequences containing the four MSSP genes showed a great similarity not only in coding regions but also in introns and the DNA surrounding the genes. The a2 MSSP gene is almost identical to the cDNA clone which has been used as a probe for the isolation of the genomic clones, with only one nucleotide substitution. Comparison of a1 and a2 copies at the DNA level showed 15 nucleotide substitutions in the coding region but 7 amino acid changes at the predicted polypeptide sequence. Comparison of b2 and a2 coding regions showed 38 nucleotide substitutions and an insertion of 3 nucleotides. These preliminary results showed that the MSSP genes belong to a small multigene family. The remarkable similarity at the DNA and protein level suggests that they have resulted from recent duplications.

09-062

THE EVOLUTION OF AN INTRON IN THE ACETYLCHOLINESTERASE GENES OF DIPTERA

G.K. Banks^{1,2}, C.A. Malcolm², A. Ascolillo², L.M.C. Hall³ and A.S. Robinson^{1*}

¹ IMBB, FORTH-HELLAS, Heraklion, Crete

² School of Biological Sciences, Queen Mary and Westfield College, University of London, UK

³ Dept. Of Medical Microbiology, London Hospital Medical College, University of London, UK

Acetylcholinesterase (AChE) hydrolyses the neurotransmitter acetylcholine. It is the target for carbamate and organophosphate insecticides. Resistance to these insecticides conferred by an insensitive form of AChE has developed in several pest insect species. This has stimulated studies on the molecular genetics of insect AChE genes. The DNA sequence and genomic organisation of several Dipteran AChE genes have been determined. In each case the gene has been complex with eight or nine introns. Despite up to ten fold variation in intron size between species, the exon sizes and exon intron boundaries are conserved. However in two species, *Anopheles stephensi* and *Culex pipiens*, an additional intron splits the exon corresponding to exon 4 in *Drosophila melanogaster*. In addition to *D. melanogaster*, the intron is absent from the AChE genes in *Ceratitus capitata* and *Anopheles albimanus*. It is this last finding which makes the results interesting, since *A. stephensi* is more closely related to *A. albimanus* than *C. pipiens*, it appears that the intron has either been lost from the gene in the other species, or that there have been two separate insertion events into an identical position within the gene. An alternative, but perhaps more intriguing explanation may be the possibility of two genes in some species.

These observations and a discussion of the various explanations will be presented. Further data now being accumulated on the presence or absence of this intron in AChE genes of other Dipteran insects for which sequence and/or clones are available will also be presented.

09-064

NEW ANEUPLOID STRAIN DERIVED FROM ANTENNAPEDIA MUTANT LINE, *Nc* OF *BOMBYX MORI* (LEPIDOPTERA : BOMBYCIDAE)

K. Mase, T. Yamamoto, W. Hara¹

Research Team of Silkworm Breeding, National Institute of Sericultural and Entomological Science (NISES), Matsumoto Nagano, Japan - 1 Research Team of Insect Genome, National Institute of Sericultural and Entomological Science (NISES), Tsukuba Ibaraki, Japan

We got a new abnormal morphological strain (*Nct*) derived from the *Nc* · *U Antennapedia* mutant line maintained in Laboratory of Genetic Resources (NISES) in the process of the detouching between 6th and 14th chromosome. This *Nct* larva forms the incomplete eye spot and crescent like *Nc* heterozygous larva. But *Nct* does not have embryonic lethality with the incomplete formation of the thoracic legs although *Nc* homozygous embryo does not hatch because of the incomplete formation of their thoracic part. Southern hybridization analysis of the genomic DNA extracted from the PSG of the individual larva with *Bombyx-Antennapedia* (*BmAntp*) cDNA and genomic probes showed that *Nct* larva has three doses regarding Antennapedia locus, namely two normal and one *Nc* locus which deletes the homeobox region. The mixed chromosomes constitution of *n*=28 and 29 was also observed in *Nct* testis cell. These results indicate that *Nct* is (partially?) trisomic line at least regarding *BmAntp* locus and suggest that the product of *Nc* locus may prevent the correct formation of the thoracic part even on the condition with the normal doses of the *Antennapedia* homeobox region.

09-063

SEQUENCE AND STRUCTURE OF THE DIPHENOL OXIDASE GENE IN *ANOPHELES STEPHENSI* AND ITS RELATIONSHIP TO AN UNSTABLE MELANOTIC MUTANT *BLACK LARVAE*

C.F. Garvey and C.A. Malcolm

School of Biological Sciences, Queen Mary and Westfield College, University of London, UK

The diphenol oxidase gene (*Dox 2A*) in *Drosophila melanogaster* is found within a densely packed region of at least 34 genes covering approximately 100 kb. Many melanotic mutants have been found within or close to these clusters. A study on *Anopheles gambiae* (P. Romans per comm.) suggests synteny conservation of the region.

A 4.3 kb *A. gambiae* genomic DNA clone containing a gene with homology to *Dox 2A* was used to screen a *A. stephensi* genomic DNA library. This identified a ~16 kb fragment containing a region hybridised by the whole probe. DNA sequence from part of the conserved region showed homology to *Dox 2A*: the complete gene (1.5 kb) gave a predicted amino acid sequence with 67% identity. The single intron present in *Dox 2A* was absent.

Melanotic mutants resulting in black larval body colour have been found several times in *An. stephensi*, but are often homozygous lethal. One viable mutant (*BI*), co-dominant with wild type, has been used as a linkage marker and to develop a genetic sexing mechanism. These studies determined its approximate position towards the centromere on chromosome arm 3R. This mutant showed occasional instability, suggesting an insertional mutation involving a transposable element where most the population showed mosaic black phenotypes and a few revertants to wild type. Re-selection for the full black phenotype took several generations, despite the co-dominance. The possibility that this mutant gene was in, or close to, the *Dox/Ddc* gene clusters was examined by *in situ* hybridisation of the *Dox* clone to polytene chromosomes. The result was consistent with this hypothesis and more detailed mapping studies are now in progress.

09-065

NUCLEOTIDE AND DEDUCED AMINO ACID SEQUENCE OF A cDNA CLONE ENCODING STORAGE PROTEIN-1 OF *HYPHANTRIA CUNEA* DRURY.

Hyang-Mi Cheon, In Hwan Hwang¹, Hak Ryul Kim², Sook-Jae Seo

Department of Biology, College of Natural Science, - 1 Plant Molecular Biology and Biotechnology Research Center, Gyeongsang National University Chinju 660-701 - 2 Department of Biology, College of Natural Science, Korea University, Seoul, Korea

N-terminal and peptide sequence were determined from purified storage protein-1 of *Hyphantria cunea* Drury. In order to clone the storage protein, the DNA probe was generated by PCR using two degenerate oligonucleotide primers encoding N-terminal region and region for residue 84-91. Using probe we isolated the cDNA clone of storage protein-1 from cDNA library. The deduced amino acid sequence was highly homologous to methionine rich storage protein of *Manduca sexta*, sex specific storage protein of *Bombyx mori*, and basic juvenile hormone suppressible protein of *Trichoplusia ni*.

09-066

Expression and the biochemical characterization of an *Anopheles dirus* gene encoding an insect class I glutathione S-transferase.

Prapanthadara¹, L., Promtet¹, N., Ranson², H. and Hemingway², J.¹-Research Institute for Health Sciences (RIHES), Chiang Mai University, Chiang Mai, 50200, Thailand. ²-School of Pure and Applied Biology, University of Wales, College of Cardiff, Cardiff, CF1 3TL, United Kingdom.

We have used a 5' RACE (rapid amplification of cDNA ends) reaction with the primer designed from a region of high N-terminal sequence homology in *An. gambiae* GST-I enzymes to amplify a full-length glutathione S-transferase cDNA from *An. dirus*, a malaria vector in Thailand. This GST has high N-terminal homology with GST-I from *Drosophila melanogaster* and *Musca domestica*. The cDNA was cloned into PET vector for expression in E.coli and the resultant protein biochemically characterized. Characterization included steady state kinetics, substrate specificity and xenobiotic inhibition. The capability of the expressed enzyme to catalyze DDT-dehydrochlorination is compared with earlier studies on the partially purified isoenzymes from whole insect homogenates.

09-067

MOLECULAR EVOLUTION OF THE α -ESTERASE GENE CLUSTER THROUGH THE *DROSOPHILA* RADIATION

G.C.deQ. Robin, R.J. Russell, J.G. Oakeshott
CSIRO, Division of Entomology, Canberra, Australia.

We present a molecular analysis of the α -esterase cluster of *Drosophila melanogaster*. The cluster spans 60kb and contains 11 esterase genes, each of at least 1.6kb. Reconstruction of the gene phylogeny using the amino acid sequence of the esterases reveals three simple gene duplication events. Two of these resulted in the duplicate genes inverted with respect to each other, while the other resulted in a 'head-to-tail' arrangement. The most recent of the three duplications is particularly unusual because it involves non adjacent genes; one of which is now a pseudogene that is located in the intron of another esterase gene. Other features of the α -esterase cluster's evolution include: the diverse pattern of intron presence/absence that requires multiple independent intron gain/loss events, the apparent lack of recent gene conversion events, and the saturation of silent sites indicative of relatively old gene duplication events.

In order to further investigate the events and processes that have shaped the cluster, we have attempted to superimpose the gene phylogeny onto the well established phylogeny of *Drosophila* species. The α -esterase cluster of *D. buzzatii* contains at least nine of the esterase genes represented in *D. melanogaster*, demonstrating that these genes are at least as old as the divergence of the *Drosophila* and *Sophophora* subgenera (an estimated 30-60 million years). The pseudogene however is not present in the *D. buzzatii* cluster so to trace its evolution we have focused upon other species within the *Sophophora* subgenus. We are particularly interested in the timing of its inactivation because both relative rate tests and the pattern of amino acid replacements suggest that it may have been functional for some time after the gene duplication event.

Other genes in the α -esterase cluster can be traced back to at least the divergence of drosophilids and calliphorids (80-100 mya). In *Lucilia cuprina* (sheep blowfly) and probably *Musca domestica* (housefly), orthologs to the *D. melanogaster* α -esterases have been implicated in metabolic resistance to OP insecticides. There is also some evidence to suggest that the amplified esterase genes in OP-resistant *Culex* mosquitoes may be distant orthologs of the α -esterases of *D. melanogaster*.

09-068

SEQUENCE ANALYSIS OF THE RIBOSOMAL DNA INTERNAL TRANSCRIBED SPACER 2 IN PALEARCTIC SPECIES OF THE *ANOPHELES MACULIPENNIS* COMPLEX (DIPTERA: CULICIDAE).

P. Mancini, F. Silvestrini, R. Romi, C. Severini, M. Marinucci.

Laboratorio di Parassitologia, Istituto Superiore di Sanità, Roma, Italy.

Mosquito rDNA shows typical eukaryotic structure and organisation in which multiple copies of the ribosomal genes are tandemly arranged. In general, comparison of nucleotide sequence of various portions of the ribosomal RNA has proved to be a useful molecular tool to studying evolutionary affiliations among taxa. Certain areas of rDNA evolve rapidly, while other areas tend to be highly conserved even in distantly related organisms, particularly the coding regions. Non-genic, internal transcribed spacers (ITSs) have been useful in elucidating phylogenetic relationships between species of mosquitoes, including sibling ones.

The present study was designed to study the ITS-2 (internal transcribed spacer-2) sequence variation in Palearctic species of the *An. maculipennis* complex, i. e. *Anopheles atroparvus*, *An. maculipennis*, *An. labranchiae*, *An. messeae* and *An. sacharovi*, which includes both potential malaria vectors and non-vectors sibling species, in order to elucidate their phylogenetic relationships (speciation within the group is probably of recent origin) and to compare the phylogeny so inferred with those resulting from the morphological characters, polytene chromosomes, hybrid fertility and from isoenzymatic variability. Data concerning the ITS-2 intraspecific variation as well as the ITS-2 secondary structure are also presented.

09-069

PRIMARY AND SECONDARY STRUCTURE OF ITS2-rDNA IN *CULEX PIPIENS* L. AND IN *CULEX QUINQUEFASCIATUS* SAY.

C. Severini, F. Silvestrini, M. Marinucci.

Laboratorio di Parassitologia, Istituto Superiore di Sanità, Roma, Italy

DNA sequences including the second internal transcribed spacer (ITS2) and some flanking 5.8S and 28S ribosomal RNA coding regions were compared within the two sibling mosquito species *Culex pipiens* L. and *Culex quinquefasciatus* Say. For correct species identification, male terminalia were identified by the DV/D ratio. Sequences were determined from polymerase chain reaction amplified DNA from seven field populations of both species (three populations of *Culex pipiens* from Italy, three populations of *Culex quinquefasciatus* from Africa and one from North America).

The consensus sequences showed a 97% identity and identical G+C content; in fact the only differences observed are 6 mismatches (3 transitions/3 transversion), 6 single-base and 1 triple-base deletions/insertions. Secondary structures of ITS2-rDNA from both species were calculated with the FOLD program and drawn with SQUIGGLES program of Genetics Computer Groups (GCG version 7.0); the observed ITS2 secondary structures were very similar and presented areas of homology with three putative U3 snRNA boxes near the juncture of the spacer with the coding regions. The intraspecific variation was studied and the possibility that the two mosquito species may be distinct by restriction sites analysis is discussed.

09-070

FIRST PHYSICAL MAP OF THE MALARIA VECTOR *ANOPHELES GAMBIAE* REVEALS NON-RANDOM DISTRIBUTION OF CODING REGIONS

A. della Torre, G. Favia, G. Martotti, M. Coluzzi, K.D. Mathiopoulos

Istituto di Parassitologia, Fondazione "Pasteur-Cenci Bolognetti", Università "La Sapienza", Roma, Italy.

Random cDNA clones, cosmid clones and RAPD polymorphic fragments have been localized by *in situ* hybridization to the ovarian nurse cell polytene chromosomes of the malaria vector *Anopheles gambiae*. We thus established 86 molecular markers for 110 sites within the whole *An. gambiae* polytene chromosome complement. The cDNA clones analysed were isolated at random and their exact localizations were determined by *in situ* hybridization. For fifteen of the cDNA clones, a partial nucleotide sequence has been obtained; and for nine of them, sequence searches in the GenBank database revealed high degrees of similarity with published sequences. The cosmid clones analysed were obtained as the result of screening with a few of the aforementioned cDNA clones of particular interest, or taken from a small set of randomly isolated cosmid clones. The RAPD clones are polymorphic fragments, potentially diagnostic for the various chromosomal forms of *An. gambiae* s.s. that are currently being analysed. Of particular interest is the non-random distribution of the cDNA clones on the three *An. gambiae* polytene chromosomes. The possible evolutionary implications of such an observation are presented with reference to the non-random distribution of paracentric inversions.

09-072

COMBINED MAPPING OF EST, TAS, RAPD AND PHENOTYPIC MARKERS IN *B. MORI* (LEPIDOPTERA:BOMBYCIDAE)Y. Yasukochi, N. Komoto, Y. Takasu, T. Kanda, T. Tamura
National Institute of Sericultural and Entomological Science, MAFF, Tsukuba, Japan

Genome maps are one of the most important tools for molecular biology and genetics. To construct such a map in the domesticated silkworm, we have screened RAPD markers using 100 10-mer arbitrary primers. In combination of them, we have found more than 500 RAPDs. Moreover, we isolated telomere associated sequences (TAS) in order to use them as a landmark specific for chromosome end region. Using a ligation mediated PCR method, 162 TAS were cloned and sequenced. The resulting sequences were utilized to establish sequence tagged sites. Known sequences derived from DNA data bases were also converted to expressed sequenced tags (ESTs).

We performed linkage analyses with landmarks described above and several phenotypic markers. As a result, we have constructed a genetic map containing 28 independent linkage groups corresponding to 27 autosomes and X chromosome of the silkworm.

09-071

PHYSICAL MAPPING IN AN ARTHROPOD VECTOR OF ANIMAL DISEASES: *CULICOIDES VARIIPENNIS* (DIPTERA: CERATOPOGONIDAE) AND THE BLUETONGUE VIRUSESR.A. Nunamaker, S.E. Brown¹ and D.L. Knudson¹Arthropod-borne Animal Diseases Research Laboratory, USDA,ARS, Laramie, WY USA - ¹ Department of Entomology, Colorado State University, Fort Collins, CO USA

A recombinant cosmid library is being used as probes in FISH physical mapping of *Culicoides variipennis*, the primary vector of bluetongue virus in North America. Metaphase chromosomes were prepared from a *C. variipennis* cell line (KC). Probes were nick-translated with biotin-11-deoxyuridine triphosphate using standard protocols. To eliminate the confounding effects of KC DNA repetitive sequences, suppression hybridization with a KC Cot-1 DNA fraction was necessary. The specific hybridization was detected with avidin-fluorescein isothiocyanate (FITC). Slides were counterstained with diamidino-2-phenylindole (DAPI). The DAPI- and FITC-stained digital images were captured with a cooled-array, charge-coupled device collector mounted on a Zeiss Axioskop microscope. Digital images were enhanced, colorized, and merged, and chromosomal lengths and features were measured. A physical map of the *Culicoides* genome will be constructed to enable mapping of loci that control vector competence for bluetongue virus. Specific probes for vector competence loci will allow monitoring of vector populations and assessment of their potential as vectors for bluetongue virus and related, introduced pathogens.

09-073

ISOLATION OF CHROMOSOMAL INVERSION BREAKPOINTS IN THE *ANOPHELES GAMBIAE* COMPLEXK. D. Mathiopoulos, R. D. C. Saunders¹, A. della Torre, G. Mariotti, V. Predazzi², M. ColuzziIstituto di Parassitologia, Fondazione "Pasteur-Cenci-Bolognetti", Università "La Sapienza", Roma, Italy; ¹Department of Anatomy and Physiology, University of Dundee, Dundee, UK; ²Dipartimento di Genetica e Biologia Molecolare, Università "La Sapienza", Roma, Italy.

The six sibling species of the *An. gambiae* complex are characterized by fixed paracentric inversions on their chromosomes. The two principal malaria vectors of the complex, *An. gambiae* s.s. and *An. arabiensis*, are themselves subdivided into discrete units, carrying typical sets of polymorphic chromosomal inversions. Cloning both fixed and polymorphic inversion breakpoints is of particular interest since their DNA structure can provide unique information on naturally occurring inversions, point to a mechanism for their generation and maintenance in nature, as well as clarify the possible involvement of transposable elements. Furthermore, it should provide specific molecular probes for identification of the different inversion karyotypes.

Here we report the cloning of the first two breakpoints, the distal 2Rb of *An. gambiae* s.s. and the proximal 2Rd of *An. arabiensis*. For the 2Rb breakpoint, we used random clones from a library made from microdissected material from a breakpoint neighbourhood to localize, by *in situ* hybridization, the ones that lied closest to the breakpoint. These clones were then used as starting point for cosmid library screening and walking. One of the obtained cosmids seemingly spans the breakpoint, as judged by the two hybridization signals on the two breakpoints it gives in Fluorescent In Situ Hybridization (FISH) on polytene chromosomes of the inverted karyotype. Cloning of the 2Rd breakpoint of *An. arabiensis* was a result of screening of the cosmid library with a cDNA clone that cytologically mapped very close to that breakpoint. FISH of the cosmid gave three signals on the 2Rd/+ heterokaryotype, as expected. The two cosmid clones are being further characterized.

09-074

DNA FINGERPRINTING OF *BOMBYX MORI* L.: THE PROBLEM OF IDENTIFICATION OF INDIVIDUALS, OVIPOSITIONS AND BREEDS (LEPIDOPTERA: BOMBYCIDAE)G.A.Sevastyanova, A.P.Tretjak, A.P.Ryskov¹, Ju.B.Filippovich.

Department of Biochemistry, V.J.Lenin Moscow Pedagogical State University, Moscow, Russia - ¹ Institute of Gene Biology, Russian Academy of Sciences, Moscow, Russia.

DNA fingerprinting based on M13 phage DNA as a hybridization probe was used to analyse individual, oviposition and breed DNA's of *Bombyx mori* L. Each oviposition and breed DNA consisted of the mixture of hundreds and thousands individual genomes consequently. Nevertheless, similar, although not identical distribution of the hybridization bands in individual, oviposition and breed DNA's was found. The hybridization bands specific for breed fingerprints are also seen on individual and oviposition fingerprints. On the other hand, individual-specific hybridization bands are sometimes absent from oviposition and breeds fingerprints, due to a phenomenon of "individual genome dilution". Four most frequently observed hybridization bands characteristic of different breeds of *Bombyx mori* L. were designated as specific population markers. We assume that DNA fingerprinting can be useful of identification of *Bombyx mori* L. breeds.

09-076

MOLECULAR ANALYSIS OF OVERWINTERING DIAPAUSE IN THE SPRUCE BUDWORM

S.R.Palli, T. R. Ladd, R.Kothapalli, A.Pang and A.Retnakaran
Canadian Forest Service, Sault Ste.Marie, Ontario, Canada

The Spruce budworm, *Choristoneura fumiferana* exhibits an obligatory overwintering diapause as a second instar larva. The role of proteins and carbohydrates associated with this overwintering diapause was investigated. This insect uses both trehalose and glycerol as antifreeze agents to survive the winter. Trehalose levels in the hemolymph begin to increase as soon as they molt into the second instar and reach maximum within a week. This high level of trehalose is maintained throughout the 30 weeks of diapause. Glycerol levels on the other hand start to increase only after the second instar is exposed to cold conditions for four weeks and reach maximum by 10 weeks into diapause. The high levels of glycerol are maintained throughout diapause. Within three days after termination of diapause both trehalose and glycerol decrease to minimum levels. *C. fumiferana* larva also produces large quantities of two hexameric proteins (sub unit size 72 and 74 kDa) that are diapause related. These proteins accumulate in the first instar larval hemolymph beginning at four days after emergence and reach maximum levels by seven days after emergence. High levels of these proteins are maintained throughout diapause. The mRNAs (2.4 kb) coding for these proteins were present in large quantities during all seven days of the first instar. The mRNAs however decreased to undetectable levels as soon as the larvae molted to the second instar and entered the diapause. The mRNAs reappear in the middle of the last larval instar for 2-3 days before they disappear again. We have used differential display of mRNAs technique to identify genes whose mRNAs either increase or decrease during overwintering diapause. One of them is an insect homologue of Tcp20, a subunit of the eukaryotic TRiC chaperonin cloned from humans and yeast. One hundred and seventy six out of 331 amino acids are identical between human and *C. fumiferana* Tcp20. Supported by Canadian Forest Service and Science and Technology Opportunities Fund.

09-075

MOLECULAR GENETIC TECHNIQUES FOR DIFFERENTIATING CENTRAL EUROPEAN *ORINOCARABUS* SPECIES (COLEOPTERA, CARABIDAE)

R. Gerstmeier, D. Sedlmair

Technische Universität München, Angewandte Zoologie, D-85350 Freising, Germany

Due to a relatively high number of species, subspecies, micro-races and hybrids within the genus *Carabus*, there are many different opinions about subgeneric and subspecific classification.

In the present study we use molecular genetic techniques for taxonomic differentiation. Infra- and interspecific classification was inferred from SSCP (Single-strand conformation polymorphisms) analysis and RAPD-PCR (Random amplified polymorphic DNA) pattern based on the genomic Ubiquitin gene, which occurs both as single copy unit and in tandem repeats.

Investigations of mitochondrial NADH-Dehydrogenase (subunit 1) gene, which should infer phylogenetic relationships using sequence data, were also started.

09-077

GENOMIC INSTABILITY IN THE MEDFLY *CERATITIS CAPITATA*: AN EFFECT OF TRANSPOSABLE ELEMENT ACTIVITY?A.R. Malacrida¹, C. Torti¹, S. Costa¹, G. Gasperi^{1,2}¹Department of Animal Biology, University of Pavia, Pavia, Italy²Institute of Zoology, University of Sassari, Sassari, Sardinia, Italy

Our long term goal is to identify naturally occurring functional transposable elements in the geographic populations of the medfly *Ceratitis capitata*. To this aim we are analysing the genomic instabilities recurrently observed in the medfly. These instabilities are manifested by germline and somatic abnormalities. In particular our focus is centred on: 1) analysis of the hybrid dysgenesis syndrome recovered in the medfly (Torti et al., 1994, *J. Heredity* 85: 92-99), which resembles that of *Drosophila* where it is caused by the mobilisation of functional copies of transposable elements. The analysis of the dysgenic traits recovered in different medfly hybrids obtained from different crosses supports the hypothesis that more than one system is activated in the considered crosses. 2) The analysis of unstable mutations with particular attention to *white eye*. The *white eye* mutation of *C. capitata* affects, as in *Drosophila*, the pigmentation of larval and adult Malpighian tubules and the adult eye. It has been found to be localised on chromosome 5, on which most of the genes homologous to the X linked genes of *D. melanogaster* are located.

Genetic instability at the *white eye* locus has been observed in dysgenic crosses and in a *white eye* revertant line; it affects both the germline and the somatic cells. In the revertant line the germinal mutation rate of w^+ to w is 5.2×10^{-4} .

Preliminary Southern blot analyses on *white eye* and revertant w^+ flies indicate the presence of an insertion in the *white eye* locus. The nature of this insertion is now under investigation.

09-078

THE POTENTIAL OF GENE TARGETING FOR MANIPULATION OF THE MOSQUITO GENOME

Zhao Yu-Guang¹, P. Eggleston²

¹Wolfson Unit of Molecular Genetics, Liverpool School Of Tropical Medicine, Pembroke Place, Liverpool L3 5QA, UK - ² Department of Genetics and Microbiology, University of Liverpool, Donnan Laboratories, Liverpool L69 3BX, UK.

The exploitation of transgenic mosquitoes requires methods for the introduction of DNA both into living insects and into cultured cells. Ideally, this will involve a transformation vector which is capable of directing efficient and stable integration into the chromosomes of the recipient. Previous approaches have relied on transposition mediated mechanisms, principally those involving the P element from *Drosophila melanogaster*. However, the few reported cases of mosquito transformation show no evidence for the involvement of transposition, and there are currently no other transposable sequences (either from the mosquito or elsewhere) which have been developed into efficient transformation systems. We have been investigating the potential for gene targeting in mosquitoes through homologous recombination between donor and recipient sequences. A variety of constructs have been introduced into cultured cells derived from both *Aedes aegypti* (Mos20) and *Anopheles gambiae* (Ag55). Initially, this work focused on the optimisation of selectable markers for the identification of transformed cells, and a number of stably transformed cell lines have been generated in both species. We have also investigated negative selection strategies for the enrichment of targeted events, by exploiting the sensitivity to gancyclovir of cells expressing the HSV-*tk* gene. More recently, we have investigated the behaviour of a variety of targeting sequences in these constructs, and their ability to direct targeted integration in mosquitoes.

RIBOSOMAL GENES AND INSERTION ELEMENTS WITHIN AND BETWEEN *APHIDIUS* NEES (HYMENOPTERA, BRACONIDAE) SPECIES

P. Varricchio, F. Pennacchio¹, E. Tremblay, C. Malva²

Dipartimento di Entomologia e Zoologia Agraria, Università di Napoli "Federico II", Portici (Na), Italy - ¹ Dipartimento di Biologia, Difesa e Biotecnologie Agro-Forestali, Università della Basilicata, Potenza, Italy - ² Istituto Internazionale di Genetica e Biofisica, CNR, Napoli, Italy

The ribosomal gene structure of a set of closely related Aphidiinae species belonging to the genus *Aphidius* Nees, of relevant interest in biological control, has been analyzed. *Aphidius ervi* genomic libraries have been constructed, several rDNA repeating units have been cloned and characterized and different regions of the rDNA cistrons have been sequenced. Insertion elements interrupting the *A. ervi* 28S rDNA genes have been identified and sequenced. The sequence of the two 5' and 3' insertion-28S junctions shows that the elements are inserted in the 28S gene at exactly the same position where R1 elements are present in *Drosophila melanogaster*, *D. virilis*, *Bombyx mori* and other insect species. In addition, also in the *A. ervi* rDNA, the insertion of the element produces a duplication of the 14 nt target region. The various *A. ervi* rDNA cloned regions have been used in Southern blot experiments with genomic DNA of closely related Aphidiinae species belonging to the genus *Aphidius*. The data will be presented and discussed in relation to the origin, function and evolution of rDNA insertions within these insect species.

TELOMERIC REPEAT ASSOCIATED RETROPOSONS IN THE SILKWORM *BOMBYX MORI*

S. Okazaki, H. Takahashi, and H. Fujiwara

Department of Biological Sciences, Graduate School of Science, University of Tokyo, Tokyo, Japan

Telomeres of the chromosomes of a lepidopteran insect, *Bombyx mori* consist of pentamer-repeat sequence, (TTAGG)_n. This sequence is conserved in most insects except for dipteran and several other orders. A dipteran insect, *Drosophila melanogaster*, has no such short repeat at chromosome ends, but has retroposons (HeT-A and TART) instead. To study the general mechanism of telomere formation in insects, we analyzed the telomeric structure of *Bombyx* chromosomes. Within the telomeric repeat of *B. mori*, we have identified three different retroposons (TRAS1, 2 and 3). FISH has demonstrated that TRAS1 and TRAS2 are clustered at the tips of chromosomes of *B. mori*. All of these retroposons have the ORFs which are homologous to reverse transcriptase (RT) domain of non-LTR retroposons. The amino acid sequences of the RT domains of the three retroposons fall into one lineage with a retroposon R1 which is identified in rDNA of most insects. TRAS1, 2 and 3 are novel families of non-LTR retroposons which are inserted into the telomeric repetitive sequences as target sites.

Ecology and Population Dynamics

10-001

THERMAL SENSITIVITY AND POPULATION RESPONSES TO CLIMATE CHANGE

J. G. Kingsolver

Department of Zoology, University of Washington, Seattle WA 98195

Holometabolous insects perform quite different tasks during their larval and adult stages. As a result, the effects of temperature on fitness components in larvae (e.g. larval survival, feeding and growth rates, development time) and adults (e.g. flight, mating, oviposition) may differ substantially. I will combine evidence about thermal sensitivities for different life stages with simple ecological models to explore how climatic variation may alter larval and adult fitness components, and their consequences for demography and growth rates of temperate insect populations.

10-002

THE POPULATION DYNAMICS AND CONSERVATION OF A RARE BUTTERFLY: THE CASE MODEL OF *MACULINEA REBELI* (HIR.) (LEPIDOPTERA: LYCAENIDAE)

M.E. Hochberg, R.T. Clarke¹, G.W. Elmes¹, J.A. Thomas¹

Laboratoire d'Ecologie, Ecole Normale Supérieure, 46 rue d'Ulm, 75230 Paris 05, France - ¹ Institute of Terrestrial Ecology, Furzebrook Research Station, Wareham, Dorset BH20 5AS, England

Caterpillars of the butterfly, *Maculinea rebeli*, feed sequentially in flower-buds of *Gentiana cruciata* and in nests of *Myrmica schencki* ants, with which they have a sort of 'cuckoo bird' relationship. Ants feed them in preference to their own larvae, reducing the production of new workers and hence the colony size the following year. Other species of *Myrmica* compete with *M. schencki* for nest-sites. They adopt caterpillars with equal facility, but fail to rear them to maturity and are consequently less damaged.

Using a mathematical model we explore how species interactions can influence the populations of the butterfly, *M. schencki*, and other *Myrmica* species.

Addition of the butterfly to the system reduces dramatically both the number and average size of *M. schencki* nests. As a result, the number of nests of other *Myrmica* increases as they encroach onto the drier areas. In intermediate areas, where most competition occurs between the ants, the nest-size of other *Myrmica* increases, but overall, their average size also falls because of the direct effect of the caterpillars.

From a conservation stand-point, we suggest that a subtle combination of changes in the environment can either benefit or endanger the butterfly population depending on how each of the ant species are affected.

10-003

BUTTERFLY MOVEMENTS, METAPOPOPULATIONS AND CONSERVATION

I. Hanski

Department of Ecology and Systematics, Division of Population Biology, University of Helsinki, Finland

Large numbers of butterfly species have severely declined or have become already extinct in many countries in especially northern Europe. Habitat destruction and fragmentation appear to be the main causes of extinctions in most species. Increasing numbers of species now occur as metapopulations, consisting of extinction-prone local populations. The persistence of such species depends critically on movement behaviour and factors affecting it. Butterflies range from very sedentary species to very mobile species, with important implications for the consequences of habitat fragmentation on their dynamics. Density-dependent and patch size-dependent emigration and immigration rates increase the extinction risk of small populations, and may create an Allee effect in local population dynamics. Substantial movement among small populations in a metapopulation may lead to a rescue effect and multiple equilibria in metapopulation dynamics. Such complex spatial dynamics may lead to a rapid and catastrophic extinction of species from a large region without any or substantial change in the environment. One important question of which little is presently known is how fast the movement behaviour may evolve in butterflies in response to a changing environment.

10-004

DYNAMIC MOSQUITO BEHAVIOUR: IMPLICATIONS FOR MALARIA EPIDEMIOLOGY

Bernard D. Roitberg¹, J.J. B. Smith², WG Friend¹

¹Behavioral Ecology Research Group and Centre for Pest Management, Department of Biological Sciences, Simon Fraser University, Burnaby, BC, Canada; ²Dept. Zoology, U. Toronto, Toronto, Ont., Canada

Recent work on theories of malaria epidemiology conclude that deviations from constant biting terms can have profound effects on infection rates. What is not clear, however, is what form the biting terms should take. To remedy this, we employ concepts from Behavioral Ecology to develop a dynamic life history model that predicts changes in blood and sugar host preference as a function of several factors, including: 3 physiological states (i) crop nectar volume and concentration; (ii) somatic energy; and (iii) age; and two ecological states; (iv) nectar availability; and (v) blood availability. Explicit constraints are: (vi) maximum crop volume; (vii) maximum midgut volume; (viii) nectar processing rates; and (ix) life expectancy.

We use the dynamic model to elucidate the population distribution of Host Attack Thresholds under different ecological conditions. We then show how one can use this distribution along with descriptors of Host Quality, Host Defense Thresholds and Vector Attack Persistence to develop a realistic biting term. From there, we explore the impact of such complex terms on infection rates.

Our talk is concept-dense and detail-light and is meant to demonstrate how an evolutionary approach can be used to enhance our understanding of population-level phenomena.

10-006

EGGLOAD DYNAMICS, FORAGING EFFORT AND OVIPOSITION RATE IN A PARASITIC WASP

J. Casas, R. Nisbet¹, S. Swarbrick¹.

University of Tours, Tours, France - 1 University of California, Santa Barbara, USA.

Estimating the oviposition rate in the field is a very difficult yet important problem in insect population dynamics. Two approaches are available: a direct approach, observing foraging females in the field; an indirect approach, using the dynamics of the number of mature eggs carried by a female at any moment in time, called the eggload. The second approach is used here to estimate the rate of oviposition of the parasitoid *Aphytis melinus* (Hym. Encyrtidae), the biological control agent of the California red-scale on citrus. The eggload at different points in time and the rate of egg maturation are known from field and laboratory experiments. We model the dynamics of the eggload using a family of queuing models, which includes the simplest birth-death model and much more complex ones where the rate of oviposition is a function of the eggload and with an upper limit for the storage of mature eggs. The eggload does not reach a steady state over the period of one day. This implies that a careful choice of the characteristics of the eggload distribution must be made when testing the models, as the bulk of the distribution does not behave dynamically as the tails do. These models enable us to predict how often and when *Aphytis* runs out of eggs during the foraging period, and, if so, what the chances are of generating and laying more eggs during the same day and to what extent the upper capacity of storage is limiting. Finally, we compare the rate of oviposition obtained by this modeling approach with that obtained from direct observations of females foraging in the field.

10-005

DYNAMICAL EFFECTS OF PARASITOID ATTACKS DEPENDENT ON HOST SIZE AND PARASITOID STATE

W.W. Murdoch, C.J. Briggs, R.M. Nisbet

Department of Biological Sciences, University of California, Santa Barbara, CA, USA

Some parasitoids mature new eggs by feeding on (and killing) hosts. On encountering a host individual, such parasitoids may reject the host, feed on it, or parasitize it and, if the last, may lay only 1 or multiple eggs, which may be either male or female or a mixture. The actual outcome depends on both properties of the host, especially size in many instances, and also the state of the parasitoid, especially its egg load. We have developed host-size-and parasitoid-state-structured models that explore the population dynamics consequences of such decisions. We show that several apparently disparate aspects of parasitoid behavior in fact have the same dynamical outcome because they are actually different manifestations of a broader phenomenon. We also show that the competitive displacement of one *Aphytis* parasitoid by another species of this genus, which led also to improved control of Californian red scale, can be explained by rather subtle differences in size-dependent behavior between the two species. Parasitoid behavior can thus be shown to have potentially important consequences for the stability of parasitoid-host interactions and for biological control of insect pests.

10-007

DO PARASITIC WASPS AFFECT THE SPATIAL RESOURCE USE OF THEIR HERBIVOROUS HOSTS? AN EVOLUTIONARY GAME BETWEEN ROSE HIP FLIES AND THEIR PARASITOIDS

T.S. Hoffmeister¹ and B.D. Roitberg²

Zoologisches Institut, Ökologie, Christian-Albrechts-Universität Kiel, Germany - 2 Department of Biological Sciences, Simon Fraser University, Burnaby, BC Canada

Rose hip flies (*Rhagoletis basiola*, Diptera: Tephritidae) visit clusters of rose hips, where they lay single eggs beneath the skin of the fruits. There, fly eggs are vulnerable to the attack of a specialized egg-larval parasitoid (*Halticoptera rosae*, Hym.: Pteromalidae). Female flies were found not to oviposit into every fruit of a cluster, but to spread their eggs out across clusters. In turn, parasitoid females were found to be more effective in the search for hosts on heavily infested compared to mildly infested clusters. We used theoretical models to elucidate how competition between flies, habitat variability, and the threat of parasitoid attack affect reaction norms for the spatial distribution of fly eggs across rose hip clusters. We investigated different scenarios, with evolutionary games between flies only, between flies and a constant threat of parasitoids, and evolutionary games where reaction norms of flies and parasitoids could coevolve.

10-008

CARABID POPULATION AND COMMUNITY FEATURES AS AN "ADAPTATION" TO THE LANDSCAPE SYSTEM: IMPORTANCE OF THE ECOTOPE AS LANDSCAPE UNIT.

P. Brandmayr, T. Zetto, R. Pizzolotto.

Dipartimento di Ecologia, Università della Calabria, 87036 Arcavacata di Rende - Italy.

The landscape system contains smaller landscape units called ecotopes by landscape ecologists. The most useful definition of ecotope refers, in our experience, to well delimited geomorphic units, like rivers, lakes or other riverside habitats, mountain slopes belonging to homogeneous geologic formations, etc.

The authors compared the Carabid beetle groupings of two landscapes: the Northern Adriatic system (with about 400 species censused and 7 ecotope-types sampled) and the Mediterranean system of Calabria (8 ecotopes, 180 species).

The ground beetles living in a single ecotope may be more or less numerous, (differences in diversity values); interesting differences are observed also in: reproduction rhythm (summer larvae versus winter larvae); dispersal power (high versus low percentages of flying species or individuals); population densities; life tactics; population distribution and migration within the ecotope; choice of hibernation sites; hygrophily and resistance to desiccation, etc.

The coenoses assemblages within an ecotope are strictly interrelated through ecological succession processes, but, on the contrary, exchanges from one ecotope to the neighbouring one are often extremely weak, depending especially on differences of geomorphology and subsoil-water level.

On the whole, two extremes could be recognized: **zonal ecotopes**, where the climax ecosystem is easily reached, and carabid populations and communities show more sedentary features, and **azonal ecotopes**, where the beetles (and the other animals) are living in a more instable situation, with more opportunistic, discontinuous or temporary populations. The adaptive "space" of many species seems to be shaped on the habitat complex of an ecotope, more than on the conditions of a single habitat type. Ecotopes could be used in animal cartography.

10-010

STRONG INTERCONNECTION BETWEEN ADAPTIVE TRAITS AND POPULATION STABILITY IN AN HERBIVOROUS LADY BEETLE

T. Ohgushi

Institute of Low Temperature Science, Hokkaido University, Sapporo 060, Japan

An herbivorous lady beetle *Epilachna niponica* exhibited a high stability of population densities in terms of host plant abundance. Field experiments revealed that reproductive females resorbed eggs in the ovary in response to host plant deterioration. Also, females selected oviposition site carefully, by laying eggs on plants with less egg load. These specified oviposition tactics resulted in a temporal resource tracking of populations, through density-dependent reduction in realized eggs per female. Lifetime fitness of offspring decreased with increasing egg density. This implies that oviposition on plants with less egg density improves lifetime reproductive success of an ovipositing female. Egg resorption could have adaptive significance when offspring fitness drops considerably due to resource deterioration late in the reproductive season or habitat disturbance such as inundation. It also enhances a chance of future oviposition in the second reproductive season, through increasing subsequent survival of egg-resorbed females. Consequently, the oviposition behavior of reproductive females in time and space is highly correlated with lifetime fitness of their offspring.

10-009

CHANGING INTERPRETATIONS OF ADAPTATIONS INFLUENCE VIEWS ON POPULATION DYNAMICS

M.P. Zalucki, G.H. Walter

Department of Entomology, The University of Queensland, Brisbane, Australia

The most widely accepted view of evolutionary change is that of ongoing adaptive change in all populations. The development of ecological and evolutionary theory is thus confounded by general acceptance, either tacitly or explicitly, that species are adaptive devices. The alternative view disassociates the process of speciation from its ecological consequences. The two views contrast sharply on how speciation occurs. In the former, isolationist view of species, speciation is a continuous process driven ultimately by competition. Consistent with the isolationist view of species is the body of population ecology theory that emphasises demographic parameters. The alternative, recognition, view of species is more positive because it emphasises adaptations of the fertilisation system. Here, speciation is an incidental consequence of a change in the fertilization system. Such change is constrained to take place only in small isolated populations undergoing directional selection in a habitat to which the species is not currently adapted. The recognition view of species is inconsistent with changing abundance being driven by demographic or population features. Rather, the dynamic interaction between individual and environment is given special prominence. The two views therefore have different implications for the study of population ecology. The former, when not idealistic is merely descriptive, with low predictive power. The latter is predictive once the basic biology, adaptations and environmental requirements of the species are defined through adequately designed observations and experiments.

ANCIENT POPULATIONS IN ANCIENT WOODS: DISPERSAL,
AGE STRUCTURE, AND VARIABILITY OF *CARABUS GLABRATUS*
PAYKULL IN NORTHWEST-GERMANY (COLEOPTERA:
CARABIDAE)

Th. Assmann

Department of Ecology, University of Osnabrück, Osnabrück, Germany

Woodlands were extensively destroyed by man in Northwest-Germany during Middle Age and early Modern Times. But not all of them were cleared away; those belonging to aristocracy or to ecclesiastical institutions were preserved. Since about 1800 modern forestry has been established entailing reforestation on a large scale. According to their age, woods can be divided in ancient and recent ones. Some Ground Beetles show a relict distribution in ancient stands, whereas other Carabids have spread widely and occur also in recent woods.

Patterns of movement of the relict species *Carabus glabratus* were studied by harmonic radar and, in an circular enclosure, with capture-recapture experiments of individually marked beetles. Locomotory activity is lower in this species than in *Carabus problematicus* living in ancient and recent woods.

Allozyme studies of esterases and the phosphogluconate dehydrogenase in 20 populations show a common genetic variability with up to 7 allozymes (EST-X) per population. Therefore, long lasting extreme bottlenecks resulting in the loss of genetic variability must be excluded for the studied populations.

The populations are composed of young and two or more year old individuals, as revealed by the presence or absence of the Corpus luteum before the reproduction period, and by mark-recapture experiments in an enclosure. The possible role of old individuals in preventing strong population dynamics is discussed.

10-013

THE DEVELOPMENT OF THE AGE PYRAMID IN A LOCAL
POPULATION OF *CARABUS AURONITENS* FABRICIUS
(COLEOPTERA, CARABIDAE)

F. Weber, B. Horstmann, A. van den Boom, M. Landwehr,
A. Bechtel

Institute of General Zoology and Genetics, University
of Münster, Münster (Westphalia), Germany

In the Westphalian Lowlands *Carabus auronitens* is a spring breeder. Preimaginal stages develop during 3-4 months in summer. Young beetles emerge asynchronously in late summer/early autumn. They are obligatorily active for food during 3-5 weeks. Surviving old beetles are dormant from the end of the spring season until the beginning of the next spring season. During the spring season adults of at least 3 generations are active. We measure the rate of yearly net reproduction and the rates of interseasonal age-dependent mortality of a local population fenced in a beetle-proof enclosure (0.2 ha). We analyse the dependence of the surviving probability of individually marked adults on (1) time of hatching in the late summer/early autumn season, (2) body size, (3) weight development, (4) level of locomotor activity and (5) start and end of the individual season in spring.

10-015

STABILIZATION OF A *LAEMOSTENUS SCHREIBERSI* POPULATION
(CARABIDAE) AS AN EFFECT OF ADULT LONGEVITY - RESULTS OF A
LONG-TERM INVESTIGATION OVER 10 YEARS.

E. Rusdea

Institut für Landespflege, Universität Freiburg, D-79085 Freiburg/
Germany

A population of the microphthalmic carabid *Laemostenus schreibersi* was studied in a cave near Villach in Carinthia (Austria). Results of a long-term investigation over ten years (1986 - 1995) are presented. During 15 seasons of field observations the beetles were trapped in pitfalls, individually marked and released inside the cave. Using the mark-recapture method it was possible to estimate population size and the patterns of locomotion activity.

Other aspects of population dynamics are concerned with seasonal and spatial distribution in the different cave-compartments, sex-ratio, reproduction and development.

The portion of recaptured beetles was very high (62 %). The rate of exchange with other populations living in the fissure-system was evaluated. Population size is small, but rather constant (50 - 110 individuals). The beetles of *Laemostenus schreibersi* can reach the remarkable age of at least 7.5 - 8 years. Longevity is discussed as a factor stabilizing population size. The survival time of adult beetles throughout some years is known from several carabid species, but such an extreme longevity has not been reported before. Reproduction-rate seems to be rather low.

Cooperation within Europe in a Study of *Pterostichus oblongopunctatus* F. (Coleoptera, Carabidae) - Survival and Reproduction.

J. Szyszko - Department of Zoology Warsaw Agricultural University, 02-528 Warsaw, Rakowiecka 26, Poland.

H.J.W. Vermeulen - Biological Station Wijster, Kampsweg 27, 9418 PD Wijster, Drenthe, Holland.

P.J. den Boer - Biological Station Wijster, Kampsweg 27, 9418 PD Wijster, Drenthe, Holland.

N. Schaffer - Department of Ecology Bayreuth University, D-8580 Bayreuth, Universitätsstrasse 30, Germany.

Abstract

Observations were made of the carabid fauna in more than dozen forest stands in Germany, Holland and Poland. Special attention was paid to *P. oblongopunctatus*. Wherever possible the following were estimated for this species: the male-to-female ratio; individual biomass at the moment of capture, after 24 h. of starving and after 24 h. of feeding; respiration; consumption; number of eggs laid; number of eggs in ovaries; age structure of adults and the period of activity. Differences in the characteristics studied were found between groups of individuals from different stands frequently there were differences between neighbouring stands, and these were more pronounced than those between stands some hundred kilometres apart. It is suggested that, with successional changes of habitat *P. oblongopunctatus* changes its life history pattern by having larger body dimension, lower respiration and consumption, a shorter lifespan of the adults, a larger number of eggs in the ovaries and different activity of males and females giving rise to a difference in the sex ratio in pitfall traps. The supposition is advanced that the main factor governing the way of life strategy is food. The food conditions for larvae and adults respectively may be estimated by the dimensions of the adult and the ratio of males to females in pitfall traps.

10-018

PROLONGED DIAPAUSE AND POPULATION DYNAMICS OF THE NOBLE FIR SEED CHALCID *MEGASTIGMUS PINUS* PARFITT (HYMENOPTERA: CHALCIDOIDEA)

T.S. Jensen

Department of Zoology, Institute of Biological Sciences, Aarhus University, Aarhus, Denmark.

Over a seven year period the interactions between Noble Fir (*Abies procera*) and the seed chalcid *Megastigmus pinus* were investigated. Imagines seed chalcid population size was estimated from emergence traps placed on the forest floor and overwintering larval population size from cone production and infection rates. Furthermore, imagines were reared each year from freshly collected cones which were kept in emergence boxes in the forest.

Megastigmus pinus larvae were shown to overwinter two-three years thus entering prolonged diapause. In years of extremely low cone production prolonged diapause was high, i.e. few imagines emerged from cones of the preceding year. In years of abundant cone production almost no larvae of the preceding year entered prolonged diapause and thus emerged as imagines that year. In years of moderate cone production prolonged diapause varied considerably between trees.

The pattern of prolonged diapause exerted a moderating effect on the population dynamics of the seed chalcid. In the study period, population densities of emerging imagines varied only 7-fold, whereas cone production varied 100-fold. This leads to high infection rates in low seed years and low infection rates in years of high cone production.

10-017

LIFE CYCLE EVOLUTION OF CARABID BEETLES IN GALÁPAGOS: A LONG TERM SAMPLING STUDY

K. Desender¹, S. Abedrabbo²

¹ Royal Belgian Institute of the Natural Sciences, Brussels, Belgium - ² Zoological Institute, University Innsbruck, Austria

As part of a long term study on terrestrial arthropods (especially spiders and carabid beetles) and in cooperation with Austrian, Canadian and Ecuadorian scientists, we have been able during recent years to sample the most important islands and volcanoes of Galápagos in complete transects or in altitudinal gradients. The carabid faunal diversity is now estimated at some 40 species, the majority of these being endemic to the Galápagos Archipelago or even to single islands or volcanoes. In previous papers we have addressed already several questions related to the biogeography, evolutionary ecology and speciation of some of these beetles in Galápagos.

In this contribution we present the first results of a long term sampling study, conducted by continuous pitfall trapping in several habitats of Isla Santa Cruz during more than two complete year cycles (1991-1993; in cooperation with the Charles Darwin Research Station). This monitoring project aimed at understanding additional aspects of the biology of this intriguing fauna, in particular with regard to population dynamics and life cycle timing and evolution in the extreme circumstances of Galápagos. Such studies on invertebrates have, to our knowledge, never been performed before in Galápagos. These data also extend our current knowledge on dispersal power and habitat preference of particular species. Both are important aspects in the study of adaptive radiation.

The life cycle of the most abundant carabids is reconstructed by analyzing the seasonal occurrence (phenology) of larvae and adults and by unravelling the population structure. Dissection of beetles enables to ascertain their reproductive state and yields information on the age composition of the population. Finally an attempt is made to relate the timing and duration of the life cycle to possible environmental (climatological) or biotic (presence of prey species) cues and these results are discussed in an evolutionary context.

10-019

CAN LOCAL ADAPTATIONS EMERGE IN ISOLATED POPULATIONS OF THE WATERSTRIDER *LIMNOPORUS NAJAS* (HETEROPTERA GERRIDAE)?

P. Ahlroth, R. Alatalo, J. Suhonen

University of Jyväskylä, Department of Biological and Environmental Science, Jyväskylä, Finland

Local adaptations are suggested to benefit individuals in the local conditions under which they evolved. In isolated populations, however, the homozygosity caused by bottlenecks and genetic drift may reduce the genetic variance available for selection and may therefore prevent the evolution of such adaptations. Furthermore, the relatively short time elapsed since the last glaciation in Northern Europe has limited the possibility of local adaptations to emerge.

We have experimentally studied the possibility of appearance of local adaptations in the overwintering behavior of *Limnopus najas* in ten isolated populations. The species overwinters in streamsides as an adult and copulation begins in the spring. In Southern Finland winter is several weeks shorter than in Central Finland. To test if populations differ in their overwintering behavior we transferred five populations from Southern Finland and five populations from Central Finland to five rivers in Central Finland in which there are no natural populations of *L. najas*. The time taken to begin overwintering in each of the five rivers by each pair of populations was subsequently measured.

Preliminary data obtained suggests that there may be differences in the overwintering behavior of some of the populations. The reasons behind such differences are discussed.

POPULATION GENETICS AND DYNAMICS OF
TRANSGENIC ARTHROPOD NATURAL ENEMIES: AN
OVERVIEW OF POTENTIAL RISKS AND LOGISTICAL
ISSUES

Marjorie A. Hoy

Department of Entomology and Nematology, University
of Florida, Gainesville, Florida 32611 USA

The development and deployment of genetically-manipulated arthropod natural enemies has, to date, involved predators and parasitoids that have been altered by traditional breeding methods. The use of recombinant DNA methods should improve the efficiency of developing new strains but will require careful consideration of environmental risks and approval of various regulatory agencies.

An overview of previous genetic improvement programs will be provided with discussion of the gaps that were discovered in our knowledge of the population genetics and biology of the target species involved, including the predatory mite *Metaseiulus occidentalis*, the predator *Chrysoperla carnea*, and the parasitoids *Trioxys pallidus* and *Aphytis melinus*. The deployment of transgenic arthropods for practical pest management programs will require the collaboration of molecular biologists, population ecologists and geneticists as well as entomologists with an understanding of the logistical difficulties of large scale pest management programs. Several issues remain to be resolved regarding appropriate risk assessment methodologies.

10-022

THE POPULATION BIOLOGY OF CYTOPLASMIC
INCOMPATIBILITY: DATA AND THEORY

M. Turelli

Center for Population Biology, University of California, Davis, CA
USA

In many insect species, cytoplasmically transmitted microbes related to *Wolbachia pipientis* cause reduced egg hatch when infected males mate with uninfected females. This "cytoplasmic incompatibility" (CI) tends to confer a reproductive advantage on infected females in polymorphic populations, allowing the maternally transmitted, CI-inducing infections to spread within and among populations. In *Drosophila simulans*, a CI-inducing microbe has rapidly spread northward from southern California over the past decade. The intra-population dynamics of this spread and the equilibrium infection frequency can be understood in terms of a simple mathematical model with parameter values—describing maternal transmission and levels of incompatibility—estimated directly from natural populations. The infection's wave of advance has been accompanied by predicted changes in mtDNA haplotype frequencies. This infection is now widespread in *D. simulans* populations throughout North and South America and Europe, and it serves as a model for the possible manipulation of insect pests via CI. Both empirical and theoretical work on population dynamics will be reviewed, along with results concerning the population biology of multiple infections and coevolutionary changes in CI-inducing microbes and their hosts.

POPULATION GENETICS AND POPULATION DYNAMICS
MODELS: WHERE DO WE GO FROM HERE?

A. Hastings

Division of Environmental Studies, University of California,
Davis, CA 95616, USA

Recently, the ecological theory of metapopulations has greatly advanced by focussing on structured models of metapopulations which include population sizes within patches. The population structure assumed in metapopulation models is appropriate for many terrestrial arthropod species. I will outline research directions which will focus on structured models of metapopulations which include allele frequencies as well. This work will thus focus on the joint action of ecological and genetic forces in maintaining diversity within a metapopulation. I will contrast these approaches with alternate approaches using cellular automata and reaction diffusion equations.

ANALYSIS OF THE GENETIC CONTROL PROGRAM FOR THE AUSTRALIAN SHEEP BLOWFLY, *LUCILIA CUPRINA* IN AUSTRALIA: A PARADIGM FOR RELEASES OF TRANSGENIC PEST ARTHROPODS?

R.J. Mahon

CSIRO Division of Entomology, Canberra, Australia

The Division of Entomology CSIRO, has developed methods to control the Australian Sheep Blowfly, *Lucilia cuprina* using genetical techniques. As one of the largest and most "mature" genetic control programs in existence, sharing the lessons that this species has taught us over the last 25 years may prove useful to those contemplating the use of transgenic insects to control pests. Some of the problems and gaps in our knowledge that impeded progress are species specific, while others are specific to the use of chromosomal rearrangements as a means of imparting genetic load to a natural population. Yet other difficulties encountered while attempting to implement genetic control strategies for *L. cuprina*, are likely to be more general, and thus may complicate the implementation of any attempt to impose genetic change on a natural population through the release of genetically modified insects.

10-025

MODELLING THE DYNAMICS OF AGE-STRUCTURED ARTHROPOD POPULATIONS

G. Di Cola, J. Baumgärtner¹

Dipartimento di Matematica, Università di Parma, Italy - 1 Agricultural Bureau of the Grisons, Chur, Switzerland

The von Förster and the discrete Leslie analogous models are concise descriptions of the dynamics of age-structured populations, but have limited predictive capabilities. The exclusive use of chronological age has been found inadequate for modelling the population dynamics of poikilotherms. The quality of the model predictions is improved if physiological age in terms of developmental level (e.g. thermal units, size, biomass) is incorporated into temperature-dependent development. Since there is variation between the individuals in a population and in environmental factors, the model should embody a stochastic or random element; biological and environmental variability are described by means of stochastic differential equations. Two main approaches are possible: macroscopic models which describe gross changes in population development, microscopic models which describe the life history of individuals. The latter models appear to be particularly useful in pest management system and in population ecology. Simulation studies, with several models, are analyzed and discussed.

QUANTITATIVE ANALYSIS OF GYPSY MOTH SPREAD IN THE CENTRAL APPALACHIANS

Alexei A. Sharov

Department of Entomology, Virginia Polytechnic Institute and State University, Blacksburg, VA 24061 USA

Gypsy moth, *Lymantria dispar* (L.), was introduced into North America near Boston in 1869 and since that time it has been slowly expanding its range to the west and south. In attempt to slow its spread, USDA Forest Service has established several barrier zones in which isolated colonies are detected and eradicated. To evaluate the effect of barrier zones on the rate of gypsy moth, I suggested a new method for measuring the rate of spread. It was measured as the average distance between regular population boundaries (regular boundaries have no "islands", gaps or folds) in consecutive years. Population boundaries were estimated using male moth counts in pheromone traps, egg mass counts, and defoliation maps in the central Appalachian Mts. in 1988-1995.

The boundary of 1 moth/trap was on average 110 km from the boundary of defoliation, and male moth capture rate increased 10 times per 29 km perpendicular to the population front. Approximately 11 yr separated the time when traps caught 1 moth/trap until defoliation first occurred in the same area.

Gypsy moth spread rate declined from 1988 to 1995 by ca. 30-60%, as measured from 1) time series of spread rates and 2) boundary "compression" (reduction of the distance between adjacent boundaries). Reduction of gypsy moth spread rate may have been due to eradication of isolated colonies in the study area.

I developed a model of gypsy moth spread that considered establishment of isolated colonies beyond the moving population front due to inadvertent transportation of life stages on human vehicles. The probability of colony establishment decreases with increasing distance from the population front. The model predicts that the barrier zone in the Appalachian Mts. should reduce the rate of gypsy moth spread by ca. 50% which is consistent with our data.

Measurements of spatial pattern and spatial association for counts of insects

Joe N. Perry
Department of Entomology & Nematology, IACR Rothamsted Experimental Station, Harpenden Herts. AL5 2JQ, England

A system will be described to measure the spatial pattern of counts of insects that has an improved intuitive basis, compared with traditional more abstract, mathematical approaches, and utilises fully all the available spatial information in the sample. Indices and tests of non-randomness will be described. An algorithm will be presented to simulate permutations of a given set of insect counts to achieve a new arrangement with a specified degree of aggregation. This is particularly useful in the generation of realistic data to compare several sampling strategies. A further algorithm finds a permutation of a given set of counts of one species over predefined locations, at each of which there is also a count of a second species, for a specified degree of association between the two. Various visual aids to the analysis of spatial pattern will be presented. The problem of measuring and testing for association for two sets of counts sampled at the same locations will be discussed and recent progress summarised. Fortran software is freely available from the author.

GEOSTATISTICAL METHODS FOR TESTING CORRELATIONS: APPLICATION TO LANDSCAPE LEVEL FOREST DATA

A.M. Liebhold, A.A. Sharov¹

Northeastern Forest Experiment Station, USDA Forest Service, Morgantown, WV USA - ¹ Department of Entomology, Virginia Polytechnic Institute and State University, Blacksburg, VA USA

Testing the statistical association among two or more variables is one of the most common approaches to evaluation of hypotheses in ecological research. Classically, researchers test these associations by collecting multiple samples of each variable replicated through space and calculate correlation coefficients. The assumption in this approach is that spatially stratified samples are independent. However in many (if not most) systems values may be spatially autocorrelated at the scale at which samples are separated. We present here a method for testing for correlations between two variables that are known to be autocorrelated. Sample variograms are first estimated from sample data in order to quantify spatial autocorrelation. Variograms and frequency distributions are then used in a sequential simulation procedure to generate multiple realizations of samples that honor the sample variogram and histogram but are not inherently correlated. The frequency distribution of simulated correlation coefficients are then used to test the statistical significance of the observed correlation coefficient.

IMPLICATIONS OF DIFFERENT TYPES OF ADAPTATION FOR INTERACTIONS IN FOOD WEBS

P. A. Abrams
Department of Zoology, University of Maryland, College Park, MD 20742 U.S.A.

A lack of any dynamic equations describing adaptation has been a failure of many previous dynamic models of food webs. Adaptation can occur by behavior, evolution, or shifts in the distributions of different age classes or phenotypes within a species. I use a series of simple models of two- and three-trophic-level communities to explore the implications of these different types of adaptation for food web behavior. The main behaviors investigated are how population densities respond to top-down and bottom-up environmental effects.

10-032

MECHANISMS AND PROPERTIES OF RATIO-DEPENDENT MULTITROPHIC MODELSAlan A. Berryman¹, R. Arditi², J. Michalski², X. Chen¹¹ Department of Entomology, Washington State University, Pullman WA USA - ² Institute of Zoology and Animal Ecology, University of Lausanne, 1015 Lausanne, Switzerland

The general structure and underlying mechanism of ratio-dependent (R-D) trophic models will be described and contrasted to those of traditional Lotka-Volterra models. Some static and dynamic properties of R-D models will be described and predictions of R-D theory will be compared to empirical observations on the biological control of insect pests.

TRITROPHIC MODELING: A QUEST FOR REALISM, WHOLENESS AND GENERALITY

Andrew Paul Gutierrez

**Environmental Science, Policy and Management
Division of Ecosystem Science
University of California, Berkeley, CA USA 94720**

The term, tritrophic system, is used here to mean an autotroph-herbivore-carnivore relationship that may be a linear food chain or a food web of any degree of complexity. The question of how to model such interactions has provided grist for controversy since the mid 1920's. Theorists simplified the biology for mathematical tractability and biologists were often lost in minutia. The former sought high level theory and the latter practical solutions to real world problems. We now recognize that the use of mathematics to describe weak biology (or *vice-versa*) is unlikely to be achieved for population ecology. Holling's goals of realism, wholeness and generality -- i.e., unifying principles. Today the schism between theoretical and field ecologists is being breached and annealed via educated discussion. The notions of meta-organisms and meta-populations capture the details that concerned field ecologists. Increasingly models that include the behavior and physiology of resource acquisition and allocation are appearing in the literature, and field ecologists are examining the underlying properties of their models. In this paper, tritrophic models based on the supply - demand metabolic pool paradigm and the underlying theory are reviewed. A range of models including analytical models, numerical simulations of meta-organisms and object oriented models of meta-populations based on a supply-demand paradigm are reviewed and tested against field data.

10-034

UNDERSTANDING THE POPULATION DYNAMIC INTERACTIONS BETWEEN PARASITOIDS AND THEIR HOSTS

H.C.J. Godfray, M.P. Hassell

Department of Biology & NERC Centre for Population Biology, Imperial College at Silwood Park, Ascot, Berkshire, U.K.

Parasitoid wasps have proved excellent systems with which to investigate many aspects of predator-prey interactions and a rich theoretical literature on their population dynamics has developed. We review recent research in three areas. (i) The importance of spatial processes in influencing host-parasitoid dynamics. (ii) The population dynamics of communities of hosts and parasitoids. (iii) The application of host-parasitoid dynamics to specific systems, especially to answer questions raised in the design of biological control programmes, using "models of intermediate complexity". The review will illustrate the dual function of classical population dynamic modelling: to answer general questions about population dynamic behaviour, and to aid the interpretation of more complex models of individual interactions.

10-035

HOW COMMUNITY STRUCTURE INFLUENCES PREDATOR PERSISTENCE AND PREY REGULATION

Sebastian J. Schreiber, Andrew P. Gutierrez

Division of Ecosystem Science, Department of Environmental Science, Policy and Management, University of California, Berkeley, CA, USA

The effect of community structure and the interaction strengths between its constituents on persistence and regulation is examined using a model of multispecies interactions. The model employs a metaphysiological paradigm driven by a supply/demand functional response. Using it, we develop criteria for species persistence that address how various forms of competition and predation result in either coexistence, species displacement or multiple stable steady states. In all cases, relative ecological efficiencies between species that share prey determine these persistence criteria. We also examine two types of prey regulation. In the first case with only one prey species, we define regulation as the ratio of mean prey density with predation to mean density without predation. In the second case with two prey species exploiting a common resource, the ratio of mean resource density with prey to mean resource density with prey and predator determines regulation. In both instances, better regulation corresponds to a smaller value. Using these definitions, we determine what combination of predators regulates the prey most effectively and how it depends on the physiological and behavioral characteristics of the predator and prey species. For example, depending on relative values searching efficiencies between predators the introduction of an intraguild predator to a predator-prey system can improve or disrupt regulation by coexisting with or displacing its intraguild prey. Combining these analyses, we discuss why predator introductions may fail and therefore not effect regulation, succeed and improve regulation, or succeed and disrupt regulation.

10-036

APPLICATIONS OF MULTITROPHIC POPULATION MODELS TO FIELD PROBLEMS

N.J. Mills

Department of Environmental Science, Policy and Management, University of California, Berkeley, CA, USA

Insect pests occupy an intermediate trophic level and their abundance is affected both by bottom-up effects from the foodplant and by top-down effects from natural enemies. A tritrophic perspective is required to understand the dynamics of these interacting populations and to investigate the role that natural enemies play in the biological control of insect pests.

The application of tritrophic population models, based upon physiological determinants of resource acquisition and transfer between trophic levels, to biological control will be illustrated with reference to two pest systems. Firstly, a cotton-whitefly-aphelinid parasitoid system will be used to examine the influence of parasitoid reproductive strategies (primary parasitism, obligate autoparasitism and facultative autoparasitism) on the outcome of biological control. Assuming that sex allocation in autoparasitoids is dependent upon the relative abundance of parasitized and healthy whitefly nymphs, the model reveals the potentially disruptive nature of facultative hyperparasitism in biological control.

The second application of the tritrophic model examines whether the host stage attacked by a parasitoid influences the success of biological control in an alfalfa-aphid-aphidiid parasitoid system. Assuming that the per capita reproductive rate of an aphid is a linear function of the stage at which it is attacked, the model clearly shows the benefit to biological control of early parasitoid attack in the life cycle of the aphid.

10-038

THE ROLE OF PARASITOIDS IN STRUCTURING GRACILLARID LEAFMINER COMMUNITIES ON *CRATEGUS MONOGYNA* JACQ.

S.M. Gardner

Centre for Extra-Mural Studies, Birkbeck College, London, UK

It has been proposed that the occurrence of shared natural enemies between host species can limit the abundance of individual species within a community. This proposal is explored for the community of gracillarid leafminers (Lepidoptera: Gracillariidae) living on hawthorn (*Crategus monogyna*). Using data from eight leafminer generations, I examine the role of parasitoids in influencing leafminer population growth and in determining indirect interactions between leafminer species. The data suggest that host-specific parasitoids exert the largest effect on leafminer population growth, but shared parasitism, due to non-specific parasitoids, is significant in the dynamics of at least one leafminer species. The population growth of this species is influenced by the abundance of other leafminer species in the community.

PREDATORS, PARASITOIDS AND PATHOGENS AS MORTALITY AGENTS IN PHYTOPHAGOUS INSECT POPULATIONS

H. V. Cornell, B. A. Hawkins²

Department of Biology, University of Delaware, Newark, DE USA -
2 Department of Ecology & Evolutionary Biology, University of California, Irvine, CA USA

Various ecological and biological factors influence the rate of enemy-induced mortality suffered by herbivorous insect populations. Life tables compiled for 82 holometabolous herbivore species were used to quantify such influences. Enemy-induced mortality by all three types as well as by each type separately were tested for differences associated with the developmental stage and five ecological characteristics of pre-adult herbivores (feeding biology, invasion status, and the successional stage, cultivation status, and latitudinal zone of the habitat). Total enemy-induced mortality is higher in the late developmental stages, and is heavier for exophytic than endophytic feeders; it does not differ with respect to any of the other four variables. Overall, parasitoids kill proportionately more victims than either predators or pathogens. The enemy-type X developmental stage interaction was not significant, indicating that increased attack by parasitoids as herbivores age is independent of predator or pathogen attack. However, enemy-type did interact significantly with four ecological variables: (1) predators and pathogens kill fewer endophytes than exophytes, whereas parasitoids are generally unaffected by concealment, due to heterogeneity in attack rates on leaf miners vs. gallers and borers; (2) Predation increases and disease decreases as succession proceeds (early vs. late) whereas parasitism is unaffected by successional status; (3) Predation and disease are greater in natural vs. cultivated habitats, whereas parasitism is unaffected by cultivation status; (4) Predation dominates in tropical/sub-tropical habitats, whereas parasitism does in the temperate zone. The herbivore's invasion status (native or non-native) is unrelated to mortality by any enemy type. Our results reiterate feeding biology as fundamental to herbivore population dynamics and identify several general patterns in insect demographics that should be useful for hypothesis testing.

INTRAGUILD PREDATION AMONG PREDATORS OF THE POTATO APHID; CHARACTERIZATION AND INFLUENCE OF THE EXTRA-GUILD PREY DENSITY.

E. Lucas¹, D. Coderre² & J. Brodeur¹

1- Centre de recherche en horticulture, Département de Phytologie, Université Laval, Québec, Canada

2- Département des Sciences Biologiques, Université du Québec à Montréal, Montréal, Québec, Canada

Intraguild predation (IGP), a common interaction among competing species of predators, influences both the abundance and distribution of members of a given guild. In the laboratory, within a system involving three species of aphid predators, *Aphidoletes aphidimyza* (DIP: Cécidomyiidae), *Chrysoperla rufilabris* (NEU: Chrysopidae) and *Coleomegilla maculata* (COL: Coccinellidae), we examined the role of predator size, mobility and diet breadth on the level and symmetry of IGP. Results indicated that (i) sessile stages were most susceptible to IGP, (ii) small individuals were more likely to be killed by large predators, and (iii) the aphid specialist *A. aphidimyza* suffered high risk of predation by generalist predators. We also examined the relationship between IGP and the abundance of an extraguild prey, the potato aphid *Macrosiphum euphorbiae*. Several patterns were observed along with increasing extraguild prey density. However, IGP sometimes remained elevated and constant at very high aphid densities.

COMPLEX POPULATION DYNAMICS IN A HOST-PATHOGEN-PARASITOID INTERACTION

S.M. Sait^{1,2}, M. Begon¹, D.J. Thompson¹.

1 Population Biology Research Group, Department of Environmental and Evolutionary Biology, University of Liverpool, Liverpool, U.K. - 2 NERC Institute of Virology and Environmental Microbiology, Oxford, U.K.

Whilst theoretical studies have encompassed multispecies interactions, empirical studies of these complex systems have been rare.

Here, a laboratory-based interaction between the Indian meal moth, *Plodia interpunctella* (Hubner) (Lepidoptera; Pyralidae), its granulosis virus, and the solitary endoparasitoid *Venturia canescens* (Gravenhorst) (Hymenoptera; Ichneumonidae), is described. Replicated populations consisting of the host alone, host-pathogen, host-parasitoid and host-pathogen-parasitoid combinations were established and monitored weekly to determine the patterns in abundance of each of the three species.

The host alone and the two-species systems predictably exhibited long term persistence and cyclic fluctuations of approximately one host generation in length. In striking contrast, the three-species populations were characterized by instability and almost inevitable extinction of the host and parasitoid. Furthermore, the increase from two to three species gave rise to a marked shift in cycle period in which both the host and parasitoid exhibited multigeneration cycles.

10-042

LOCAL DYNAMICS OF TROPHIC INTERACTIONS IN ACARINE SYSTEMS

G. Buffoni, G. Di Cola¹, J. Baumgärtner²

ENEA CRAM, La Spezia, Italy - 1 Dipartimento di Matematica, Università di Parma, Parma, Italy - 2 Agricultural Bureau of the Grisons, Switzerland

A lumped parameter model representing the dynamics of interacting species is presented; the model is described by a system of O.D.E. in terms of biomass with few observable parameters, with the aim of reducing the complexity of the system and of supporting practical use. Methods are proposed for estimating demographic and physiological parameters related to birth, growth and death processes as well as to food consumption and conversion. For this purpose numerical simulations with single-species age-structured models have been carried out.

The dynamics of the system is characterized by the growth function of the prey, the functional response of the predator, and death functions of both populations; these functions depend on both ecophysiological and behavioural parameters.

Basic model properties are studied with particular reference to functional response functions. The model is used to study the dynamics of acarine systems, relevant to poultry houses and protected crops.

10-041

FROM STABILITY TO CHAOS: CHANGES IN DYNAMICAL PROPERTIES IN 1 HOST-2 PARASITOID EXPERIMENTAL SYSTEMS

M. Shimada¹, H. C. J. Godfray² and M. P. Hassell²

1) Department of Systems Science (Biology), University of Tokyo, Komaba, Meguro-ku, Tokyo 153, Japan - 2) Department of Biology and Centre for Population Biology, Imperial College, Silwood Park, Ascot, Berks SL5 7PY, U.K.

Theories have predicted that "top-heavy" ecological systems with more predatory species than that of prey cannot persist for a long time. Assuming different functional responses between consumers, Armstrong and McGhee (1980) showed a long-term coexistence in an 1 resource-2 consumer system with non-equilibrium dynamics. The scenario had been presented by Utida's (1957) 1 host-2 parasitoid experimental systems.

Using the same organisms as Utida's, the present paper studied changes in dynamical properties of the 1 host-2 parasitoid systems based on time-series analysis and model simulations. Providing 10 g of azuki beans (*Vigna angularis*) at 10-day intervals, Shimada continued long-term population census. He started host populations first (a seed beetle, *Callosobruchus chinensis*), then introduced a pteromalid wasp, *Anisopteromalus calandrae* (A. c.) on day 150, and finally added a braconid wasp, *Heterospilus prosopidis* (H. p.) on day 440. The two wasps parasitize from the fourth instar larva to the pupa, though H. p. prefers a slightly younger host stages than A. c.. The attacking rate of A. c. depends strongly on host density per bean but not for H. p.. In larval competition between the two parasitoids, the first attacker is likely to be more advantageous irrespective of the species.

The population oscillated mildly in the host-A. c. system. After adding H. p., the host and A. c. increased gradually the amplitude of population fluctuations and, finally, the two populations fluctuated quite large like "chaos" in the 3 species system. H. p. population went extinct on day 1220 in a replicate system, then the host and A. c. returned original, mild oscillations soon.

We constructed two types of models. One is a matrix population model which includes competitions and parasitism, and the other is a delayed differential-equation model based on daily-based age structures. Using these, we examine which factor(s) and process(es) change the host and A. c. populations from stable to chaotic dynamics in the 3 species system with H. p..

10-043

EVOLUTION IN HOST POPULATION STRUCTURE PROMOTES PERSISTENCE OF HOST-PARASITOID SYSTEMS

M. Tuda

Department of Biology, University of Tokyo, Komaba, Meguro, Japan

Many theoretical studies have suggested that population structures can promote persistence of otherwise non-persistent host-parasitoid systems. However, there have been very few empirical tests on their effects and none on their evolution. In this study, the effects of the spatial structure (local capacity, i.e., number of larvae per resource unit) and temporal structure (vulnerable period) in host populations on the persistence of host-parasitoid systems are quantitatively evaluated by laboratory experiments and by well-parameterized model analyses. Bruchid beetles, *Callosobruchus*, were used as hosts and *Heterospilus prosopidis* as parasitoid.

Local capacity: Fewer larvae are able to complete development in a bean in *C. maculatus* than in *C. chinensis*. Two long-term systems, *C. maculatus*-*H. prosopidis* and *C. chinensis*-*H. prosopidis*, were maintained, with constant resource supply for the hosts. The system with *C. maculatus* persisted longer, which is the 'paradox of enrichment' predicted by Rosenzweig.

Local capacity and vulnerable period: Two host species, *C. maculatus* (few larvae per bean) and *C. phaseoli* (many larvae per bean), and two kinds of beans, mung and azuki, were combined to construct four (2 x 2) host-parasitoid systems that differed in spatial and temporal structures. The persistence of host-parasitoid systems was promoted by the reduction either in local capacity or in vulnerable period, and the effect of local capacity, i.e., intraspecific competition, was greater. A model with host population structures supported this experimental result.

Evolution in host population structure: An increase in the system stability was observed around day 400. Host population structures were compared between before and after the long-term coexistence.

10-044

RANDOMIZATION TESTS FOR COMMUNITY ASSESSMENT

Y. Natuhara, C. Imai

Osaka City Institute of Public Health and Environmental Sciences, 8-34 Tojo-cho, Tennoji-ku, Osaka 543, Japan

Community parameters have seldom been evaluated with statistical tests because of discrepancy from statistical assumptions. However, randomization tests require less assumptions to test the community parameters. The randomization tests for community parameters are classified to two types; 1) a randomized community and 2) a randomization ANOVA and two pair tests..

The randomized community, in which individuals or species are randomly allocated to several communities or samples, was first adopted by Connor and Simberloff (1979) as a null-hypotheses to test an assembly rule of island birds. There have been controversy concerning the reality and logic of randomized community as a null-hypotheses. In the other test, the randomization ANOVA in which the parameters are randomly allocated to experimental blocks, observed Mean Squares are compared with randomized MS and it does not require the normality and homogeneous variance.

We tested these models for transect records of butterflies and quadrat samples of soil arthropods. Although it is suspected that the arthropods are distributed and found at random, our conclusion from the assumption of random community does not conflict with results obtained from other methods, such as a standard ANOVA and cluster analysis. The significant levels by the randomization ANOVA were higher than those by the standard ANOVA.

10-046

MONITORING OF Helicoverpa armigera (Hubner) WITH LIGHT AND PHEROMONE TRAPS

B.V. Patil, N.S. Kulkarni.

Department of Entomology, College of Agriculture Raichur-584 101, Karnataka, India.

Light and pheromone trap catch analysis for eight years from 1987 to 1994 and comparison with 1995 data indicated maximum activity of Helicoverpa armigera (Hb.) from October to December with a peak on 50th standard week at Raichur, India.

Trap catches preceded and succeeded by larval population and incidence on different crops. Egg population was coincided with same week and one week after the trap catches.

Maximum and minimum temperature and rainfall recorded highly significant negative correlation whereas morning relative humidity showed positive significant correlation with trap catches.

10-045

POPULATION MODELS WITH STOCHASTIC DISPERSAL, REPRODUCTION, AND MATE-FINDING: IMPLICATIONS FOR INSECT INTRODUCTIONS

K. R. Hopper

Beneficial Insect Introduction Research Laboratory, Agricultural Research Service, United States Department of Agriculture, 501 South Chapel Street, Newark, Delaware 19713, USA

Deterministic, reaction-diffusion models suggest that Allee effects may be important barriers to biological control introductions. However, these models require one to assume that local heterogeneity in density, caused by stochastic dispersal, reproduction, and mate-finding, is unimportant. To test whether the conclusions of these models hold when this assumption is relaxed, a stochastic population model was developed that simulate development, survival, dispersal, mating, and reproduction of each individual in a population. The effects of mate detection distance, dispersal rate, and net reproductive rate on the numbers of insects needed to establish introduced species were compared for the two types of models. The potential for single-locus multiple-allele sex determination to prevent establishment or restrict spread of introduced parasitic Hymenoptera was also tested using a stochastic, individual-based model. The implications for biological control introductions are discussed.

10-047

CHANGES IN THE STAPHYLINID POPULATIONS IN THE CONIFEROUS FORESTS UNDER HUMAN IMPACT

A.S.Babenko

Research Institute of Biology & Biophysics, Tomsk State University, Tomsk, Russia

The successions of rove beetles (Coleoptera, Staphylinidae) in process of forest resumption in pine and cedar-silver fir forests of West Siberia were studied. The maximum diversity of rove beetles populations (56 species) were found in old cedar-silver fir forests. Tachinus rufipes, T.laticollis, T.marginellus, Philonthus decorus are predominate here. There are 35 species of rove beetles in the first stage of successions. Drusilla canaliculata and Philonthus lepidus are typical for open territory. Philonthus decorus, Xantholinus tricolor, some species of Tachinus and Atheta are predominate in young, 25-30-years forests. On the whole, staphylinid fauna at early stages of secondary successions are characterized by poorer variety of species and low quantitative

10-048

LONG-TERM DYNAMICS OF GRASSHOPPER COMMUNITIES IN THE FOREST-STEPPE LANDSCAPES OF WEST SIBERIA

M.G. Sergeev

Department of General Biology, Novosibirsk State University, Novosibirsk, Russia, and Laboratory of Insect Ecology, Institute for Systematics and Ecology of Animals SO RAN, Novosibirsk, Russia

Long-term dynamics of Orthopteran (mainly grasshoppers) communities has been studied in natural and anthropogenic landscapes of the West-Siberian forest-steppes in 1981-1995.

Our data show that the general level of taxonomic diversity is more or less stable. On the contrary, grasshopper abundance fluctuates significantly and is evidently connected with climatic fluctuations. The maximum of grasshopper abundance on the forest-steppe, meadow and lawn plots have been observed during dry and hot summers of 1984-1985 and 1988. In the local agricultural landscapes, the dynamics pattern seems to be mainly determined by grasshopper migrations from more stable habitats.

10-049

EFFECTS OF INUNDATION ON BEETLE COMMUNITIES IN A DEGENERATED FEN GRASSLAND

J. Perner

Institute of Ecology, University of Jena, Germany

The structure and composition of the beetle community were studied in a degenerated fen grassland in Germany ('Großes Bruch', Saxony-Anhalt). Three different managed sites (intensively grazed pasture, extensively grazed pasture, hay meadow) were investigated by pitfall trapping during three years. A total of 343 beetle species with 39,400 individuals were collected.

From 1992-1994 a rapid decrease of numbers of species and individuals and a high species turnover were noted in all study sites. It is suggested that the seasonal inundation of 1993 and particularly in 1994 are responsible for the observed community dynamics.

By means of multivariate techniques it could be shown that the contrasts between the different managed sites of one year are smaller than the contrasts between the three sampling years in one site. This is a renewed reference to the problem of interpreting short-term data to characterize communities. Finally, the results are discussed in the view of ecological memory, inundation tolerance of species and in the diversity-stability relationship.

10-050

ANT COMMUNITY UNDER THE BEECH FOREST AT TANZAWA MOUNTAINS, CENTRAL JAPAN

M. Kondoh

Laboratory of Biology, Shiraume Gakuen College, Kodaira, Tokyo, Japan

A study of ant community was done under the beech forest at Tanzawa Mountains, during June to September, 1995.

The research was made by using one-third diluted honey on aluminium dishes, which were set at the interval of 3-4 m and exposed during 90-120 minutes. Trapped ants were counted by species to make a table analysis.

The ant fauna under beech forest are classified in two types of community, one of which is *Myrmica kotokui* community and another is *Aphaenogaster japonica*-*Myrmica kotokui* community. They are corresponding to the associations of vegetation taxonomics, and segregated by the line of 1300 m of altitude. Namely, the former correspond to *Micicacalio*-*Fagetum crenata* (Miyawaki et al., 1964) and the latter correspond to *Corno*-*Fagetum crenata* (Miyawaki et al., 1964). These ant communities are classified again in two subtypes by moisture condition, that is, wet and semi-arid. Ant subcommunities under semi-arid beech forest which look like marginal with shrubby components, include usually *Lasius japonica*.

10-051

REACTION OF RIPICOLIC CARABIDAE AND ANTHICIDAE (COLEOPTERA) OF THE RIVER RHINE TO IRREGULAR FLOODING, AND THEIR SPATIAL AND TEMPORAL ECOLOGICAL NICHES.

T. Aßmuth

Institut für Zoologie, Technische Hochschule, Darmstadt, Germany

The banks of the river Rhine near Gernsheim, (Hesse, Germany) are broad, with well developed zones of gravel, sand and mostly natural vegetation. Due to the variation of the water level of the river, the investigation of the population dynamics of the riparian arthropods has to be carried out with an unusually high spatial and temporal resolution. Pitfall traps were set in transects perpendicular to the water's edge with an average separation of approximately 4 m. The traps had to be changed at an interval of 2-4 days (depending on variation of the water-level). The trap locations were not only described by their static environmental properties (e.g. substratum and vegetation), but also dynamic values (e.g. humidity, distance to waterline). Thus it was possible to correlate shifting species populations with environmental changes. With the help of multivariate statistical methods (principal component analysis; canonical correspondence analysis) ordinations of the traps were carried out to find ecological guilds. In contrast to the literature it could be shown that the river bank fauna is autochthonous. Two main ecological types could be defined according to their migration behaviour:

- 1) statically zoned species: These species are bound to characteristic static (as a rule in higher laying) Zones of the riverbank. Migration is not dependant on the water level.
- 2) dynamically zoned species: These species migrate to maintain a more or less constant distance to the waterline. This behavior is switched off only in winter.

INSECTS AS BIOINDICATORS IN
NATURE CONSERVATION AND LANDSCAPE PLANNING

- COMMENTS ON TAXA-SELECTION, SAMPLING METHODS AND INTERPRETATION

W. E. Holzinger

Ökoteam - Institut für Faunistik und Tierökologie, Graz, Austria

Bioindication is a rapid-growing field of activity in applied entomology. In Central Europe, the use of insects as passive monitor-organisms in evaluation of nature conservation measures and in environmental assessments (EIAs) is already today's standard. Though the principles of selecting the used insect-taxa as well as the choosed sampling and interpreting methods are often insufficient or inadequate.

Each insect taxon is in principle qualified for being used as bio-indicator, unless insuperable taxonomical or methodological problems are existing. Obviously the sampling methods must be corresponding to the selected taxa and to the statement of the question. Today's greatest problem of entomological reports is the preperation of results: reproducible interpretations founded upon previously fixed, as far as possible universally valid (i.e. for other areas as well as for comparable taxa) criterions are not standard yet.

Development of quality control (minimum standards, criterions concerning comparability) in entomological reports - which will become an important field of activity for future entomologist as well as a valuable data ressource - is a very important scope of applied entomology in the beginning third millenium.

10-054

DYNAMICS OF A WEEVIL (COLEOPTERA:
CURCULIONIDAE) POPULATION ON A TROPICAL RAIN
FOREST

H.BARRIOS

Smithsonian Tropical Research Institute, Panamá

The Phyllotrox spp. complex is the most abundant with 4764 specimens, while Camarotus sp2, with 4 specimens only, is the least collected species. During our 4 years survey the increment of the population occurred usually during the rainy season, most specially during the monthly of April, May, and June. This was true for all 10 species, thus showing that insects present seasonality in the Tropical rain forest. Seasonality and abundance seem to be mostly correlated with rain fall, while temperature, relative humidity, and wind speed seem to play a much lower role in those parameters. Interesting enough weevil yearly relative abundance correlate well with rainfall. In Barro Colorado Island, with very well delimited rainy and dry seasons, weevil abundance shows a maximum during the first rainy months, decreasing there after. Insect abundance also correlates with the altitude where the traps were placed, being higher in the 27 meters trap.

HOW MANY CARABIDS? GENERAL PATTERNS OF DENSITIES.

K.D. Sunderland, G.L. Lövei¹

Horticulture Research International, Wellesbourne, Warwick, United Kingdom - ¹ Horticulture and Food Research Institute of New Zealand, Palmerston North, New Zealand

The ground beetle literature is replete with 'density' data collected by methods which are likly to give inaccurate results. We have conducted a critical, world-wide review of carabid densities, including only data obtained by soil sampling, soil flooding, mark-recapture, fenced pitfalls, quadrat sampling and vacuum sampling. Such data are more numerous than generally acknowledged by carabidologists. Our database contains >250 records of 71 adult and 13 larval taxa, collected in 14 countries in Europe and North America. Small species (<5 mm) have density ranges of 0.2 - 77 individuals per sq. m, large species (>5 mm) range between 0.02 - 33 ind. per sq. m. Suitable hibernating sites regularly held very high densities (500-1113 ind. per sq.m). The total ground beetle densities average 31.7 ind. per sq.m in arable habitats, and 233.3 ind. per sq.m in field boundaries. Fewer data are available on larvae; total larval density ranges between 29.4 - 87 ind. per sq.m, that of individual species between 0.07 - 42 ind. per sq. m. Trends and patterns according to season, geographic location, habitat type, food habits, and species size are described and discussed.

INFLUENCE OF REWETTING AND INUNDATION OF FEN
GRASSLAND ON SELECTED GROUND BEETLES (COLEOPTERA:
CARABIDAE)

U. Fuellhaas

Department of Ecology, University of Osnabrück, Osnabrück

During the last decades the intensified use of fen grassland (mineral and organic fertilizing, draining etc.) caused fundamental changes in the vegetation, accompanied by the loss of original ground beetle communities. The hygrophilous carabids of the wetlands disappeared and were replaced by eurytopic species, frequently with a high density of individuals.

In a three-year-field experiment in the Dümmer lowland (Northwest Germany, Lower Saxony) with four enclosures (each 500m²), the influence of rewetting and seasonal inundation was investigated on *Pterostichus melanarius*, *Poecilus versicolor*, the most abundant carabids in the research area, as well as *Carabus granulatus*. Two enclosures were moistened by ditches, two non-moistened used as control, the cutting treatment took place twice a year. The complete range was flooded during the winter. Grinding-marks on the elytra made it possible to distinguish the beetles individually. According to the rate of captured and recaptured beetles, body mass, amount of young individuals and phenology, different population parameters could be estimated. The ecological consequences of a modied water management on carabid populations in degraded fen grassland will be of interest in course of changing agricultural land use by changing areas from intensive cultivation to extensive use of grassland.

This research is supported by the German Ministry of Education, Science, Research and Technology

NON-TARGET EFFECTS OF A BROAD-SPECTRUM VETERINARY AGENT ON DUNG INSECT COMMUNITIES

K. Krüger, C.H. Scholtz

Department of Zoology and Entomology, University of Pretoria, South Africa

The increasingly widespread use of broad-spectrum veterinary agents has been considered to pose a serious threat to the dung-degrading insect fauna and consequently to the ecology of pasture ecosystems. This is the first study of its kind to investigate the ecotoxicological effects of the parasiticide ivermectin at dung insect community level.

Two field trials were conducted to examine short- and longer-term effects of ivermectin on dung insect communities under normal extensive farming conditions in South Africa. Different community measures (univariate, graphical and multivariate) were used to assess the impact of the drug. Under drought conditions ivermectin appears to affect dung insect communities for up to three months after treatment, primarily through a reduction in Shannon's species diversity and an increase in species dominance compared with untreated controls. No effect was found one year after treatment. Under more favourable weather conditions with relatively high rainfall, little or no effect was observed.

The results of the field studies suggest that the seriousness of the impact of ivermectin on the dung insect fauna depends on several factors, including climatic conditions, spatial scale of treatment (i.e. size of paddocks) and number of animals treated in a herd.

Laboratory assays indicate that ivermectin could have adverse effects on populations of the dung beetle *Euoniticellus intermedius*. However, the field trials have shown that populations of *E. intermedius*, the most abundant scarabaeine species at the study site, appeared unaffected under both drought and high rainfall conditions.

10-057

DYNAMICS OF GRASSHOPPER (ORTHOPTERA: ACRIDIDAE) COMMUNITY IN RESPONSE TO LIVESTOCK GRAZING ON ARID STEPPES OF INNER MONGOLIA

L. Kang

Department of Insect Ecology, Institute of Zoology, the Chinese Academy of Sciences, Beijing, 100080, China

Plant and grasshopper community variables were monitored on the natural steppes grazed by livestock in Inner Mongolia. Biomass, richness and abundance of the plant and grasshoppers were compared between different seasons and between grassland sites under different grazing intensities. Change in plant community structures directly affected grasshopper species composition and abundance. Grasshopper abundance and diversity were negatively correlated with plant biomass and diversity in early growing season, positively in middle season, and no correlation in late season. Moderate grazing could preserve more diverse grasshoppers with lower proportion of pest species. The vegetation played a more important role as grasshopper habitat than as food resources. Soil compactness and water content also significantly affected grasshopper abundance and richness. Multidimensional resource utilization in grasshopper assemblages was analyzed. There were sufficient differences between grasshopper species for overall overlaps associated with resource use to explain coexistence in the assemblages by resource segregation. Grasshopper species-specific use of resource may be due to primarily adaptive differentiation and to coevolution interactions between grasshopper and plant rather than interspecific competition among grasshopper species. The significance of some grasshopper indicators to the change of grassland environment was discussed.

10-058

LOCUST SITUATION IN THE ZONE OF THE ARAL SEA ECOLOGICAL CATASTROPHE

Alexandre V. Latchininsky¹, Furkat A. Gapparov²

Department of Plant, Soil and Insect Sciences, University of Wyoming, Laramie, WY USA - 1. Uzbek Institute for Plant Protection, Tashkent, Uzbekistan - 2.

The delta of the Amudarya river, situated to the south-east of the Aral sea, was one of the most important permanent breeding zone of the Asiatic Migratory locust, *Locusta migratoria migratoria* (L.), in the former Soviet Union. The area of reeds that could be colonized by this locust was as high as 14 million km². In the outbreak years, it was necessary to control the Migratory locust on 500,000 ha. Another species of economical importance, the Italian locust *Calliptamus italicus* (L.), was restricted only to the irrigated zone. It colonized the habitats of the anthropogenous origin (road-sides, fallows, uncultivated lands with weeds etc.). The drying of the delta after the excessive uptake of water from the Amudarya river for irrigation which began in the 1960s, has led to the radical changes in the environment, and, consequently, in the locust situation. The delta was subject to rapid desertification. The area of the humid habitats (reeds) dramatically decreased. The fluvial forests are at the limit of extinction. The mesic Orthoptera species were substituted by the xeric ones, and their diversity declined: out of twelve species registered from this zone in the sixties, only seven were found in 1990-1993. The habitats favourable for *L. m. migratoria* are reduced, its economical importance became of the second level. On the contrary, the environment became most favourable for *C. italicus* which, due to its ecological tolerance and broad polyphagy, colonized readily the vast surfaces menacing the crops of value (cotton, rice). To protect them, it is necessary to apply chemical treatments over the areas of hundreds of thousand ha annually. This aggravates the risk of environmental pollution in the conditions of ecological catastrophe. Possible alternatives to the curative chemical locust control in the region, including the use of bio-pesticides and the methods of cultural control, are discussed.

10-059

INTRA- AND INTERSPECIFIC AGGREGATION OF DUNG BEETLES (COLEOPTERA: SCARABAEOIDEA) IN ALPINE PASTURES

E. Barbero, C. Palestini, A. Rolando

Dipartimento di Biologia Animale, Università di Torino, Torino, Italy

Spatial distribution of scarabaeoid beetles on dung pats was studied in the Argentera Natural Park (south-western Italian Alps) from June to October in 1994 and 1995. Artificial dung pats were distributed evenly within the study area (about 1400 m. a.s.l.) and sampled at suitable dung ages (1-13 days). Two experimental tests were also carried out. In the first test experimental pats were covered with metallic nests which prevented the largest species from arriving at the dung, whereas in the second one a variable number of individuals of a certain species was added to experimental pats after their distribution in the study area.

The community was dominated by *Aphodius* species (20 out of 25 species), which usually were also the most abundant in the pats. Geotrupidae were represented by only two species and Scarabaeidae by three. The period of colonization of the dung was very short since pats older than seven days housed virtually no individuals.

Patterns of spatial distribution showed some degree of intra- and interspecific aggregation. Preliminary results suggest that resource quality, resource detectability, and soil type did not significantly affect interspecific association. In fact species seemed to have an intrinsic disposition for aggregation, maybe dependent upon not specific signals from any abundant species aggregating in a dropping. Cost and benefits of such a behaviour are briefly discussed.

10-060

PRIMARY SUCCESSION AND COMPOSITION OF CARABID POPULATIONS ON A COAL MINING WASTE DISPOSAL (COLEOPTERA: CARABIDAE)

L. Zwiebel, K.Epperlein

Institut für Pflanzenzüchtung und Pflanzenschutz.

M.-Luther-Universität Halle. Halle. Germany.

In Central Germany the landscape of highly intensive agriculture is interrupted by many waste hillsides and mines from mostly finished coal mining. On one of these hillsides investigations over a period of four years were carried out to follow the changes of carabid populations in different habitats by means of pitfall traps. Eventhough in none of the habitats a constant increase in species and individuum numbers over the whole period was evident, the trapped beetles indicated an ongoing succession. Where vegetation, inclination, soil acidity etc. were closer to the conditions on the surrounding fields many species in high numbers appeared. In more extreme habitats a slower and different kind of succession was found.

10-062

THE TEMPORAL DYNAMICS AND THE ADULT MOVEMENT OF CLAVIGRALLA TOMENTOSICOLLIS STÅL (HETEROPTERA: COREIDAE) IN BENIN'S COWPEA FIELDS WITH REFERENCE TO TRAP CROP EFFECTS ON IMMIGRATION

H.Dreyer, J. Baumgärtner¹

Swiss College of Agriculture, Zollikofen, Switzerland -

¹ Agricultural Bureau of the Grisons, Chur, Switzerland

The temporal dynamics and the adult movement of *Clavigralla tomentosicollis* Stål were related to cowpea phenology using visual counting and mark-recapture methods. Colonization by immigrating adults closely coincided with cowpea pod formation and ceased thereafter. Analyses of adult movement yielded daily emigration rates of 7 to 20% of the resident adult densities. Daily in-situ mortality of adults was below 5%. The decline in adult numbers towards harvest is thus mainly due to emigration. Given the high mobility of *C. tomentosicollis* the effect of pigeonpea trap crops on adult movement was tested. Immigration rates of *C. tomentosicollis* adults were generally smaller into cowpea fields with traps than into cowpea fields without traps.

10-061

THE ECOLOGY AND POPULATION DYNAMICS OF AN ENDANGERED WEEVIL (*HADRAMPHUS SPINIPENNIS*) ON THE CHATHAM ISLANDS, NEW ZEALAND - A CONSERVATION APPROACH
K. Schops, S.D. Wratten, R.M. Emberson
Department of Entomology and Animal Ecology, Lincoln University, Canterbury, New Zealand
H. spinipennis belongs to a small genus of large, flightless weevils (Family Curculionidae). Its distribution is restricted to two predator-free outlying islands of the Chatham Islands group (New Zealand), but it is believed that the weevil had a much wider distribution before rodents and cats were introduced. The phenology, ecology and population dynamics of *H. spinipennis* have been investigated in the summers of 93/94 and 95/96, during five visits to one island. The adult weevils reach at least two and a half years of age and feed on foliage of *Aciphylla dieffenbachii*, Apiaceae. The larvae develop on the roots. The impact of the feeding weevils and larvae has caused the disappearance of *Aciphylla* patches in the past, leading to a fragmental, but interacting metapopulation of weevils. One subpopulation was chosen for an intensive mark-recapture study. The plants in one patch were mapped annually and a total of over 9000 weevils were marked individually. The number of weevils in the patch increased rapidly from just over 2000 individuals in the summer of 93/94 to over 6000 in the summer of 95/96 causing a decline in the number of host plants from 625 adult plants to 250. For the adult weevil population, death and survival rates were calculated as well as the dispersal rates within the patch. The future demographic development of the studied weevil subpopulation, its interaction with the population dynamics of the host plant and its dispersal ability are discussed. By using the results of this study a management plan for this endangered weevil species has been developed.

10-063

ESTIMATES OF POPULATION SIZE AND DISPERSAL RATES OF THE SHEEP BLOWFLY *LUCILIA SERICATA* FROM MARK RELEASE RECAPTURE EXPERIMENTS.

K.E. SMITH & R. WALL

School of Biological Sciences, University of Bristol, Bristol, BS8 1UG, UK.

Mark release recapture studies were carried out using the ectoparasitic sheep blowfly, *Lucilia sericata*, in sheep pastures in South West England. Marked flies were released and recaptured using liver baited sticky targets in concentric rings surrounding a central release point. Estimates of the maximum and average distance travelled were obtained by fitting a model to the number of flies recaptured against distance from the release point. The results show that flies dispersed in an approximately random pattern from the release point at an average rate of approximately 100m per day. Estimates of the size of the wild population were derived using the Lincoln index, after correcting for underlying rates of mortality and emigration of marked flies. The results show that *L. sericata* populations increase in abundance throughout the summer but, even peak population densities are relatively low. The implications of these results for sheep blowfly control will be discussed.

10-064

COMPETING RISKS ANALYSIS, RISK ASSESSMENT, AND SIMULATION OF POTATO TUBER MOTH *PHTHORIMAEA OPEECULELLA* (ZELLER) (LEPIDOPTERA:GELECHIIDAE) MULTI-COHORT SYSTEMSO. Roux & J. Baumgärtner¹

International Potato Center, Ariana, Tunis, Tunisia; Present address: Federal Office of Agriculture, Bern, Switzerland - 1 Agricultural Bureau of the Grisons, Chur, Switzerland

The larvae of Potato Tuber Moth (PTM), *Phthorimaea operculella* (Zeller) (Lepidoptera: Gelechiidae) mine potato foliage and borrow deep galleries into tubers. In Tunisia, PTM is a major pest in rustic shelter of potato tubers.

The separation and integration of mortality factors is a prerequisite for the design of a pest management system. For a single cohort system, elements of the competing risk theory were incorporated into the analysis of cohort survival. Thereby, each mortality factor is characterized by a force of mortality and a corresponding survival distribution function. Mortality factors are combined using forces of mortality in order to describe different states of the PTM single cohort system.

Subsequently, the variability of the effect of the most important mortality factor is introduced into the system and the resulting risk for damage is analyzed.

To illustrate the effect of varying mortality factors on the dynamics of multi-cohort population systems, we use a simulation model based on time varying distributed delays.

10-066

DISTRIBUTED DEVELOPMENTAL TIMES OF POIKILOTHERM COHORT INDIVIDUALS AND THE USE OF THE ERLANG FREQUENCY DISTRIBUTION

M. Severini & J. Baumgärtner¹

Institute for Atmospheric Physics, IFA-CNR, Rome, Italy, and University 'La Sapienza', Rome, Italy - 1 Agricultural Bureau of the Grisons, Chur, Switzerland

Under constant temperature the observed exit flow from an arthropod life stage, illustrated by immature development of the boll weevil *Anthonomus grandis* Boheman (Coleoptera, Curculionidae), can adequately be described by a recursively expanded stage balance equation. The resulting equation has the ERLANG frequency distribution as solution, that depends on two parameters: the first parameter represents the number of substages within a life stage, while the second parameter is the probability for an individual to move from one life stage into the succeeding one.

Published data on several arthropod cohorts are used to test the validity of the ERLANG frequency distribution for representing the observed distribution of developmental times.

10-065

ANALYSIS AND MAPPING OF SPATIAL DISTRIBUTION OF MASSON-PINE CATERPILLAR, *DENDROLIMUS PUNCTATUS* (WALKER), (LEPIDOPTERA: LASIOCAMPIDAE), IN DIFFERENT PINE FORESTS USING GEOSTATISTICS

Li Dianmo, Shi Gensheng

Institute of Zoology, Chinese Academy of Sciences, Haidian, Beijing, China

Studies were conducted in 1995 to investigate the spatial distribution of the pupae and larvae densities of *Dendrolimus punctatus* (Walker), as well as the parasitic guilds of pupae in three different types of pine forest (i.e., pure masson pine stands of high and low caterpillar population density, and mixed pine forest). Samples were collected in 20x20 and 36x12 grid in these pine forests. The regionalized variables and kriging technique in geostatistics were used to assess the spatial pattern of *D. punctatus* and its parasitic guild. Geostatistical analysis offers advantages over traditional indices of spatial dispersion. Kriging technique makes optimal, unbiased estimates of regionalized variables at unsampled locations using initial set of data values and the structural properties of the semivariogram.

These analyses revealed spatial distributions of pupae, larvae and parasitic guilds of pupae in three pine forests, which varied as pine caterpillar density and different pine forests. In mixed pine forest, semivariograms of pupae and larvae were fitted by spherical model ($r^2=0.923$ and $r^2=0.879$, respectively), indicating an aggregated spatial arrangement. Their localized discontinuity was 0.354 and 0.277 at 5m scale, respectively. Spatial dependence occurred at a range of 38.7m and 13.9m, respectively. Semivariogram of pupae parasitic guild was fitted by level linear model, sill was 0.297. In pure masson pine stands of high density, semivariogram of pupae was fitted by linear model with no slope, localized discontinuity equals to sill, which is 1.42; in low density stands, semivariogram was linear with a very low slope 0.072, indicated random or uniform spatial pattern. The punctual kriging procedure can use these semivariograms to generate maps of interpolated estimates of pupae and larvae densities in the mixed forest. The results and methods will be useful for insect pest management of forest in developing sample maps and understanding the spatial relatedness of pine caterpillar populations.

10-067

METAPOPOPULATION STRUCTURE OF *CARABUS PROBLEMATICUS* HBST. (COLEOPTERA, CARABIDAE) IN A FRAGMENTED LANDSCAPE, - SIMULATION RESULTS IN COMPARISON WITH FIELD DATA.

H. Gruttke and H. Engels

Bundesamt für Naturschutz, Institut für Tierökologie, Bonn, Germany

The ground beetle *Carabus problematicus* is a species usually living in forests, but exhibiting a certain degree of dispersal activity outside wooded habitats, too. Within an intensely cultivated agricultural landscape in Germany the spatial distribution patterns of this species were studied for three years (1992, 1994 and 1995). In this region, today only a few, mostly isolated patches of woodland have remained. *Carabus problematicus* was only caught in large forest remnants or in forest islands not too much distant from these. However, in some of the smaller and more remote forest patches the species could not be found every year. This finding (result) is interpreted as an indication for the existence of metapopulation dynamics of *C. problematicus* in this landscape area.

On the basis of a GIS generated map containing the spatial distribution of suitable habitats at landscape scale, of own field results on the occurrence of this species and of informations from literature on different biological population parameters, a metapopulation model is developed using the program RAMAS-GIS. Simulation results obtained are corresponding well with the field data. According to the model the spatial arrangement of habitats and the distance between neighbouring occupied habitat patches belong to the most important parameters stabilizing populations of *C. problematicus* at landscape level. Applicability and limitations of the model as well as consequences for nature conservation planning in agricultural landscapes are discussed.

10-068

INVESTIGATION OF THE FEEDING PREFERENCES OF *STETHOPHYMA GROSSUM* (ORTHOPTERA: ACRIDIDAE) IN FIELD AND LABORATORY EXPERIMENTS

S. Sakowski

Zoologisches Institut, Technische Universität Braunschweig, Deutschland
In field and laboratory experiments both sexes of *Stethophyma grossum* were tested for differences in their feeding preferences because of the differences in their body size and behavior.
Therefore diverse species of grass were offered under standardized conditions. As expected, females need more food on a account of their larger body size.
But the study also shows that males and females of this species prefer the same grasses. As *St. grossum* is limited to wetland it is interesting that in no offered combination a grass of the species *Carex* was preferred.
For the field experiments the test animals had to hunger for at least two days. These grasshoppers seem not to be as selective as in the laboratory. So in some cases even straw and herbs were tested for a short time until a grass was chosen twice.

This research was supported by the German Ministry of Education, Science, Research and Technology under Grant BEO-0339559

NEW BIOLOGICAL DATA ON THE APTEROUS BEETLE *ELYTROSphaera LAHTIVIRTAI* BÉCHYNE (CHRYSOMELIDAE: CHRYSOMELINAE) IN BRAZIL.

M. V. Macedo¹ J. Vasconcellos-Neto²

¹ Laboratório de Ecologia de Insetos, Departamento de Ecologia, IB, Universidade Federal do Rio de Janeiro, RJ, Brazil. Curso de Pós Graduação em Ecologia, IB, UNICAMP. - Bolsista CAPES
² Laboratório de Interações Insetos/Plantas, Departamento de Zoologia, IB, Universidade Estadual de Campinas, CP 6109, CEP 13083-970. Campinas, SP, Brazil.

The biology and ecology of the apterous genus *Elytrosphaera* is poorly known. It was only recently that P. Jolivet and J. Vasconcellos-Neto published two papers, one dealing with the biology of *E. xanthopyga* and another with the genus distribution. The subgenus *Elytrosphaera* s. str. occurs mainly on the Brazilian plateau (8 species) and one occurs in Bolivia.
Elytrosphaera lahtivirtai is an endemic species at Itatiaia National Park, Rio de Janeiro state, Brazil. We found both larvae and adult of this species feeding on *Solanum caeruleum* Vell., the first record of this genus on Solanaceae. *Adenostema brasilianum* (Asteraceae) was previously recorded as the host plant of *E. xanthopyga* at Viçosa, Minas Gerais state, Brazil.
E. lahtivirtai occurs at near 1000m altitude where it is apparently more common on plants near streams. Adults appear in the field during November, reproducing from December until February, and disappearing in March. The adults probably diapause in the soil until the following spring.

10-069

HOST PLANT PREFERENCE IN *PLAGIOMETRIONA* SP (COLEOPTERA: CHRYSOMELIDAE: CASSIDINAE)

F.N.de Sá & M.V. Macêdo

Laboratório de Ecologia de Insetos, Depto. de Ecologia, Inst. Biologia, Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brasil

At Poço das Antas Biological Reserve, Rio de Janeiro State, Brazil, *Plagiometriona* sp has been observed feeding, throughout the year, as both larval and adult forms, on two Solanaceae species: *Aureliana fasciculata* (Vell.) Sendt. and *Acnistus arborescens* (L.) Schecht. In order to evaluate host plant preference, two sites were chosen where, in one of them *A. fasciculata* was about twice more abundant than *A. arborescens*, in the other site *A. arborescens* was about four times more abundant than *A. fasciculata*. Seven individuals of each plant species were marked in each area and numbers of immature and adult beetles were recorded in three different seasons: winter (July, 1995), spring (October, 1995) and summer (January, 1996). In general, *A. fasciculata* was significantly preferred by the beetle larvae regardless of the plant relative abundance. Adults as a whole did not show any significant difference in numbers on the two host plants, except for the spring where they occurred more often in *A. fasciculata* in the area where *A. arborescens* was more abundant. This preference may be due, in part, to the higher abundance and the wider distribution of *A. fasciculata* in the reserve. Other possible explanations, related to the host plant quality, are being investigated. Financial Support: CNPq and Fundação O Boticário de Proteção à Natureza.

10-071

A SPECIAL CASE OF CAMOUFLAGE IN A TROPICAL CURCULIONID BEETLE, *PERIDINETUS ZINCKENI*

R. F. Monteiro

Lab. Ecologia de Insetos, Depto Ecologia, Universidade Federal do Rio de Janeiro, Rio de Janeiro, RJ, Brasil

Adults of *Peridinetus zinckeni* Rosenschold, 1837, are often found in Southeast Brazil, feeding on Piperaceae leaves. When feeding, during the night, this beetle leaves several circular holes, already recorded for *P. sellatus* elsewhere.
P. zinckeni also produces elliptical holes inside which it rests laterally during the day. The elliptical holes occur in a much lower density than the round ones. The rest is made in such a way that half of its black and white body can be seen in each side of the leaf. Besides this, the insect also defecate in each extremity of the elliptical resting hole producing an image consisting of three black dots quite similar to bat feces, frequently observed on the leaves of *Piper*. It is likely that this behavior of *P. zinckeni*, already observed in *Piper arboreum*, *P. gaudichaudianum*, *P. amplum* and *P. mollicornum*, corresponds to an adaptive camouflage. Even though such a curious behavior has not yet been recorded, it may occur in other insects with similar biological aspects and host plants, such as other Baridinae species. Financial support: CNPq, FUJB/UFRJ, Fundação O Boticário de Proteção à Natureza.

HISTORICAL ETHOLOGY IN THE EMPIDOIDEA (DIPTERA: HETERODACTYLA: EREMONEURA)

C. Daugeron

Laboratoire d'Entomologie, Muséum National d'Histoire naturelle & EP 90 CNRS, 45, rue Buffon, 75005 Paris, France

The phylogeny of the Empidoidea is briefly discussed in comparison with the works of different authors, especially Chvála (1981, 1983), Cumming et al. (1995) and Sinclair (1995). The questions of the monophyly of the Empididae and the validity of the Hybotidae are especially approached.

Several ethological characters including the predaceous or nectar-feeding habit, the presence or absence of swarms, the mating activity on the ground or in the air, the presence or absence of the 'nuptial gift', the nature of the gift... are analyzed in the Empidoidea in reference to their phylogeny. The method consists to map the ethological characters or attributes (traits upon which *a priori* homology and polarization are so hazardous that one prefers to make these operations in reference to an extant phylogeny, Grandcolas et al., 1994) on the cladogram to follow their evolution. It is an objective test of the classical hypotheses relating the reproductive behavior as regards the traditional scenarios (Poulton, 1913, Kessel, 1955) and the sexual selection.

It is more particularly considered that the 'nuptial gift' has not appeared repeatedly in the Empidinae but that this behaviour has an monophyletic origin. The phylogeny hypothesis of the subfamily provides evidence that the subgenera *Xanthempis*, *Lundstromiella* and *Holoclera* are groups exhibiting numerous derived characters contrarily to the classical hypothesis, consequently the absence of the 'nuptial gift' in these subgenera is considered as the result of reversals.

All other attributes are analyzed according to the same method, in reference to the phylogeny and as regards the parsimony principle.

THE ASSEMBLY OF A THREE-LEVEL FOOD CHAIN IN WATER-FILLED CONTAINERS WITHIN FOUR AUSTRALIAN, SUBTROPICAL RAINFORESTS

B.A. Jenkins

Department of Geography and Planning, University of New England, Armidale, New South Wales, Australia

A number of water-filled containers were placed in subtropical rainforest along a short latitudinal gradient in four regions of Eastern Australia. Several dipteran species selected the containers as oviposition sites. Among these species, the predaceous larvae of *Anatopynia pennipes* (Freeman), a tanypodine chironomid, feed predominantly on larvae of the mosquito *Aedes notoscriptus* (Skuse). The mosquito colonized habitat units within the first three months in all four regions while the tanypodine chironomid was generally slower to colonize. Initial colonization by *A. pennipes* took longer at higher latitude. Consequently, a three-level food chain took twice as long to form in container habitats in the forests at higher latitudes. I propose that seasonal droughts act as a disturbance to depress populations of *A. pennipes* in the higher latitude forests.

10-073

ZOOSAPROPHAGY AND PHYTOSAPROPHAGY IN MYRMECOPHILOUS CHRYSOMELID BEETLE LARVAE, *MACROLENES DENTIPES* AND *PACHYBRACHIS ANOGUTTATUS* (COLEOPTERA: CHRYSOMELIDAE: CRYPTOCEPHALINAE)

M. Schöller

Johann-Wolfgang-Goethe University, Working Group Ethoecology, Frankfurt am Main, Germany

Controversy exists about the nutritional ecology of larvae of the chrysomelid tribe Clytrini. Previous studies resulted in two opinions, claiming that these myrmecophilous larvae are either phytosaprophagous and/ or predators of ant progeny. Little is known about larvae of the tribe Cryptocephalini living in the vicinity of ants.

Food selection of the larvae of two species found in the vicinity of an ant nest in Mallorca, Spain, *Macrolenes dentipes* OLIVIER (Clytrini) and *Pachybrachis anoguttatus* SUFFRIAN (Cryptocephalini) was studied in the laboratory.

In multiple choice tests, dried and rehydrated leaves of *Quercus ilex* and dead larvae and adults of the Lepidoptera, *Ephestia kuehniella*, were offered.

Whereas the larvae of *P. anoguttatus* fed exclusively on wet and dry leaves of *Q. ilex*, the larvae of *M. dentipes* fed on all four substrates offered and showed no significant preference for vegetable or animal material.

The data support the hypothesis that in the Clytrini, the larvae feed on remnants of prey deposited by the ants in certain areas of the nest.

10-075

THE SIGNIFICANCE OF DITCHES FOR *STETHOPHYMA GROSSUM* (ORTHOPTERA: ACRIDIDAE) WITH SPECIAL CONSIDERATION OF DISPERSAL

C. Frosch

Zoologisches Institut der TU Braunschweig, Braunschweig, Germany

A mark-release-recapture experiment was carried out in order to see if the dispersal of *Stethophyma grossum* is influenced by the presence of a drainage ditch (within a relatively unsuitable habitat). Additionally, by walking on 100m transects, about 150 ditches together with the adjacent areas were mapped with regard to colonization by *S. grossum*. Further parameters describing the structure and vegetation of the ditches were also recorded.

As for the dispersal of *S. grossum* when released at a single point, it seemed to be insignificant whether the releasing-point was situated directly at the borders of the ditch or at some distance from it on the meadow. Furthermore, consistently fewer individuals were found within a distance of 1m from the water's edge than were on the adjacent land. Correlations between „ditch type“ and the numbers of individuals occurring on the ditch borders could not be ascertained as they were either non-significant or extremely weak. However, a strong correlation was found between the numbers of *S. grossum* on the ditch borders and on the adjacent areas.

THE DEVELOPEMENT OF A HABITAT-SUITABILITY-MODEL FOR *CONOCEPHALUS DORSALIS* (ORTHOPTERA: TETTIGONIIDAE)

D. Helms

Zoologisches Institut der TU Braunschweig, Braunschweig, Germany

For the scientific assessment of areas it is increasingly important to be able to make quantitative statements using objective measurable parameters.

In this study the special requirements of *C. dorsalis* regarding habitat quality serve as the main parameters.

Using geographic information systems (GIS) certain structural types were ascribed to the plots of the research area in a fen.

921 test sites and 289 trench borders were selected and investigated with regard to significant key factors (e.g. plant species, plant height, land-use, etc.) and abundance of these regional target species.

The frequency and density of *C. dorsalis* were determined for a wide range of parameters in each case. The results were applied to develop a habitat-suitability-model.

The relationships described by this model should supply the basis for a simple or quick forecast for the habitat-quality for *C. dorsalis* in an area which has not been investigated up to the present.

This research was supported by the German Ministry of Education, Science, Research and Technology under Grant BEO-0339559.

ON THE CLASSIFICATION AND EVOLUTION OF ECOLOGICAL NICHES OF INSECTS

V.G. Kaplin

Department of Plant Protection, Samara Agricultural Academy. Ust-Kinel, Russia

Ecological niche is the comparatively homogeneous functioning sphere of living organisms in physical, chemical and biological respects that bring about the necessity of formation of special adaptations for the existence and development, first of all for feeding and movement. At present the classification of ecological niches is absent. They can be divided into two types: aquatic and terrestrial niches. Soil surface, soil and litter, surface of the seed plant above-ground organs, plant tissues, body surface, tissues and internal organs of animals are the main subtypes of insect terrestrial ecological niches. Formation of the highest taxa of insect life-forms is related with exploitation by them of main and complementary (caves, burrows, nests and excrements of vertebrates, nests of ants and termites, fungi carposomes etc.) ecological niches. Insects came off the aquatic ancestors on the soil surface with loose plant remains near the water bodies. Then they settled plant tissues, soil, animal body surface and tissues, burrows and nests of vertebrates. Insect transition to development from one type and subtype ecological niches another had taken place more than once.

ECOLOGY OF A GALL WITH GLANDULAR TRICHOMES IN *CUPHEA CF CALOPHYLLA* (LYTHRACEAE), IN BRAZIL

F.F.F. FERRAZ^{1,2}, R.F. MONTEIRO², J. VASCONCELLOS-NETO¹.

1- Lab. Interações Insetos-Plantas, Dept^o Zoologia, Inst. Biologia - Universidade Estadual de Campinas - Campinas- SP, Brazil. *Pós-Graduação em Ecologia -Unicamp, Bolsista CNPq. 2- Lab. Ecologia de Insetos, Dept^o Ecologia, Inst. Biologia -Universidade Federal do Rio de Janeiro- RJ, Brazil.

The family Lythraceae has only two types of entomogenous galls described for the Neotropical region, both of them occurring in plants of the genus *Cuphea*. This study has been carried out at Poço das Antas Biological Reserve, Rio de Janeiro state, Southeast Brazil. There, we find *Neolasioptera* sp (Diptera, Cecidomyiidae) galling apical shoots and stems of *Cuphea cf. calophylla*. The gall has several chambers containing one larva per cell. It is densely covered by glandular trichomes, absent at the beginning of the gall development, which show intense glandular activity when the gall is fully developed. The purposes of this work are to describe the biology of the gall maker, the fluctuation of its population, and the possible role of the glandular trichomes on the protection for the gall maker against its natural enemies.

We have chosen sites to obtain gall makers and parasitoids, where twice a month we have been collecting galls. The latter occur throughout the year, showing an increase of its abundance during the summer. Experiments in field and laboratory are being carried out to test the possible role of the trichomes in the protection of the gall maker.

Up to now we have obtained only one parasitoid species, Eulophidae, which emerges during the late development of the larva or in pupae. Parasitism rate was relatively low for all the period of study. Many chalcid wasp species have been found attached to gall trichomes. This observation as well as the relatively low parasitism rate suggest that trichomes may have an important role on the gall maker survivorship.

COLEOPTERA: ELATERIDAE, CANTHARIDAE AND MALACHIDAE AREAS WITH STOPM DAMAGE IN SWITZERLAND

N. Bassangova

Kalmyk State University, Elista, Russia

Beetles of the Elateridae, Cantharidae and Malachidae were sampled in two different regions (Dissentis, Limpachtal) in four habitats and four different traps. The traps were controlled once a week between the period from 01.05. to 01.10. during the years of 1987 to 1990. Statistical analysis produced interesting results of the distribution of the insects in time and place as well showed as meaning of areas with storm damage for the fauna of specific beetles.

10-080

NUTRITIONAL PREFERENCE OF THE DUNG BEETLE, *SCARABAEUS CRISTATUS* F. (COLEOPTERA - SCARABAEIDAE) FROM KUWAIT

W. AL-Houty and F. AL-Musalam

Department of Zoology, Faculty of Science, University of Kuwait, Kuwait

Adult *Scarabaeus cristatus* F. consumed the fluid components of the dung; when three herbivorous animal dung such as horse, camel and sheep were offered, the beetles preferred the horse dung to the others. The sheep dung was preferred to the camel dung. The carnivorous animal dung, such as that of dog and fox were also consumed but to a lesser extent. The dog dung was preferred to the fox dung. As a whole, the herbivorous animal dung was preferred to the carnivorous one. The physical and the chemical characters of the dung play an important role in the dung consumption by the beetle. The odour of the dung is a vital clue that guides the dung beetles to its food.

PRELIMINARY REPORT ON HIGH TEMPERATURE TOLERANCE OF RICE LEAFFOLDER, *CNAPHALOCROCIS MEDINALIS*R. Zhang¹, K.L. Heong, I.T. Domingo²

1. Research Institute of Entomology, Zhongshan University, Guangzhou, P.R. China-2. Entomology & Plant Pathology Division, International Rice Research Institute, Los Banos, Philippines

The high temperature tolerance of rice leaffolder (RLF), *Cnaphalocrocis medinalis*, was measured in temperature range between 34 and 40°C, 70%RH, and 12:12 illumination and the quantal response data were subjected to probit analysis using the computer program developed by Finney. The median lethal dosage (LT₅₀, expressed in hours) was used to determine the survival ability of RLF in high temperature conditions.

Different values of LT₅₀ were found among stages of egg, larva, pupa, and adult. The highest LT₅₀ is in larva stage (186.5 hours) whereas the lowest exists in the stage of egg (30.1 hours). At range of 35 and 40°C, LT₅₀ of eggs decreased from 69.9 to 30.1 hours with increasing temperature, which was described by the linear regression equation in form of $LT_{50} = 330.9 - 7.6T$. The experimental results also showed that there are no significant differences in LT₅₀ among three different local populations.

DUNG BEETLES ASSEMBLAGES INHABITING BOVINE AND OVINE DROPPINGS IN URUGUAYAN PRAIRIES

E. Morelli, P. Gonzalez-Vainer¹, A. Baz²

Departamento de Biología Animal, Facultad de Ciencias, Universidad de La Republica, Montevideo, URUGUAY - 1
Departamento de Biología Animal, Facultad de Ciencias, Universidad de La Republica, Montevideo, URUGUAY - 2
Departamento de Biología Animal, Universidad de Alcalá, Alcalá de Henares, ESPAÑA.

Dung beetles have been studied along a two year period (January 92-April 94). Monthly samples were taken by directly examining bovine and ovine feces (480 bovine feces and 330 ovine feces). A grand total of 1846 individuals in 12 different species has been obtained (1279 individuals in 12 different species in bovine droppings and 567 individuals and 11 species in ovine droppings). The most abundant species are *Onthophagus hirculus* (488 ex. and 115 ex. respectively) and *Canthidium moestum* (322 ex. and 369 ex. respectively). However, density values are extremely low and seasonal activity is restricted to a short period (October, November and December). Maximum density in both bovine and ovine droppings, has been found in November 93 (8.55 and 8.87 individuals/dung respectively), whereas mean density along the study period is 2.57 ind./dung in cattle dung and 1.53 ind./dung in sheep droppings. In sum, this preliminary study shows that populations of native dung beetles in these pastures cannot adequately remove the tons of livestock feces deposited daily throughout the country (near 11 millions head of cows). In consequence, the introduction of carefully selected species of foreign dung beetles seem to be the only alternative that could aid the native fauna in rapidly removing this dung from pasture surfaces.

ELEVATED CO₂ AND ITS EFFECT ON THE POPULATION DYNAMICS OF LEAFMINERS AND APHIDS

P.H.D. Smith, T.M. Bezemer, T.H. Jones

NERC Centre for Population Biology, Imperial College at Silwood Park, Ascot, United Kingdom

The effects of an elevated CO₂ environment (200 ppm above ambient) on the population dynamics of two herbivorous insects in a model, four-trophic level, terrestrial community were investigated in the controlled environment facility, the Ecotron, at Silwood Park. Results from greenhouse studies were used to explain the findings in more detail.

For the aphid, *Brevicoryne brassicae*, increasing CO₂ levels led to earlier reproduction and an increase in population size. This response may be a consequence of an increased production of carbon based plant volatiles.

The leafminer, *Chromatomyia syngenesiae*, appeared unable to compensate for the higher C:N ratio of plants grown in elevated CO₂ environments. Marked reduction in pupal weight were recorded.

The consequences of these effects on the population dynamics of the species and their rates of parasitism are discussed.

10-084

SEASONAL ABUNDANCE OF THE NEOTROPICAL BROWN STINK BUG, *EUSCHISTUS HEROS* (HETEROPTERA: PENTATOMIDAE) IN OVERWINTERING NICHES AND BREAKUP OF DORMANCY

A.R. Panizzi, L.M. Vivan

Centro Nacional de Pesquisa de Soja (CNPSo), EMBRAPA, Caixa Postal 231, Londrina, PR 86001-970, Brasil

The seasonal abundance of the neotropical brown stink bug, *Euschistus heros* (F.) (Heteroptera: Pentatomidae) in overwintering niches in northern Paraná state, Brazil (latitude 23° 11'S, longitude 51° 11'W) was monitored from September 1994 to August 1995. The breakup of dormancy (oligopause) was studied in the laboratory comparing the feeding activity and reproduction of adults collected in the field on different physiological condition (i.e., dormant and non-dormant). No bugs were found in overwintering niches during summer months (December to February) and during early autumn (March). From mid autumn toward winter (April-August), the number of *E. heros* captured in these niches gradually increased, decreasing thereafter with the start of spring in September. *E. heros* dormant and non dormant, taken to the laboratory at 25± 1°C, 65 ± 5% RH, and 14 HL: 10 HD photoperiod, plus suitable food (i.e., soybean pods or seeds) reassumed feeding immediately. The number of stylet sheaths deposited/day on the food was greater for non-dormant than for dormant adults. Feeding activity was greater on immature pods compared to mature seeds of soybean. Dormant females taken to suitable biotic and abiotic conditions lasted ca. 2 weeks to start reproduction.

10-086

LEAFHOPPERS (HOMOPTERA, AUCHENORRHYNCHA) OF SELECTED PEAT-BOGS IN POLAND

J. Szwedo, C. Gębicki

Department of Zoology, University of Silesia, Katowice, Poland

The leafhoppers communities of natural highmoors of class Oxycocco—Sphagnetia in the Sudetes, Nowotarska Valley and Bieszczady Mountains in southern Poland were examined. These insects of lowmoors and transitional moors (class Scheuzerio—Caricetea) in southern and northern Poland were also considered.

Totally 136 species of leafhoppers were registered, of which two are new to Polish fauna: *Cicadella lasiocarpae* Oss. - known only from a few localities in northern part of Europe, and *Cicadula longiventris* (J. SHLB.) - a species related to taiga biome.

The leafhoppers of the examined peatbogs are characterised by the high step of heterogeneity. Variability of the species composition of leafhoppers communities of highmoors in West — East direction was observed.

In the examined material a few very interesting montane endemic and relict species were found. The characteristic species of leafhoppers communities were assigned; in most cases they were oligophagous, monophagous and higrophilous species (tyrphophiles and tyrphobiontes).

The species composition of all examined peatbogs in Poland was analysed and groups of the mutual similarities were fixed. The chorology and ecology of investigated leafhoppers were also analysed.

STUDY OF *AN. GAMBIAE* S.L. BY MARK-RELEASE-RECAPTURE IN THE VILLAGE OF BANAMBANI IN MALI.

G.Dolo¹, S.F.Traoré¹, M.Bouaré¹, N.Sogoba¹, C.E. Taylor², R. Sakai¹, V. Petrarca³, Y.T.Touré¹.

1.MRTC/DEAP. Ecole Nationale de Medecine et de pharmacie. Bamako. Mali.

2.UCLA, Department of Biology, Los Angeles, CA, USA.

3.Institute of Parasitology, University of Rome "La Sapienza", Rome, Italy.

A capture-mark-release-recapture experiment was conducted in July in 1993 and 1994 in the village of Banambani at 25 Km northeast of Bamako in the North Sudan Savanna of Mali, to assess vector composition, population size and dispersal. The mosquitoes were captured by mouth aspirators and placed into paper cups, marked with fluorescent powders, and released at two sites: one in the center of the village and another 1Km away near the mosquito breeding sites. They were recaptured on two consecutive days following each release session. The vector population was composed of *An.gambiae* s.s (38.8% in 1993 and 76.4% in 1994) and *An.arabiensis* (61.1% in 1993 and 23.5% in 1994), which showed significant annual variations in their relative frequencies. The recapture rate for *An.gambiae* s.l. was 2.1% in 1993 and 4.2% in 1994. The mean population size of the vectors varied significantly between the two years: 10775 in 1993 and 28243 in 1994. The mosquitoes which were released in the center tended to disperse much more than those which were released near the breeding sites. In general, the mosquitoes did not disperse beyond 1 km from the release site. These results can have implications for the understanding of potential dispersal of mosquitoes from one village to another under vector control conditions.

THE EFFECTS OF CATTLE FARM SIZE AND ISOLATION ON LOCAL DUNG BEETLE COMMUNITIES

T. Roslin

Department of Ecology and Systematics, Division of Population Biology, University of Helsinki, Finland

The cattle stock and the number of cattle farms have decreased by 37 and 86 % in Finland over the past 35 years. Therefore, the habitat of specialist dung-breeding insects has become increasingly fragmented. Metapopulation models predict that species may be lost from networks of 'too' small and/or 'too' isolated habitat patches. In Finland, significant population declines have been observed in several dung beetle species (Coleoptera: Scarabaeidae: *Aphodius* and *Ontophagus*). I hypothesize that this is the result of metapopulation-level dynamics.

To evaluate the effect of farm size and isolation, I sampled the local *Aphodius* communities in individual cattle farms on the Åland islands (SW Finland). The number of specialist species breeding exclusively in the dung of domestic cattle increased with farm size (number of cows). No such effect was found for generalist species. The number of species present represents a dynamic balance between local extinctions and recolonizations. In specialist species, small cattle farm size is likely to be associated with small population sizes of beetles, and thus with a high risk of local extinction. This will shift the local species richness to a lower level.

The degree of isolation of the farm did not have any detectable effect on the number of species encountered. The lack of isolation effect is probably caused by frequent movements of dung beetles between the farms at the scale of this study. Dung beetles are strong flyers, and the patchwork of cattle farms studied is relatively dense (farms were mostly isolated by less than 4 km). Furthermore, the average local population size in dung beetles is relatively large, and hence the probability of extinction is likely to be low for most local populations. Isolation effects will probably be detected at larger spatial scales (tens of km).

THE FIRST EXPERIMENT IN LONG-TERM
PREESTIMATION OF ARMYWORMS BY MEANS OF ACCUMULATED TEMPERATURE (Digest)
--- Song Guangzhen
(Zhangqiu City Agricultural
Broadcasting School)

It's an inverse proportion in temperature with armyworm growth days($NT=K$). If the beginning growth temperature (C) and the standard error (SK) are considered into, the mathematical module must be $N=K+SK/T-(C+Sc)$. When used into the preestimation, it is to be used either in additional or divisional calculation and furthermore, there's different growing temperature in each state of worm. This makes the calculation complicated. According to the quality of screen function, with even function instead of single function, and through general calculation, I've summed up the mathematical module of the preestimation development period as follows: $K-a_1T_1^2-a_2T_2^2-.....-a_nT_n^2=0$, and upon the research of the armyworms' long-term migration flying principles, I've mapped out the programme of the armyworms' long-term preestimation: With the eggs in foreign area as the main preestimation worm state and with development period preestimation on the basis, the development tendency can be analyzed and the long-term broadcasting can be achieved.

Key words:
accumulation temperature method
armyworm
long-term preestimation

10-089

TECHNOLOGY TO PREESTIMATE
BOLLWORM EGG PEAK BY MEANS OF ACTIVE ACCUMULATED TEMPERATURE (Digest)
--- Song Guangzhen
(Zhangqiu City Agricultural Broadcasting School Shandong PRC)

Upon understanding that temperature is a molecular energetic grade in moving energy and the growth beginning temperature is the energetic grade in motivating bio-chemical reflection, as the effective accumulated temperature concept is taken away and the square of the active temperature is done, the mathematical module of the preestimate development period is founded as follows: $K-a_1T_1^2-a_2T_2^2-.....-a_nT_n^2=0$, able to be used in preestimation of appearance numbers of the bollworm egg peak in its second generation, egg peak day and egg peak velocity and as a result, the preestimation is comply with the practical estimation.

Key words:
active accumulated temperature
bollworm egg peak
preestimation

10-090

SEASONAL OCCURRENCE OF *LYGUS* BUGS (HETEROPTERA: MIRIDAE) ON FIELD CROPS IN FINLAND
A.-L. Varis
Department of Applied Zoology, University of Helsinki, Finland

A long-term survey of *Lygus* populations on eight field crops showed that the hibernated bugs, which appeared on field crops in May, at the sowing time of spring-sown plants, first sought food and shelter from overwintered crops such as winter rye, red clover-timothy mixture, and winter turnip rape. Turnip rape and clover-timothy mixture harbored most adults until the end of June, even if some of them started to move to spring cereals (wheat, oats and barley), potato and sugarbeet after the emergence of these plants. The numbers on cereals remained small until the crops reached the heading stage. The peak occurred in the first half of August. The numbers on potato and sugarbeet were also highest in August. The total number of adults was highest on wheat. The most common species on all crops was *L. rugulipennis* Poppius, which consisted 92% of the adults.

Nymphs were found on all the studied crops. Their occurrence started in the second half of June and reached its peak from mid-July to mid-August. The numbers were highest on wheat.

10-091

PHENOLOGY AND MONITORING OF *LIRIOMYZA HUIDOBRENSIS* (DIPTERA: AGROMYZIDAE) IN POTATOES IN ISRAEL
P.G. Weintraub and A.R. Horowitz
Department of Entomology, Agricultural Research Organization, Gilat Regional Experiment Station, Israel

The pea leafminer, *Liriomyza huidobrensis* (Blanchard), was monitored using yellow sticky traps in locations in southern Israel in the spring of 1995. Initial populations were low until the second week of April, in which there was a sudden population increase in all localities. This population peak was independent of potato plant age and was not apparently related to the average daily temperature or hours of daylight.

Sampling techniques for adult leafminers were compared using yellow sticky traps and hand vacuuming. With respect to yellow sticky traps, comparisons were made between traps placed parallel and perpendicular to the ground, and at various heights above the ground in 50 cm tall potato plants. Traps placed at plant height caught the most flies with both orientations. A higher percentage of females were caught lower to the ground, presumably because there were more ovipositional sites on secondary and tertiary branches close to the ground.

Diel activity was monitored using yellow sticky traps and hand vacuum sampling in May and June in two locations (one with high and one with low leafminer populations) from 0500 to 1900. Activity patterns were identical; immediately after sunrise (0545) there was a burst of activity that declined rapidly through the morning hours as the temperature increased (to 28°C), there was no corresponding increase in activity at the end of the day as temperatures declined. Sampling activity with a hand vacuum confirmed these results under conditions of low, but not high, adult populations.

10-092

SURVEY OF THE ENTOMOLOGICAL FAUNA IN PARANÁ STATE, BRAZIL. III. SATURNIIDAE (LEPIDOPTERA)

R.C. Marinoni, R.R.C. Dutra

Departamento de Zoologia, Universidade Federal do Paraná, Curitiba, Brazil

In addition to the Survey, Saturniidae was studied in its ecological and faunistic aspects. The material was collected using light traps installed in eight different sites of Paraná State, from October, 1986 to September, 1987. Indices of diversity and evenness (Shannon, Brillouin, Berger & Parker and α of Williams) were used to discuss richness and dominance of species. Besides using ecological indices, the data were also compared by Clustering Analysis, Principal Coordinate Analysis and Linear Correlation Coefficient. Faunistic data gathered in these sites were compared. The results were compared with a former study on Ctenuchidae (Lepidoptera).

10-093

EFFECT OF BORDER STRUCTURE ON INTERCHANGES OF EPIGEIC ARTHROPOD COMMUNITIES BETWEEN ABANDONED FIELDS AND ADJACENT WOODLANDS

G. Torta, A. V. Gourov¹

Istituto di Selvicoltura, Università degli Studi di Firenze, Firenze,

Italy - ¹ V. N. Sukachev Institute of Forest, Siberian Branch of Russian Academy of Science, Krasnoyarsk, Russia

General trends in the distribution of epigeic arthropods and interchanges of Carabidae communities between formerly cultivated fields and adjacent woodlands were studied during the period July-October 1995 in five different sites on the Northern Apennines (Firenzuola, Tuscany, Central Italy). Results suggest that the structure of forest borders determines the degree of permeability to epigeic arthropods. The presence of a well-developed and closed mantel prevents grassland species from moving into the forest, whereas some woodland species (e.g. *Pterostichus micans*, *Carabus rossii*) usually penetrate into the fields. Human practices affect interchanges. Man-made tunnels across the mantel stimulate some active meadow species (e.g. *Brachynus crepitans*) to move into the forest. In young coppices, the woodland arthropod communities are characterised by a comparatively poor taxonomic structure (3 carabid species vs 7 species in mature coppices) and low active density (<1 exemplar/trap/3 days). Furthermore, some meadow species (*B. crepitans*, *Carabus violaceus*) can penetrate into such recently-disturbed forest at least up to 20 m from the border. When forest borders coincide with natural borders, such as the upper edge of a slope, interchanges between ecosystems are strongly reduced.

10-094

ECOPHYSIOLOGICAL ASPECTS OF COLD TOLERANCE OF *EPIPHYAS POSTVITTANA* WALKER (LEPIDOPTERA: TORTRICIDAE), THE LIGHT BROWN APPLE MOTH IN AUSTRALIAW. Danthanarayana¹ and H. Rohitha²Department of Zoology, University of New England, Armidale, NSW 2351, Australia¹. HortResearch, Hamilton, New Zealand²

E. postvittana can be classified as a "chill-tolerant" species. Supercooling point (SCP) varied as a function of developmental stage and geographical strain. A two-week period of winter conditioning significantly lowered SCPs. For early larval instars, winter feeding was a prerequisite for survival. Mortality occurred at sub-zero temperatures above the SCPs. The main criterion for survival - the ability of survivors to complete development and emerge as morphologically normal adults with full reproductive competence - was also determined. A proportion of larvae and pupae survived continuous exposure to sub-zero temperatures (-1 to -6°C) for periods up to 48 hours and produced viable progeny. The supercooling capacity of *E. postvittana* was not affected by season. Whilst no cryoprotective polyols were found in overwintering larvae, exposure to temperatures in the -5 to 0°C range may trigger trehalose synthesis. After exposure to overnight sub-zero temperatures for two weeks, trehalose was present as 0.4% of larval wet body weight. At such a level, trehalose is capable of preventing both freezing and desiccation damage to membranes and proteins. If increased levels of trehalose do help *E. postvittana* survive cold exposure, this may have ramifications for the disinfection of fruit leaving Australia and New Zealand. Quarantine disinfection has traditionally combined long periods of cold storage (up to three weeks) with methyl bromide fumigation. The current method of disinfection of export fruit by refrigeration at 0.55°C followed by fumigation needs to be reviewed in the light of these findings.

10-095

POPULATION DYNAMICS OF *PARNASSIUS APOLLO* (L.) IN ULUDAĞ-BURSA, TURKEY

B.Kovanci, N.S.Gencer, M.Kaya

Department of Plant Protection, Faculty of Agriculture, University of Uludağ, Bursa, Turkey

The population dynamics of *Parnassius apollo* was investigated in two different areas in Uludağ-Bursa between 1994 and 1995. In both areas, *Sedum album* and *Sedum pallidum* are the larval foodplants which are intermixed with nectar sources of adults. Larval population changes were examined by counts conducted weekly during the development period of larvae and the population fluctuations of adults were examined by counts conducted weekly during the flight period by capture-mark-recapture method.

Consequently, the adult flight in the first area was observed between 14 July and 8 September with a peak at the end of July, in 1994. A total of 812 individuals (45 % females) were marked and 62 of this adults were recaptured at least once. The adult flight period in the second area took place between 25 June and 1 September and 235 individuals (30 % females) were marked in total (19 butterflies recaptured). In 1995, *P. apollo* adult flights realized between 4 August and 24 September in the 1st area and between 25 July and 13 September in the 2nd area. A total of 621 individuals (37 % females) and 52 individuals (29 % females) were marked in the 1st and 2nd areas respectively. The number of butterflies recaptured at least once in the 1st and 2nd areas were 119 and 16 individuals respectively.

10-096

EVALUATION OF THE ENVIRONMENTAL IMPACT OF *Eucalyptus* CROPS ON THE ENTOMOFAUNA.

S. Silveira Neto¹, S.B. Alves¹, A. Laranjeiro², E. Berti Filho¹

Departamento de Entomologia - ESALQ/USP, Piracicaba-SP, Brasil - Aracruz Florestal, Espírito Santo, Brasil

This research deals with the environmental impact of the entomofauna on an *Eucalyptus* plantation located in Aracruz, State of Espírito Santo - Brazil. The insects were collected by using light traps in four eucalypt areas, from 1989 to 1992. Through the faunistic analysis the predominant species were selected to be used as ecological indicators which, together with the diversity and physiography indexes, the quotient and percentage of similarity and the non parametric tests of Kruskal-Wallis and Wilcoxon, have permitted the evaluation of such impact. The results were as follows: the mean diversity index of the region indicated a high richness of insect species in the area; there was a predominance of beneficial insects in relation to eucalypt pests; the diversity was dependent on the physiography index of the areas; one of the areas preserves the faunistic conditions close to those of a natural forest. The influence of the eucalypt areas on the entomofauna was low; when the eucalypt trees were cut it was observed a decrease in the number of insect pests in the area, but the faunistic effect was not significant; the environmental impact of the eucalypt plantation on the entomofauna was very low and did not interfere with the ecosystem.

10-098

DOES THE NATURE OF WOODLAND HABITATS AFFECT THE MOVEMENTS OF *ABAX ATER* VILL. (COL., CARABIDAE) IN A HEDGEROW NETWORK LANDSCAPE: A RADIOTRACING STUDY

S. Petit, S. Charrier, F. Burel
CNRS URA 1853 - Laboratoire d'Evolution des Systèmes Naturels et Modifiés - Université de Rennes 1 - France

Abax ater is a forest beetle which was shown to survive in bocage landscapes as metapopulations. Local populations are located in woods, lanes and nodes of the network whereas some linear wooded habitats can be used as corridors, providing paths for recolonization. The aim of our study was to assess whether the nature of woodland habitats in a bocage influence movements of *Abax ater* and thus its potential dispersal abilities.

The walking pattern and intensity of movements of the species were examined during two months using a radiotracing method in a wood, a lane, a hedgerow with continuous tree and shrub layer and a hedgerow characterised by numerous gaps in the vegetation cover. Although the walking pattern remains similar in the four habitats as soon as individuals do not enter adjacent cultivated parcels, the intensity of movements significantly differs among habitats. Mean distances covered and total space occupied during the study were the highest in the wood and progressively decrease as vegetation cover in the linear elements decreases. In linear elements, many individuals left the habitat and got lost in adjacent fields where most of them died. On the opposite, none of the individuals traced in the wood died or left the habitat.

This study indicates that the diffusion of *Abax ater* is influenced by the nature of woodland habitats. It also shows that the quality of linear features, especially vegetation cover, affects their efficiency as dispersal corridor so that attention should be paid to their management in order to maintain functional links between local populations.

10-097

INFLUENCE OF WILD CRUCIFERS ON BIOLOGY AND FLIGHT ABILITY OF THE DIAMONDBACK MOTH, *PLUTELLA XYLOSTELLA* (L.) (LEPIDOPTERA: YPONOMEUTIDAE).

R. Tsukuda, S. Begum, O. Muhamad¹, F. Nakasuji

Faculty of Agriculture, Okayama University, Tsushima, Okayama 700, Japan. 1. Crop Protection Branch, Department of Agriculture, Kuala Lumpur, Malaysia.

The larvae of *P. xylostella* were fed on five weed crucifers and crop, cabbage. The life history traits and flight activity of adults were measured. The developmental period of larvae which were fed on Indian marshcress (*Rorippa indica*) and Virginia pepperweed (*Lepidium virginicum*) was shorter than those fed on cabbage but the former larvae emerged as smaller adults. The female adults fed on weed crucifers had less fecundity than those fed on cabbage but the former had a higher flight activity. A clear trade-off was observed between fecundity and flight activity.

In the comparison of individuals which were fed on the same host plant, large sized females laid more eggs and also had a higher flight activity than the smaller one. The larger adults which flew more had larger flight

10-099

BODY SIZE, SEXUAL RECEPTIVITY AND LARVAL CANNIBALISM IN RELATION TO PROTANDRY AMONG *TOXORHYNCHITES* MOSQUITOES

L.P. Lounibos

Florida Medical Entomology Laboratory, University of Florida, Vero Beach, Florida USA

Males of *Toxorhynchites rutilus* and *T. amboinensis* emerge as adults significantly sooner than females, the difference between sexes more pronounced in the latter species. In contrast to other protandrous mosquitoes, male and female *T. rutilus* did not differ in mean body mass, and *T. amboinensis* females are only slightly larger than males. Protandry in the context of size similarity of the sexes is maintained by significantly faster growth of males. Sexual maturity is reached in both sexes approximately one day after adult eclosion, which occurs primarily in the late afternoon. Predatory fourth instar larvae of *T. rutilus* that co-occurred in treeholes were far more similar in body mass than individuals of that same stage that occupied different treeholes. In surrogate treeholes set experimentally in nature, the rate of cannibalism was significantly higher among *T. rutilus* fourth instars that differed in body mass. Presumably, the size similarity that minimizes larval cannibalism selects against sexual size dimorphism in adults of these species.

10-100

SPATIAL DISTRIBUTION OF *TETRANYCHUS URTICAE* KOCH (ACARI:TETRANYCHIDAE) ASSOCIATED WITH ITS PARENTAL LIFE TYPE AND EGG-LAYING BEHAVIOUR

C.I. Shih, C.J. Wang

Department of Entomology, National Chung-Hsing University, Taichung, Taiwan 40227 Republic of China

Aggregative spatial distribution of population of *Tetranychus urticae* Koch (TSM) on carambola orchard was evaluated by index of dispersion (ID), Green's coefficient of dispersion (Cx), mean crowding index (me), patchiness index (me/m), Morisita's coefficient of dispersion (I_{δ}, I_{β}), Taylor's power law and Iwao's patchiness regression (α, β). The magnitude of fluctuation and increment of the indices values of ID, me, and me/m were highly correlated with those of the magnitude of changes and increments of the densities of the TSM. The results of estimated slopes from the regression analyses of variances over means on the TSM populations by Taylor's power law model are all larger than 1. All different stages of the TSM populations are therefore assumed to be the aggregative ones. Iwao's patchiness regression analyses on TSM populations shows TSM population forms a high aggregation within and among the patches. Very high degree of aggregation and patchiness of egg and larval populations of the TSM are inferred as the results of female life type and egg-laying behaviour and pattern within the patches.

10-102

RELATIONSHIPS BETWEEN SUPERCOOLING POINT AND COLD HARDINESS OF THE CLOVER LEAF WEEVIL, *HYPERA PUNCTATA* (COLEOPTERA: CURCULIONIDAE) IN JAPAN

M. Watanabe

Department of Insect Physiology and Behavior, National Institute of Sericultural and Entomological Science, Ohwashi 1-2, Tsukuba, Ibaraki, Japan

Hypera punctata overwinter as any developmental stage other than pupae in Tsukuba, Japan. They appear to be able to grow continuously during winter. The lower thermal threshold of larval development is below 10°C. The proportion of late instar larvae in the population increased gradually between December and May, and 4th (last) instar larvae were found in February onwards. The supercooling point (SCP), often used as an indicator of cold hardiness, of eggs was the lowest (-22 to 27 °C) among all developmental stages. In larval stages, there was a significant positive correlation between the SCP and larval body weight. Under starving conditions, the correlation became higher, and the SCP decreased by 5 to 7°C. A similar correlation was also found for each larval instar except for the 4th instar. In the 3rd and 4th instars, most larvae exposed to -5 or -10°C survived if they were not frozen, but died if frozen. On the other hand, the prefreeze mortality (mortality without freezing) at -10°C was high in the 1st and 2nd instars. It was higher in starved larvae than in fed ones. All 1st instar larvae did not survive an exposure to -15°C, though many larvae had not been frozen. These results suggest that the SCP is not always a good indicator of cold hardiness in this beetle.

10-101

SPATIAL DISTRIBUTION PATTERNS OF *AMBLYSEIUS OVALIS* (EVANS) (ACARI: PHYTOSEIIDAE) ASSOCIATED WITH ITS PREY DISTRIBUTION PATTERN AND EGG-LAYING BEHAVIOUR

C.J. Wang, C.I. Shih

Department of Entomology, National Chung-Hsing University, Taichung, Taiwan 40227 Republic of China

The spatial distribution patterns of *Amblyseius ovalis* (Evans) on carambola orchard was evaluated by index of dispersion (ID), Green's coefficient of dispersion (Cx), mean crowding index (me), patchiness index (me/m), Morisita's coefficient of dispersion (I_{δ}, I_{β}), Taylor's power law and Iwao's patchiness regression (α, β). The behaviour of aggregation of *A. ovalis* was positively correlated with the initial incremental phase of density and aggregativeness of its prey, *Tetranychus urticae* Koch. The aggregative distribution character of *A. ovalis* found on larvae but not on the other stages' populations were demonstrated by Taylor's power law model. The egg and larval quadrat were formed by a single individual, and the degree of incremental chances with another individual in the same quadrat for nymphs, females and males, were inferred by the estimated α and β values from Iwao's patchiness regression analyses. The behaviour of one-egg-deposition following an emigration performed by females in the quadrat was also demonstrated by their egg-laying pattern at low prey density.

10-103

EFFECTS OF POPULATION AND HABITAT PARAMETERS ON MOVEMENT PATTERNS IN GRASSHOPPERS (CAELIFERA: ACRIDIDAE)

G. Köhler, J. Samietz, G. Wagner, S. Opitz, S. Bauer

Institute of Ecology, University of Jena, Germany

The activity patterns of four grasshopper species at eight study sites in Thuringia/Germany were investigated in 1993 and 1994 using several individual marking techniques. Owing to an additional marking of each individual by reflective tape, consecutive nocturnal observations could be conducted. Altogether more than 8.000 observation points of about 2.100 marked adults of *Stenobothrus lineatus* (PANZER), *Oedipoda germanica* (LATR.), *Gomphocerus rufus* (L.) and *Chorthippus parallelus* (ZETT.) were analysed by three main parameters of individual movement: mean daily movement, dispersal range and home range. The results of the study indicate a dependence of the activity patterns on size and shape of the habitat as well as on the population density. Furthermore, broadly scattered distributions occurred due to differences between individuals, sexes, and in the individual life span.

10-104

INSECT POPULATION VULNERABILITY ANALYSIS (PVA): CASE STUDIES IN GRASSHOPPERS AND BUSHCRICKETS

G. Köhler, G. Wagner, J. Samietz

Institute of Ecology, University of Jena, Germany

An approach of a grasshopper population vulnerability analysis (PVA) in fragmented landscape units is demonstrated in this video film. In two study sites near Jena /Thuringia (Germany), a semi-arid grassland and a limestone quarry, demography, movement patterns and habitat requirements of *Oedipoda germanica* (LATR.), *Stenobothrus lineatus* (PANZER) and *Phaneroptera falcata* (PODA) were studied.

The videofilm introduces in the procedure of a PVA and shows methods and techniques used in field and laboratory experiments, like measurements of vegetation structure, microclimate and insect body temperature as well as registration of nymphs with biocoenometer, individual marking of adults, night observations with head-lamps and weighing of females for the determination of oviposition. With regard to minimum viable populations, some results are mentioned.

10-105

A POPULATION VULNERABILITY ANALYSIS OF THE RED-WINGED GRASSHOPPER, *OEDIPODA GERMANICA* (LATR. 1804) (SALTATORIA: ACRIDIDAE)

G. Wagner, U. Berger

Institute of Ecology, University of Jena, Germany

The xerophilous Red-winged grasshopper, *Oedipoda germanica* (LATR.) is threatened by extinction in Germany because of a drastically decline of suitable habitats in the past. In a limestone quarry near Jena (Thuringia, Germany), which is situated at the northern area boundary of this species in Central Europe, exists one of the last populations in Thuringia. In a field study from 1993-1995 population dynamics and movement patterns of *Oedipoda germanica* were investigated as well as reproduction parameters in greenhouse experiments. Using these data an individual based model was developed to estimate the minimum viable population size (MVP) and survival rate probability of the population.

10-106

HEAVY METALS IN CARABIDS (COLEOPTERA: CARABIDAE)

R.O. Butovsky

All-Russian Research Institute for Nature Protection, 113628, Sadki-Znamenskoje, Moscow, Russian Federation

Investigations of invertebrate roadside communities, polluted by heavy metals, started in 1983, showed, that in general the ability to accumulate heavy metals followed the order: annelids (earthworms) (the best accumulators), isopods, spiders, holometabolic insects (carabids, fly larvae) (the worst accumulators). The observed differences were connected with the existence of different life strategies as related to preadaptations to heavy metal stress in different groups of animals (Butovsky, 1993). More detailed investigations on heavy metal contents in 15 carabid species, collected in roadside ecosystems of Russia and the Netherlands, showed that Russian carabids contained Cu (13.1-26.8 ppm) and Zn (56.4-184.8 ppm) and didn't accumulate the most toxic Pb or Cd. In Dutch carabids we found Cu (5.9-30.1 ppm), Zn (27.1-118.6 ppm), Pb (0-13.0 ppm) and Cd (0-1.9 ppm). In all studies heavy metal contents in carabids were not related to the distances from motorways. In Russian samples we found species-specific and sex-specific differences in accumulation of Zn and Cu. Females in most cases contained more Zn than males. We couldn't find any differences in heavy metal contents between myxophagous and zoophagous species. In most cases the correlations between relative abundance of dominant carabid species *P. cupreus* and *P. melanarius* didn't occur. However in these species we found the decrease of heavy metal contents by the end of the field season (in September). The absence of expressed differences in heavy metal concentrations between species, sexes and trophic groups was connected with (1) similar spectrum of nutrition and life strategies; and (2) high ability to excrete heavy metals. These circumstances reduce the possibilities to use carabids as indicators of environmental quality in ecosystems, polluted by heavy metals.

10-107

LARVAL DEVELOPMENT OF *BIBIO* SPECIES (DIPTERA, BIBIONIDAE) AT HIGH ALTITUDES IN NORWAY

J. Skartveit and T. Solhøy

Institute of Zoology, University of Bergen, Norway

The life cycles of the bibionids *Bibio rufipes* (Zetterstedt) and *B. siebkei* Mik from the lower alpine zone in Southern Norway were investigated. The development goes through seven instars, and takes two years, with the larvae overwintering in the fourth and seventh instar. Imagines eclose in July and August. Dry weight of *B. rufipes* larvae in their second summer increases rather rapidly between approximately 20 June and early August while there is no increase between October and June. Dry weight declines to approximately half its October value in spring, but this is probably because larvae collected in spring have no gut content.

Material from one season suggests that development in the larger species *Bibio pomonae* (Fabricius) takes three-four years in the lower alpine zone.

10-108

THE GROUND BEETLE COENOSIS (COLEOPTERA: CARABIDAE) OF THE RIPARIAN WOOD OF PANFILIA (PADANE PLAIN, NORTHERN ITALY)

R. A. Fabbri, F. Pesarini
Museo Civico di Storia Naturale, Ferrara, Italy

A three years research (1993-1995) on the ground beetle communities has been carried out at the Wood of Panfilia by using different methods (pitfall trapping, direct catching, sweep net, beating tray and soil sifting). The Panfilia Wood, originated about two hundred years ago and covering about 80 hectares, is an interesting biotope on the right bank of the Reno River both for the rarity of woodlands in Padane Plain and for the peculiarity of its phytocoenosis. The botanic association described as *Carici-Fraxinetum angustifoliae*, comparable to those present in Central-Southern Italy, is nowadays considered more similar to the alluvial plain forest type of hard wood (*Fraxino-Ulmetum* and *Ulmo-Quercetum*). The wood is bounded from the adjacent plain by a high embankment and the seasonal floods coming from the river, with the consequent frequent mud sedimentation, are one of the most important ecological factors subsisting on the biotope. The carabid assemblage, with a total of 138 species, was preliminarily analyzed from a qualitative and quantitative point of view, some diversity indices were calculated and some faunal, ecological and zoogeographical notes were reported. The most important sampled species were: *Lasiotrechus discus* (F.), *Atramus collaris* (Ménétriés), *Europhilus micans* (Nicolai), *Scybalicus oblongiusculus* (Dejean), *Parophonus planicollis* (Dejean) and *Polystichus connexus* (Fourcroy) in the riparian *Salicetum*; *Carabus granulatus interstitialis* Duftschmid, *Anillus florentinus* Dieck and *Phonias ovoideus mainardii* (Straneo) in the hard wood forest; *Cylindera germanica* (L.), *Campalita auropunctata* (Herbst) and *Leistus ferrugineus* (L.) in the alluvial terrace meadow; *Amara concinna* Zimmermann, *Anisodactylus intermedius* Dejean, *Acinopus picipes* (Olivier) and *Microderes scaritides* (Sturm) on the embankments and six species of Lebiini were found on the herbaceous plants and on the foliage of shrubs and trees.

10-110

OVIPOSITION DECISIONS BY A TREE-HOLE MOSQUITO: A TEST OF MULTIPLE HYPOTHESES IN THE FIELD.
J.S. Edgerly, M. McFarland¹, P. Morgan¹, T. Livdahl¹
Department of Biology, Santa Clara University, Santa Clara, CA, U.S.A. - ¹ Department of Biology, Clark University, Worcester, MA, U.S.A.

This field study tested hypotheses about egg-laying decisions by a tree-hole mosquito, *Aedes triseriatus* (Say). We predicted that *A. triseriatus* would exhibit choosy oviposition behavior because of their dependence on restricted, sometimes limited, resources and their potential exposure to intraspecific larval competition. We placed artificial microcosms, stocked with tree-hole water and lined with paper oviposition substrates, in a woodland. During two field seasons, we examined oviposition rates in response to larval density and to number of eggs already deposited at the site. First, females were significantly attracted by a high number of eggs. On the other hand, the response to larval density was variable. During one season (1992), females avoided higher densities early in the season, but responded positively to that factor when they laid eggs destined for diapause, later in the season. The second field season (1994) did not yield a significant response to larval density. A third factor tested in 1992, presence of predatory mosquito larvae (*Anopheles barberi*), elicited no detectable response by egg-laying *Aedes*. Our findings suggest that females may have been selected to find suitable habitats without regard to larval density. We speculate that this may be so because their offspring have a particularly relevant adaptation—pharate larvae detect cues that reflect larval density and can regulate their hatching in response, emerging when the potential for interspecific competition is low. The positive response to eggs by ovipositing females is more difficult to understand and was not expected based on findings by other investigators.

10-109

CECIDOMYIIDAE (DIPTERA) ASSOCIATED WITH MYRTACEAE AT RESTINGA OF BARRA DE MARICÁ, RIO DE JANEIRO
V. C. Maia
Museu Nacional, Rio de Janeiro, RJ, Brazil
The Restinga of Barra de Maricá (RJ) shows a great richness of higher plants (195 species belonging to 70 families, according to ARAÚJO & HENRIQUES, 1984). Among these families, Myrtaceae are represented by 11 species and show the greatest variety of Cecidomyiidae galls: 14 kinds on 6 species of host-plant (2 kinds on *Eugenia copacabanensis* Kiaersch, 3 on *E. rotundifolia* Casar, 2 on *E. uniflora* Linnaeus, 1 on *Myrcia ovata* Cambessedes, 2 on *Myrciaria floribunda* (Camb.) Legrand and 4 on *Neomitranthes obscura* (DC.) Legrand. The galls were collected from 1986 to 1994. Cecidogenous, inquiline and predators species were reared and identified in laboratory. *Stephomyia tetralopae*, *S. espiralis* and *Trotteria* sp. were found on *E. copacabanensis*; *S. rotundifoliorum*, *Lestodiplosis* sp., *Dasineura* sp., *Resseliella* sp. and one Cecidomyiidi on *E. rotundifolia*; *Neolasioptera eugeniae* and one Cecidomyiidi on *E. uniflora*; *Myrciariamya bivalva* and *Dasineura* sp. on *M. floribunda*; n. gen., and n. sp. on *Myrcia ovata*; *S. mina*, *Dasineura* sp., n. gen. and n. sp., one *Clinodiplosini* and one Cecidomyiinae on *N. obscura*. Galls were characterized by the shape (fusiform, cylindrical, elliptical, conical, spheroid, spiralled, marginal leaf roll, bivalve or pine cone shaped), color (green, red, yellow or brown), number of internal chambers (1 or 0) and plant part on which the gall is situated (leaf, stem, axillary or apical buds). Data on number of larva per gall and the period of galls occurrence are given. The material was prepared according to GAGNÉ, 1994 and is deposited in the Diptera collection of Museu Nacional.

10-111

MALE LARVAL NUTRITION INFLUENCES THE REPRODUCTIVE SUCCESS OF BOTH SEXES IN *CHORISTONEURA FUMIFERANA*
J. Delisle
Natural Resources Canada, Canadian Forest Service, Quebec Region, Canada.

Work on the polyphagous species *Choristoneura rosaceana* demonstrated that while different larval host plants did not affect the proportion of virgin males of acquiring a mate, it had a significant impact on their ability to remate. Furthermore, the total fecundity and fertility of females mated with males reared on poor quality hosts (i.e. hazelnut) was significantly lower than those mated with males fed on high quality hosts (i.e. striped maple). A parallel study was undertaken to examine the effect of larval food quality in a related, eruptive oligophagous species, *C. fumiferana*. The reproductive success of both sexes was compared when males were reared on the same host species (balsam fir) but varying the foliage quality, to reflect endemic and epidemic phases in the population cycle. Females mated with males reared on high quality foliage were more likely to remain refractory following first mating. Furthermore, the reproductive success of females mated with males reared on poor larval food were significantly lower than for conspecifics mated with males provided high quality food during larval development. These results will be discussed in relation with possible physiological mechanisms regulating reproduction and migration in *C. fumiferana*.

10-112

THE INFLUENCE OF MORPHOLOGICAL DIFFERENCES BETWEEN APHID MUMMIES ON PREDATION BY VARIOUS TYPES OF INVERTEBRATE PREDATORS

J. Brodeur

Département de phytologie, Université Laval, Québec, Canada.

Field observations indicated that aphid parasitoid cocoons are vulnerable to several species of invertebrate predators. Unexpectedly high levels of predation (>85%) were observed in both potato and alfalfa plots. It is hypothesized that *Praon* cocoons, spun underneath the mummified aphid, are less susceptible to predation than *Aphidius* cocoons, spun within the mummified aphid. In the laboratory, I measured the ability of mandibulate (coccinellidae, chrysopidae) and piercing/sucking predators (miridae) to detect and feed on *Praon* and *Aphidius* cocoons. In most cases, no clear patterns were evident. However, some experiments indicated that the physical traits of *Praon*-type mummies provide additional protection against fourth instar and adult coccinellids to the developing parasitoids. In this instance, the aphid skin seems to divert predators from attacking the parasitoid cocoon underneath.

10-114

POSSIBLE DISSEMINATION OF *SPHAEROPSIS SAPINIA* (FR.) DYKO ET SUTTON F.SP. *CUPRESSUS* SOLEL ET AL. (DEUTEROMYCOTINA) BY PSOCOPTERA PSOCOMORPHA IN ITALY

E. Porcelli**, L. De Marzo*, S. Frisullo***, L. Sparapano****.

* Dipartimento di Biologia, Difesa e Biotecnologie agro-forestali, Università della Basilicata, Potenza - Italy.

** Istituto di Entomologia Agraria, Università di Bari - Italy.

*** Istituto di Produzione e Preparazioni Alimentari, Università di Bari - Italy.

**** Dipartimento di Patologia vegetale, Università di Bari - Italy.

Due to their alimentary interest in conidia of plant pathogenic fungi, Psocoptera are suspected to be vectors of plant diseases (DE MARZO et al., 1994). Further evidence of this matter arises from the study of some species of Psocoptera, which commonly occur on the canopy of many Cupressaceae and Pinaceae in Southern Italy; in fact as two of them, *Ectopsocus briggsi* McLach. (Ectopsocidae) and *Caecilius burmeisteri* Brauer (Caeciliidae), were recognized as able to disseminate living conidia of *Sphaeropsis* by their excrements.

Conidia in the alimentary canal were observed by dissecting several specimens of Psocoptera, collected in different localities in Apulia and Basilicata on branches of *Cupressus sempervirens* and *C. arizonica*. *Sphaeropsis* conidia were present together with those of other genera: *Alternaria*, *Cladosporium*, *Leptosphaeria*, *Mucor*, *Pestalotia*, *Phomopsis*, *Seiridium* and *Stemphylium*.

Survival of the ingested *Sphaeropsis* conidia was evaluated by plating some specimens of Psocoptera in APS medium in Petri dishes. Previously the specimens were washed by sterile water and dried up with sterile blotting-paper. Growth of *Sphaeropsis* mycelium was recognized, together with that of other forms of fungi, up to 10 days in dishes incubated at 25°C.

After 30 days mature picnidia were found and were identified as *Phaeropsis sapinea* on the basis of morphometric data. This strain was used for trials of pathogenicity on *Cupressus* and showed symptoms of disease after 30 days. Biological and morphological characters let us to identify this strain as *cupressi* Solel et al.

10-113

POPULATION REGULATION OF A FOREST-FLOOR WOLF SPIDER: RELATIVE IMPORTANCE OF FOOD LIMITATION AND MORTALITY FROM ARTHROPOD AND VERTEBRATE PREDATORS

D. H. Wise, B. Chen

Department of Entomology, University of Kentucky, Lexington, KY USA

We investigated the relative contributions of bottom-up and top-down control processes to population regulation of *Schizocosa*, an abundant wolf spider in the leaf-litter community of deciduous forests in eastern North America.

We increased densities of Collembola, mites and adult Diptera in ten 2 x 5 m open plots by periodically adding mushrooms, potatoes and instant *Drosophila* culture medium for 2.5 months. In comparison to control plots, densities of *Schizocosa* doubled; individual spiders also were larger. In a second experiment, we excluded birds and removed rodents, lizards and amphibians from five fenced 50-m² plots for 1.3 years. *Schizocosa* densities did not differ between the vertebrate-exclusion plots and five open reference areas. To examine possible top-down control by arthropod natural enemies, we reduced densities of centipedes, predacious beetles, and all spiders other than *Schizocosa* in six fenced 4-m² plots for 2.5 months. *Schizocosa* mortality was high (70%), but did not differ between predator-reduction and control treatments.

These results reveal that increased productivity of prey has a greater impact on population density of *Schizocosa* than does reduced mortality from arthropod and vertebrate predators.

10-115

RICHNESS AND DIVERSITY IN THE WOODLAND SOIL FAUNA IN RELATION TO DIFFERENT DISTURBANCES

B. Massa and G. Casamento

Istituto di Entomologia Agraria, Università di Palermo, Italy

Six woody areas of western Sicily (central Mediterranean), between 800 and 1000 m a.s.l., were selected; they were characterized as follows: a) and b) mature woods dominated by *Quercus pubescens* and *Q. ilex*, the first one undisturbed, the second burnt in 1994; c) mature wood of *Q. pubescens* and *Ilex aquifolium* extensively grazed by cattle; d) as c, but without grazing and cleared of the understorey; e) mature wood dominated by *Q. ilex*, with a rich understorey; f) reafforestation of conifers, c. 30 years old.

In 1995 cores of soil were seasonally extracted in four different randomly chosen locations of each woody area; soil fauna was counted after a 7-days extraction by a Tullgren Funnels.

Undisturbed woodlands showed both the highest richness and taxon diversity. Fire depleted richness, and as probable consequence of prey biomass decrease, predators (e.g. Acari) were mostly numerically reduced; species active on the soil surface and living within the litter, particularly decomposers, also decreased after the fire passage. Grazing had an evident impact on richness and diversity in comparison with undisturbed woodlands; this agrees with the results from other mediterranean areas. Eradication of understorey possibly caused the availability diminution of the organic matter in the soil and thus the richness of detritivores, which in turn affected that of predators. Finally values of conifer reforestation show the poorness of this artificial habitat and suggest the need of long-term manage in order to transform it in a mixed woodland.

Total richness and taxon diversity showed a spring-summer peak; herbivores, mostly dependent on the growth rate of plants, were more abundant during the peak of growth season; summer drought and heat, reducing water availability, were probably responsible of seasonal variation of populations. Organic matter influenced the abundance of species, particularly detritivorous ones, and the spatial structure of the community. Predators, generally used as good bioindicators because are dependent on prey abundance, indeed resulted to be more abundant in the undisturbed woodland in respect to those affected by different types of disturbances.

10-116

STAPHYLINIDAE (INSECTA: COLEOPTERA) SOIL COMMUNITIES OF WOODLAND REMNANTS IN EASTERN SICILY

A. Adorno, G. Sabella, P. Alicata
Dipartimento di Biologia Animale, Università degli Studi di Catania, Catania, Italy.

The Staphylinidae community structure of the woodland remnants, that escaped the extensive deforestation of the last three centuries, were studied. The examined remnants are located on the Peloritani Mountains (on Oligocene-Miocene flysch), on Mount Etna (on volcanic substrata), and on the Iblei Mountains (on limestone). The structure of the remnant communities was compared with that of the communities of the Nebrodi Mountains woodlands (on sandstone and flysch), the largest forest system of the island. Quantitative data were obtained by pitfall-trap samplings carried out monthly for a year. Correspondence analysis was utilised for comparing the community structure. Despite a considerable invasion of open land species, the communities of the forest fragments generally maintain most of the nemoral species found in the large Nebrodi's woodlands. To explain the differences found in the community structures, the following factors were considered: the climate, typology and frequency of natural and anthropic disturbances, size and heterogeneity of the remnants, and the characteristics of the rocky substrata.

10-118

THE BEHAVIOURAL PECULIARITIES OF CONSUMERS OF DIFFERENT TROPHIC LEVELS IN THE SYSTEM "PLANT-PHYTOPHAGAN-ENTOMOPHAGAN".

G.I.Dorokhova & A.B.Vereschagina
Department of Entomology and Plant Immunity to Pests;
All-Russian Institute for Plant Protection,
St.-Petersburg, Russia

The interrelations within the tritrophic systems were investigated in model experiments by the example of *Myzus persicae* Sulz., *Aphis gossypii* Jlov., *Rhopalosiphon padi* L. (Aphididae) and *Aphidoletes aphidimyza* Rol.(Cecidomyiidae) at a period of plant invasion with the insects. A number of cultivars of russian turnip, cucumber, wheat and maize differing in their morphological and physiological properties has been used in the investigation. The diversity of studied insect species and plant forms makes it possible to reveal the following regularities. Orientation of aphids and *A.aphidimyza* may be similar at the stage of distant search and differ at the stage of contact choice of plant. The host plant always modifies aphid behavioural responses and physiological processes such as selectivity, development, social behaviour, migration ability and metabolism. The behaviour of *A.aphidimyza* adults is conditioned by the presence of honeydew on plants while the presence of aphids themselves is not necessary for oviposition. Honeydew is a food source for *A.aphidimyza*. The choice of oviposition sites by females is determined by honeydew quality (composition and physical condition) and localization on plant. The properties of honeydew are influenced by both host plant (phenotype and metabolism) and aphids metabolism, behaviour, topical specificity and population structure). It can be concluded that the complicated interactions take place at first stages of formation of tritrophic system. These interactions are based on trophic relations and can be defined as commensalism. Good agreement in search behaviour between the theaphids and the entomophagan is mainly determined by similarity of their requirements to the conditions which are created on plant surface. Aphid honeydew is operating as key chain which enables all the system begin to function as tritrophic one.

10-117

REPRODUCTIVE PERFORMANCE IN A NEOTROPICAL GRASSHOPPER (ORTHOPTERA: ACRIDIDAE: GOMPHOCERINAE)

M. Becker, C.M.L. Ferreira
Departamento de Zoologia, Universidade Federal do Rio Grande do Sul, Porto Alegre, RS, Brazil.

Rhammatocerus conspersus (Bruner) (R.c.) lives in open grassland habitats in south Brazil, Argentina and Uruguay. It is a polyphagous species but preferably feeds on grasses; occasionally it attains pest status in native pasturelands in Brazil. R.c. is a univoltine species with an 8 months long obligatory egg diapause. Under laboratory conditions maturation of the ovaries is incomplete and fecundity is negligible at the average air temperature (25°C) of Summer months. With a radiant heat source (35-38°C) R.c. attains a body temperature well above the air Summer average maximum (30°C); females are long lived (\bar{x} 150 days), the pre-oviposition period is comparatively short (\bar{x} 24 days), egg-laying extends for nearly 3 months and potential fecundity is high (\bar{x} 724 eggs/female). Under field conditions females die young, before the onset of Autumn. It is suggested that in subtropical Brazil (29°S 55°W), egg diapause provides the means to synchronize the active, basking stages with the months of maximal temperatures and insolation.

10-119

OBSERVATIONS ON THE HYDRADEPHAGAN COMMUNITY (COLEOPTERA: HALIPLIDAE, DYTISCIDAE) OF A DAMP AREA IN THE "PIANURA PADANA".

G. Bosi, G. Caramori
Museo Civico di Storia Naturale, Ferrara, Italy

The fresh water damp areas of the "Pianura Padana" are shown to have a limited extension; actually they are part of a territory which is widely exploited for agricultural purposes. Our sampling site, "Ercolana", is a damp area of about 60 hectares, created in 1990, at Malalbergo (Bologna, South-East of the "Pianura Padana") by conversion of agricultural lands to an area suitable for shooting and fishing. The wetlands of "Ercolana" consist of two marshes extending for 28 hectares and a damp meadow of 8 hectares which is subject to periodic flooding. From April to December 1995, a total of 2117 adult specimens of 26 species of Hydroadephaga were collected from different sampling sites of the "Ercolana". The taxonomic composition of the hydradephagan community existing in the study area has been analyzed, together with the main ecological and biogeographical traits of the species found: certain of these species (e. g. *Hydroporus planus* (F.), *H. nemnonius* Nicol. and *Ilybius subaeneus* Er.) were seen to be particularly frequent. The data collected during the present investigation was compared with the information available in literature concerning the occurrence of Hydroadephaga in other similar habitats of northern Italy. Furthermore, the index of Dice-Sørensen shows that the hydradephagan fauna of the study area has the best affinity with that of the typical pools of the "Pianura Padana". The present study was undertaken in order to assemble data concerning the presence and distribution of this group of aquatic insects of the "Ercolana". The results of hydradephagan community composition in the study area, as well as a comparison with similar habitats for this group of insect elsewhere in northern Italy, will be reported.

10-120

EGG PRODUCTION AND RESORPTION IN A PARASITIC WASP: CAN FEMALES PREDICT FUTURE EGG NEEDS?

A. Rivero¹, H.C.J. GodfrayImperial College at Silwood Park, Ascot, Berkshire, UK - ¹Current address: Dept. Biological and Environmental Science, University of Jyväskylä, Finland

The number of eggs available for oviposition inside the female's ovarioles (or *eggload*) is a crucial determinant of parasitoid reproductive behaviour. In some species of parasitoids female eggload is determined by three processes: egg production, egg resorption and egg laying. The resulting complex dynamic nature of the ovaries of these parasitoids has hampered the incorporation of realistic time-dependent variation in egg load into models of parasitoid behaviour that allow the physiological state of the parasitoid to change with time.

Egg resorption is a specific type of reproductive strategy in which oocytes in the female's ovarioles degenerate instead of being laid as eggs. It is often assumed to be a means of recycling eggs that have reached maturity but have not been required for oviposition; or a means of obtaining nutrients at times of stress. We study whether the number of mature eggs carried by the parasitoid and the rate of egg resorption can be adjusted in environments of different quality where the parasitoid can expect to encounter different numbers of hosts. We predict that wasps exposed to more profitable conditions will maintain a larger reserve of mature eggs, in expectation of greater oviposition opportunities. We further predict that this adjustment in egg load will be effected by a reduction in the rate of egg resorption rather than by an increase in egg production, since it is a less wasteful way of dealing with limited resources. We carried out a laboratory experiment to test the ability of female *Leptomastix dactylopii* (Hym: Encyrtidae) to adjust its egg load in response to environments of different quality. Wasps in the more profitable treatments were able to compensate for the increased number of eggs laid in the hosts, through an increase in their egg production rate, but were not able to predict increased future egg needs.

RESPONSE OF SPIDER MITES TO ODOURS FROM PLANTS DAMAGED BY HERBIVORES

A. Pallini^{1,2}, A. Janssen¹ & M. Sabelis¹¹Institute of Systematics and Population Biology, University of Amsterdam, The Netherlands, ²Animal Biology Department, Federal University of Viçosa, Brazil.

Plants produce volatiles in response to herbivore attack. These volatiles attract natural enemies of the herbivores. However, it is still unknown how herbivores respond to plants damaged by herbivores.

In Y-tube olfactometer experiments and release-recapture experiments in a greenhouse, we tested the response of *Tetranychus urticae* when offered a choice between clean cucumber plants and cucumber plants infested with conspecifics or western flower thrips.

We found a slight but significant preference for plants infested with conspecifics over clean plants, and a strong and significant preference for clean plants over plants infested with western flower thrips.

By avoiding plants with thrips, spider mites do not only avoid competition for the host plant, but also intraguild predation by thrips. Therefore, this kind of complex trophic interaction can also influence the pest status and the success of biological control of spider mites and thrips in crops where they occur together.

10-122

THE EFFECTS OF NUMBER, QUALITY, AND POSITION OF RESOURCES WITHIN SUCROSE PATCHES ON THE FORAGING BEHAVIOR OF THE FRUIT FLY *DROSOPHILA MELANOGASTER* (DIPTERA: DROSOPHILIDAE)

J.M. Aracena, and W.J. Bell

Department of Entomology, University of Kansas, Lawrence, Kansas, USA.

Fruit flies *Drosophila melanogaster* were allowed to forage on two patches containing wells filled with sucrose solution. We tested the effects of varying sucrose concentration (resource quality), number of wells filled (number of resources), and position of the resources on the foraging behavior of the flies.

All variables affected patch preference as well as feeding frequency. The flies were able to select patches with higher concentration of sucrose, larger numbers of resources, and larger resource density.

10-123

THE INSECT FAUNA OF ROME: SOME CONSIDERATIONS ON THE RESULTS OF A FAUNISTICAL SYNTHESIS

M. Zapparoli

Dipartimento di Protezione delle Piante, Università della Tuscia, Viterbo, Italy
Rome, Italy's largest city, has about 3 million inhabitants and covers an urban surface area of 380 km². The insect fauna of this area has been object of research since the second half of the 19th century. Rome is one of those rare cases in Europe where urban expansion in the last century took place on an area, the "Campagna Romana", which had been practically disinhabited. A recent study edited by the Author based on a critical revision of the entomological literature published from 1880 to nowadays together with other unpublished material has evidenced the presence and the microdistribution of about 5000 species belonging to not less than 300 families. Such information, although so vast, is however still incomplete. Documentation for groups such as Heteroptera, Coleoptera, Diptera, Macrolepidoptera and Hymenoptera Aculeata, which have traditionally been studied by local entomologists is quite complete but groups such as Collembola, Psocoptera, Phthiraptera, Thysanoptera and Homoptera are still poorly documented. From a preliminary global analysis of data collected, it can be clearly seen that from the end of the 40's there has been a general impoverishment of the species in particular in those communities linked to wetlands. The theoretical and applicative importance of a study on the entomofauna of Rome (microdistribution of the species in relation to bioclimatic factors, research on isolated populations, utilization of the information in environmental planning, pest control) is highlighted and at the same time certain aspects linked to urbanization which have influenced or influence the insect fauna are evidenced: 1) environmental modifications which took place in the last hundred years on a local scale (the rapid urbanization of the city from 1870 onwards due to its role as capital of Italy) and on a regional scale (land reclamation and progressive human impact on the "Campagna Romana", modifications to the flow of the River Tiber and its tributaries, chemical control of culicids as vectors of malaria); 2) the presence of large central green areas and greenways (historical villas and archaeological areas) and their role in the conservation of biodiversity.

10-124

MOVEMENT OF THE TWO WEEVIL PESTS OF SWEET POTATO, *CYLAS FORMICARIUS* AND *EUSCEPES POSTFASCIATUS* (COLEOPTERA: BRENTIDAE-CURCULIONIDAE) MEASURED BY COMMERCIALY AVAILABLE ELECTRONIC DEVICES

S. Moriya, T. Shimizu and S. Hiroyoshi

Department of Plant Pathology and Entomology, Okinawa Prefectural Agricultural Experiment Station, Naha Okinawa, Japan

In the Ryukyu archipelago, the southernmost part of Japan, *Cylas formicarius* and *Euscepes postfasciatus* are the most destructive exotic pests of the sweet potato. Attempts to eradicate them by using a sterile insect technique and a male annihilation method, respectively, are underway in Okinawa Prefecture. It is essential to assess their dispersal ability for the success of the eradication project. Therefore, we measured adult locomotion behavior of the two weevils and the flight activity of *C. formicarius* (*E. postfasciatus* has no ability to fly) using an actograph, a flight mill system and a newly developed tracking system in the laboratory.

Actograph: No clear difference was detected in the incidence of walking in the sexes of *C. formicarius*, however, aged female adults of *E. postfasciatus* moved more actively than males.

Flight mill: It is quite evident that *C. formicarius* males flew much longer than females. But these values, far less than 50 m on average during 24 hours, were very small compared with those of other insects and nearly 95% of the females tested never flew at all. Since these two systems were manually operated, they were improved by the introduction of computer-controlled devices. The new system revealed that the two weevils moved mainly in dark periods irrespective of sex.

Tracking system: A color image processing unit (Color tracker) combined with a computer enabled us to track adult locomotion of 16 individuals at an interval of one second simultaneously under a constant light condition. Analyzing the locomotion data obtained by this system, relative data by the actograph (number of counts) could be transformed exactly into absolute data (total distance).

10-126

INTERACTIONS BETWEEN ENDEMIC HERBIVOROUS INSECTS AND AN INVADDED WEED *SOLANUM CAROLINENSE* L.

O. Imura

Population Ecology Laboratory, Division of Entomology, National Institute of Agro-Environmental Sciences, Tsukuba, Ibaraki, Japan

A perennial weed *Solanum carolinense* L. invaded from North America into Japan is spreading over agricultural fields, grass lands, and lawn and abandoned areas. The weed provides endemic herbivores with a novel opportunity for their existence. So far 39 herbivorous arthropod species including two mites and three pollinators were found on the weed around Tsukuba city. The herbivore community was rather simple in terms of species diversity and feeding guilds being dominated by a leaf chewing coccinellid beetle *Epilachna vigintioctopunctata* (Fabricius). The beetle occurred two generations in a year on the weed and both of the larvae and adults caused a serious damage on the leaves. The feeding damage reduced flower and fruit settings of the weed while the number of adult beetles recruited depended on the foliage abundance of the weed in the field.

10-125

SECONDARY USE OF GALL MADE BY APHID ON MOUNTAIN ASH

A. W. Fukui, T. Ohgushi

Institute of Low Temperature Science, Hokkaido University, Sapporo, 060 Japan

Gall making aphids, *Sorbaphis chaetosiphon*, damage directly to a mountain ash *Sorbus commixta* in May, which enhances leaf abscission early in the season. Plant structure will provide a shelter for associated insects. In this context, we focus on aphid galls as shelters for secondary users on a mountain ash. The gall is colonized throughout the season by secondary using insects, not only herbivores but also predators. The secondary using herbivore should take advantage from gall structure as a shelter. It might increase damage by herbivore. On the other hand, the occupation of gall by predators might result in negative enemy-mediated interaction between gall-making aphid and the secondary using herbivore. It might decrease damage by herbivore. Therefore, the gall making aphids would play an important role in altering interactions among insects on a mountain ash.

10-127

HOW CABBAGE DENSITY AFFECTS THE ARTHROPOD POPULATIONS ?

K. Yamamura, O. Imura, K. Ohto, N. Morimoto

Laboratory of Population Ecology, National Institute of Agro-Environmental Sciences, Tsukuba, Ibaraki, Japan

Herbivorous and predatory species populations were examined in the fields with four different cabbage densities (0.25, 1, 4, 8 plants per square meter). The number of eggs per plant significantly decreased with the increase of plant density for three lepidopterous cabbage pests: the small white butterfly *Pieris rapae crucivora* Boisduval, the diamond-back moth *Plutella xylostella* (Linnaeus), and the beet semi-looper *Autographa nigrisigna* (Walker). The number of alate adults of the green peach aphid *Myzus persicae* (Sulzer) per plant showed a similar relationship. The population of spiders and that of syrphid flies per plant also decreased with the increase of plant density. On the other hand, the population per unit ground area increased approaching a maximum value with the increase of plant density for all arthropod populations. In order to clarify the cause of such a decelerating increase in the arthropod populations, the oviposition behavior of female *P. rapae crucivora* was observed. The oviposition process was divided into two components: the frequency of entrance of female adults into the field, and the frequency of oviposition from their entrance to exit. Both of the components contributed to the decelerating increase of the egg abundance per ground area and the latter component had a larger contribution.

10-128

EFFECT OF PREDATION BY THE CARABID BEETLE, *PARENA PERFORATA* BATES ON THE POPULATION CHANGE OF *THANATARCTIA IMPARILIS* BUTLER (COLEOPTERA: CARABIDAE – LEPIDOPTERA: ARCTIIDAE)

M. Hondō, N. Morimoto¹

Agros Corporation, Chuo-ku, Tokyo, Japan – ¹ Department Applied Entomology, Shinshu University, Kamiina, Nagano, Japan

In the southern area of Osaka Prefecture, southwestern part of Japan, the number of *Thanatarctia imparilis* colonies decreased abruptly from 1989 to 1991 and thereafter increased gradually from 1991 to 1995. The carabid beetle was observed in ca. 90% of the prey colonies in 1990, and it was not observed in 1991 and 1992. During 1993 to 1995, however, the density of *Parena perforata* increased as the density of *T. imparilis* increases. About 90% of *T. imparilis* larval colonies were destroyed before entering hibernation in 1990, however, the larval destruction was only ca. 10% in 1993 and 1994. In 1990, the carabid beetle deposited the eggs concentrating to the colonial nest, and many *T. imparilis* larvae of the nests were eaten by the carabid adults within a few days. In the laboratory, a carabid adult fed on ca. 100 *T. imparilis* larvae of the 1st and 2nd stadia per day. It is concluded that the predation by *P. perforata* acts as an important factor depressing the *T. imparilis* population.

10-130

SOME CHARACTERISTICS OF *CHRYSOPE CARNEA* (STEPH.) (NEUROPTERA: CHRYSOPIDAE) POPULATION COLLECTED IN THE SURROUNDINGS OF KISHINEV

E. M. Moontyan, I. A. Sekirov, I. G. Yazlovetsky

Institute of Biological Plant Protection

Moldavian Academy of Sciences, Kishinev, Moldova

Peculiarities of photoperiodic response and feeding of insect adults, activity and molecular forms of their different enzymes have been studied during annual developmental cycle of green lacewing natural population. Polymorphism has been found in the studied population on the base of photoperiodic induction of the reproductive diapause. Typical changes in spectra of molecular forms of glucose -6- phosphate dehydrogenase and acid RNA-se have been revealed in insects entering diapause. They were shown to be associated with changes in food ration of insects giving their preference (during this season) to food rich in carbohydrates. Under natural conditions the diapause of lacewings was deepest in December and January. It was accompanied by maximum activity reduction of DNA-se, digestive alkaline phosphatase, certain molecular forms of glucose -6- phosphate dehydrogenase and malate dehydrogenase. Gradual recovery of activity and the number of molecular forms of studied enzymes was observed during reactivation period in Spring. The data obtained turned out to be rather useful for establishing rearing of *Chrysopa carnea* laboratory cultures capable of diapausing.

10-129

THE FAUNA AND TROPHIC RELATIONS OF THE FUNGIVOROUS-DWELLING BEETLES OF THE FAMILY CISIDAE (COLEOPTERA) IN WESTERN RUSSIAN PLAIN

V.A. Tsinkevich

Department Zoology, Belarus' State Pedagogical University, Minsk

The family Cisidae is one of the most poorly studied coleopteran families in the East Europe. Cisid beetles are biologically connected with wood fungi.

Species composition and trophic relations of cisids were studied in the western part of Russian plain (western European Russia, Belarus') in 1989-1995.

In total, about 2000 individuals representing 31 species were collected. Records of some rare and relict species *Xylographus bostrychoides* (Dufour), *Ennearthron palmi* Lohse, *Orthocis lucasi* Ab., *Cis bidentulus* Ol., *C. fissicornis* Mellie, *Wagaicis wagaie* (Wank.) are noteworthy.

Twenty one wood-rotting basidiomycete fungi were recorded as host species for cisid beetles. *C. boleti* (Scop.) and *S. affinis* (Gyll.) appeared to have the widest host-ranges. Fungi species, condition and humidity of fruiting bodies are the main factor affecting distribution and occurrence of cisid beetles.

10-131

AN ECOLOGICAL CLASSIFICATION OF DROSOPHILID LARVAE (DIPTERA, DROSOPHILIDAE)

N.G. Gornostae

Institute of Ecology and Evolution, Russian Academy of Sciences, Leninsky prospect 33, Moscow, 117071, Russia

Drosophilidae of the world fauna are divided into 4 trophic and 10 habitat groups according to larval nutritional substrate and habitat. The following trophic groups are proposed: 1) saprotrygophages, 2) mycetophages, 3) phytophages, 4) zoophages and cleptoparasites. The type of nutritional substrate corresponds with their habitats for larvae of mycetophages and phytophages, therefore, it is possible to consider them as mycetobionts and phytobionts. The habitats of zoophages and cleptoparasites are determined by various habitats of their prey or hosts, and we assigned these drosophilids to the group of heterohabitat species. The large majority of drosophilid larvae feed on different microorganisms of decaying substrates, especially on the yeasts, therefore, we name them saprotrygophages. The habitats of these species are very diverse, and 7 groups are proposed: phytosaprobionts, xylosaprobionts, mycetosaprobionts, zoosaprobionts, coprobionts, heterosaprobionts, commensals. Phytosaprobionts are divided into 3 subgroups: carpophilic, lachanophilic and anthophilic.

10-132

WHEN AQUATIC CHIRONOMIDAE (DIPTERA) FLY THROUGH LANDSCAPES

Y.R. Delettre

CNRS (URA 1853), University of Rennes 1, Lab. Soil Ecology and Population Biology, Paimpont Biological Station, F-35380 Plélan-le-Grand (France)

In central Brittany (France), the adults' abundance of aquatic Chironomidae (Diptera) was studied by yellow trapping in four terrestrial habitats (the pondbanks, a woodlot, a mown grassland and a dry heathland) forming the transition area (ecotone) between a pond and terrestrial neighbouring systems. During one year, 43 aquatic species were found flying over these four sites, and their distribution was related to several habitat parameters: distance from the water collection, habitat openness, vegetation height and soil humidity.

The number of species as well as the total number of individuals were negatively correlated with the distance from the pond and with the habitat' closure, suggesting that aquatic chironomid species avoid densely vegetated and shaded areas which act as barriers while open and sunny terrestrial habitats are preferentially used as dispersal pathways.

The extent of the surrounding area influencing the species composition and abundance at each site was investigated using a Geographic Information System (GIS), allowing to compute Shannon's indices of habitats' diversity in a circle of progressively increasing radius around each trap.

A positive and significant rank correlation was only found between the species number at each sampling site and the habitats' diversity within a radius of 20 meters, suggesting that either flying abilities of the species are low or that adults perceive their environment at a small grain size (at a short distance).

The spatial organization and heterogeneity of landscapes is likely to influence the dispersal of adult Chironomidae originating in water collections. This fact seems of primary importance, both for the colonization of newly created or threatened aquatic habitats and for the permanency of aquatic communities, owing to the increasing fragmentation and modification of landscapes by human activities.

10-134

CARABID BEETLE COMMUNITIES OF CULTIVATED AND UNCULTIVATED AREAS IN NORTH-EASTERN ITALY (COLEOPTERA: CARABIDAE)

G. Governatori

Dipartimento di Biologia applicata alla Difesa delle Piante, Università di Udine, Italy

Investigations were carried out in the lowland area near Pordenone (north-eastern Italy) to compare the populations of carabid beetles from three contiguous environments at increasing distances from a river: a riparian thicket, a natural hedge and a monocultural corn field. The soils, originating from fluvial sedimentation, were mainly sandy. Carabid communities were surveyed every two weeks from June 1991 to October 1992 by using pitfall traps containing an attractive-preservative solution (vinegar and 5% of formalin added).

A total of 5014 adults of Carabidae were trapped and 64 species identified.

The thicket community (794 adults belonging to 36 species) retained the characteristics of that of the original lowland woods and included forest species like *Cychrus caraboides* (L.) and *Abax carinatus* (Duftschmid).

The hedge community (584 adults belonging to 42 species) included many species from both the adjacent habitats.

In the corn field (3636 adults belonging to 40 species) mainly eurytopic species were found; *Pseudophonus griseus* (Panzer) and *Pseudophonus rufipes* (Degger) were largely dominant in the samples; the number of species was comparable with that of the other environments, whereas the number of individuals was much larger.

Riparian carabids, including *Elaphrus* F., *Asaphidion* Gozis and *Ocydromus* Clairville species, were present in all the sites.

The density of activity in the thicket reached its maximum between mid spring and mid summer; in the hedge and in the corn field it occurred later, between mid summer and the beginning of the autumn.

10-133

PERCEPTION OF LANDSCAPE STRUCTURE BY EMPIDIDAE (DIPTERA): WHICH SCALE?

N. Morvan¹, F. Burel², Y.R. Delettre¹, P. Tréhen¹

Université de Rennes 1, CNRS (URA 1853), - 1 Station Biologique de Paimpont, F-35380 Paimpont, France - 2 Campus de Beaulieu, 35042 Rennes cedex, France

To study relationships between landscape structure and diversity and distribution of Empididae, adults have been sampled in three different areas using colored water traps. These landscapes are characterized by agricultural mosaic in which fields are surrounded by hedgerows. The Empididae scale of landscape perception is not a priori known. To determine the relevant scale at which the landscape must be described, we varied the extension of the study area around each sampling point. We started from a local scale at the hedgerow level, and extended step by step a window centered on this point (0.25, 1, 4, 16 and 64 hectares).

The most relevant scale happens to be an area of 4 hectares, which allows us to consider Empididae as fine grain species. The landscape mosaic is not the only factor accounting for species and community organization and one has to consider rather the interactions with the hedgerow structure.

If all Empididae are fine grain species they do not react the same way to the landscape. Functional groups of species may be defined according to the relevant scale of perception and to their relationship with landscape structure. These groups are characterized by the biological traits of their species. For example, some species of *Hilara* genus have to fly from emergence sites to confined mating sites. This leads them to use a greater space than comparably less mobile species.

10-135

DECAY RATES FOR SLUG ESTERASES WITHIN CARABID PREDATORS EVALUATED BY USING ISOELECTRIC FOCUSING

W. Paill

Institut für Zoologie, Karl Franzens Universität Graz, Austria

In order to determine slug predation by carabid beetles in field, the rate at which prey esterases decay within a predator during digestion must be calibrated.

Carabid beetles (*Carabus cancellatus* Ill., *C. granulatus* L. and *Pterostichus melanarius* Ill.) which had been shown to feed on the pest slug *Arion lusitanicus* Mab., were kept in laboratory and fed with tissue of digestive gland of *A. lusitanicus*. The effects of consumption rate, digestion period and temperature were measured. Results will be presented.

10-136

ADULT POPULATION DYNAMICS OF TYPHLOCYBINAЕ, PENTHIMIINAE AND DELTOCEPHALINAE IN VINEYARDS OF NORTH-WESTERN ITALY (HOMOPTERA CICADELLIDAE)

D. Bosco, A. Alma, A. Arzone, R. Mazzilli¹

Dipartimento di Entomologia e Zoologia applicate all'Ambiente "Carlo Vidano", Università di Torino, Italy - 1 Consorzio tutela del Bramaterra, Roasio (VC), Italy

More than 30 species of Cicadellidae were captured in two vineyards of the Piemonte region using yellow sticky traps throughout all the growing season. The population dynamics of the most common species, belonging to the subfamilies Typhlocybinae, Penthiminae and Deltocephalinae, has been checked.

The most abundant species were *Empoasca vitis* (Goethe), *Zygina rhamni* Ferrari and *Scaphoideus titanus* Ball, all typically associated with grapevine. Many other species, living on vineyard weeds or on shrubs and trees growing close to the vineyards, were captured in a high number too. Some of these species, i.e. *Penthimia nigra* (Goeze) and *Anoplotettix fuscovenosus* (Ferrari) have important relationships with grapevine since they feed and lay eggs on it.

Two population peaks were shown by *E. vitis* at the end of June and at the beginning of August, and by *Z. rhamni* at the end of July and in October. *P. nigra* was trapped in May and June, *A. fuscovenosus* in June-August, *Fieberiella florii* (Stål) in August-September, *Macrosteles sexnotatus* (Fallén) in May and October. *S. titanus* adults were present from July to September, showing a peak at the beginning of August. *Thamnotettix* spp. were trapped in April-June while *Circulifer fenestratus* (Herrich-Schäffer), *Euscelidius variegatus* (Kirschbaum), *Psammotettix* spp. were caught all along the growing season.

The sex ratio of the above species was checked. For some species, namely *C. fenestratus* and *S. titanus*, yellow sticky traps proved to attract more males than females.

10-137

TEMPORAL CHANGES IN GUILD STRUCTURE OF PARASITIDS OF THE PEACH LEAF MINER (*LYONETIA CLERKELLA*) (LEPIDOPTERA: LYONETIIDAE) IN PEACH ORCHARDS WITH DIFFERENT CONTROL INTENSITY.

I. Adachi

Laboratory of Entomology, Division of Plant Protection, Fruit Tree Research Station, Ministry of Agriculture, Forestry and Fisheries, Tsukuba, Ibaraki 305, Japan

The parasitoid complex of the peach leaf miner, *Lyonetia clerkella*, was investigated in peach orchards in Tsukuba, Japan, where the different numbers of spraying insecticides, i.e. different control intensity, were performed. Seasonal changes of the host density were estimated by the stratified sampling method, indicating that the host species has 6-7 generations in a year with each generation scarcely overlapping. In the non-insecticide-spraying orchards the host density which was high in early generations decreased with the generation, whereas the reverse curve of the host density was drawn in the insecticide-spraying orchards. *L. clerkella* larvae were sampled and the parasitism rates were estimated. Seasonal changes of the guild structure and the species diversity of the parasitoids were also examined. Nineteen species of parasitoids were identified from *L. clerkella* larvae and pre-pupae of the peach leaf miner: *Chrysocharis nitetis*, *Chrysocharis pentheus*, *Chrysonotomyia lyonetiae*, *Chrysonotomyia* sp. A, *Chrysonotomyia* sp. B, *Cirrospilus* sp., *Closteroceras trifasciatus*, *Desmatocharis* sp., *Minotetrastichus* sp., *Neochrysocharis* sp., *Pleurotropopsis japonicas*, *Stenomiesius japonicus*, *Pnigalio* sp., *Quadrastichus* sp., *Teleopterius delucchii*, *Teleopterius erxias*, *Zagrammosoma isonoi*, *Trichomalopsis* sp., and *Pholetesor* sp.

10-138

EFFECTS OF UVB AND OZONE ON INDUCTION AND INSECT FEEDING

V. A. Krischik

Department of Entomology, University of Minnesota, St. Paul, MN, USA.

Very little is known about how anthropogenically altered ozone (O₃) levels and increased UVB radiation to the Earth affect plant phytochemistry. Phytochemical induction resulting from ozone and UVB damage are compared to natural herbivore damage. Changes in plant resistance to specialist insects are discussed for three insect-plant systems: cucumber beetle-squash, mexican bean beetle-soybean, cottonwood leaf beetle-cottonwood. Comparison of damage from herbivores and global change (ozone and UVB) revealed similar responses in all three insect-plant systems. In all three systems, induction resulted in greater specialist insect feeding. Flavonoids are increased as a result of UVB and defensive systems as a result of herbivory. In some plants, one system took over the function of the other, if one system was absent.

Studied were two species of squash (garden squash, *Cucurbita pepo*; and an endangered native, *C. okeechobeensis*), and three types of watermelon (domestic American, *Citrullus lanatus vulgaris*; naturalized Australian, *C. lanatus*; and native African, *C. colocynthis*). Total cucurbitacins increased (induction) for most species in most treatments with higher levels of cucurbitacin D associated with decreases in cucurbitacin I. Insects prefer these leaves. Production of cucurbitacin glycosides (E and I) are associated with the highest damaged (UVB and ozone) in all species. Cucurbits produce few flavonoids. In soybeans, a flavonoid kemperol increased as a result of any damage, and insects prefer these leaves. In cottonwood, the phenol glycoside salicin increased as a result of herbivory, and insect feeding increased. A flavonoid pinocembrum increased from UVB damage.

10-139

THE MOST SIGNIFICANT ENVIRONMENTAL FACTORS INFLUENCING THE NUMBER, DISTRIBUTION AND SEASONAL ACTIVITY OF THE WEEVILS (COLEOPTERA: CURCULIONOIDEA: APIONIDAE, CURCULIONIDAE) IN THE TATRA MTS.

S. Knutelski

Instytut Zoologii Uniwersytetu Jagiellońskiego, Kraków, Polska

In the Tatra Mountains altitudinal effect is the most significant factor affecting the number, distribution and time of appearance of imaginal weevil forms which inhabit the above-ground parts of plants. With the altitude the weevil populations change. Both the number of species and the number of specimens drop. There are fewer lowland and more mountain species, the period of maximum occurrence is delayed and the time of occurrence shortened.

The major meteorological factors influencing the character of weevil occurrence are: 1) the time a compact snow cover lingers on the ground; 2) air temperature and, indirectly, 3) the Carpathian fen (halny) wind.

The species composition of the Tatra Mts. weevils depends, to a large extent, on the phytosociological structure of plant biotopes which constitute a feeding base for these beetles. The degree of vegetation density, especially of trees and shrubs in the forests affects their phenology too.

The host plant species play the secondary role in the distribution of mountain weevil beetles in the function of altitude.

10-140

POPULATION STRUCTURE AND REPRODUCTIVE OUTPUT IN A PALEARCTIC GROUND BEETLE, *ANISODACTYLUS SIGNATUS*
J. Fazekas, F. Kádár¹, M. Sárosspataki^{1,2} G. L. Lövei³
Department of Ecology, Attila József University, Szeged, Hungary -
1 Plant Protection Institute, Hungarian Academy of Sciences,
Budapest, Hungary - 2 Department of Zoology and Ecology,
Agricultural University, Gödöllő, Hungary - 3 Horticulture and Food
Research Institute of New Zealand, Palmerston North, New Zealand

The seasonal activity, age structure and reproduction of *Anisodactylus signatus* were studied on beetles collected by pitfall trapping in two regions of Hungary. Adult beetles showed two seasonal activity peaks: during mid-June, only "old" (overwintered) individuals formed a smaller activity peak, coinciding with the peak of the egg production. The second activity peak was in mid-July, when more than 86% of the collected individuals were "young". Egg numbers in the ovaries were low (2-4 eggs/gravid female). Females probably do not reproduce during their first adult year; in the subsequent season, they lay an estimated total of 15.56 eggs. The occurrence of iteroparity is not proven. *A. signatus* has a mixed overwintering strategy, and the age structure of the populations demonstrated regional differences. In eastern Hungary, no adults remained in the surface-active population after mid-summer; in central Hungary, adult activity continued into late September. The estimated total number of eggs significantly differed between the two regions. The significance of regional differences in population structure and reproduction is discussed.

10-142

POPULATION DYNAMICS OF SIMULIDAE (DIPTERA) IN THE MIDDLE VALLEY OF THE NEGRO RIVER (ARGENTINA).
C. L. Coscarón Arias (1), S. Coscarón (2), S. Bramardi (1)
(1) Ecología y Fitogeografía, Facultad Ciencias Agrarias, Universidad Nacional del Comahue, Cinco Saltos, Argentina.
(2) Facultad de Ciencias Naturales y Museo, Universidad Nacional de La Plata, La Plata, Argentina.

The middle valley of the Negro river (Río Negro province) in the North of Patagonia is an agricultural and cattle breeding temperate region. During the last decade the black flies became one of the most annoying pest. Farmers also claim for economic losses on cattle and some recreational areas are heavily affected in the summer season. The study was conducted to reach a better understanding on the population dynamic of the local species. *Simulium* (*Psaroniocompsa*) *bonaerense* Coscarón and Wygodzinsky, *S. (Ectemnaspis) wolffhuegeli* (Enderlein) and *S. (Pternaspatha) bachmanni* Wygodzinsky and Coscarón were observed. Sampling of natural and artificial substrate in representative habitats (Negro river, Salado river, irrigation channels and drainage channels) was carried out during the last three years (1993-1995). The three species are present the whole year with alternation of the predomination of them. *S. bonaerense* and *S. wolffhuegeli* were found breeding in all water courses predominating in habitats with wide range of conductivity (50-558 mS), while *S. bachmanni* was only found breeding in the Negro river (conductivity: 90-192 mS). *S. bonaerense* predominates in all water courses but the river, where *S. bachmanni* and *S. wolffhuegeli* predominates alternatively according to a seasonal pattern. It was observed that *S. bonaerense* is the most aggressive and anthropilic species within the area.

10-141

PATTERNS OF ATTACK ON BAIT STAKES BY *MASTOTERMES DARWINIENSIS* FROGGATT AND SYMPATRIC SPECIES IN TROPICAL AUSTRALIA (ISOPTERA: MASTOTERMITIDAE)
L.R. Miller
CSIRO Division of Entomology, Canberra, Australia
Grids of timber bait stakes have long been used to monitor termite activity and foraging patterns. Data from the first year of a long-term study of the foraging patterns of *Mastotermes darwiniensis* Froggatt are presented. The results to date indicate that in the Darwin region, where 6-8 species compete for baits consisting of unweathered radiata pine stakes, inter- and intra-specific colony boundaries are highly dynamic. Very few stakes inspected at six-weekly intervals were continuously attacked by the same species and some have never been attacked by any species after one year. Although figures are incomplete in that a full wet-season dry-season cycle has yet to be completed, there is little seasonal variation in *Mastotermes* activity apart from a predictable reduction following alate swarming.

10-143

AUSTRALIAN FRUIT FLY DISTRIBUTIONS

M. K. Robson¹, R. Osborne¹, A. Meats¹, P. Maheswaran¹, J.A. Sved¹, and M. Frommer¹
Fruit Fly Research Centre, School of Biological Sciences (A12), The University of Sydney. 2006. AUSTRALIA.

The distribution of fruit flies in endemic regions of Australia has been monitored for three successive years during February/March through National Fruit Fly Experiments. The samples were collected in collaboration with the CSIRO's Double Helix Club members. In the first year, 2,000 volunteers were provided with a lure/insecticide bait and instructions for constructing a trap. In subsequent years, sampling was repeated using a more limited number of volunteers to cover the range. Flies were classified and stored for DNA analysis. The classifications indicate trends in distributions of Australian fruit fly species.

10-144

CARABID COMMUNITIES FROM CORYNEPHORETA AND CALLUNA HEATHS IN NORTHWEST-GERMANY: COMMUNITY STRUCTURE, DISTRIBUTION, AND DISPERSAL (COLEOPTERA: CARABIDAE)

B. Falke

Department of Ecology, University of Osnabrück, Osnabrück, Germany.

The landscape in Northwest-Germany is man-made and was modified several times. Actually, only a few remnants of Coryneporeta on drifting sands and Calluna heaths are left from a former countryside dominated by them until the 18th century, when deforestation reached its maximum.

In 1995 the composition of the carabid fauna from the above-mentioned plant communities was investigated by pitfall trapping on six sites in Northwest-Germany. These sampling sites differ in total area and all are completely isolated from each other by surrounding forests or agricultural land.

Several stenotopic species of Coryneporetum-communities or open sparsely vegetated parts in dry heathlands were sampled, but the complete spectrum of potentially occurring stenotopic species could not be found on any site. At least one species, *Cicindela sylvatica*, is supposed to have totally disappeared from sandy and heathy localities in the studied area in the course of the last decades.

The number of stenotopic species decreases as expected in small and fragmented habitats. Four brachypterous species with low dispersal power were caught, each of them in only one or two of the sampling sites. Since their populations must have survived the last decades in restricted areas, they are highly endangered by extinction, especially if the habitat quality of these small patches gets less suitable for them. In contrast, characteristic winged species of these habitats are widely distributed in the investigated area, indicating that dispersal power is an important factor for survival in a changing landscape with small and isolated habitat islands.

10-145

COMMUNITY EFFECTS OF THE INTRODUCED GROUND-BEETLE *PTEROSTICHUS MELANARIUS* (ILL.) IN WESTERN CANADA

J. Niemelä, J. R. Spence

Department of Ecology and Systematics, University of Helsinki, Finland - Department of Biological Sciences, University of Alberta, Edmonton, Alberta, Canada

The distribution and community effects of the ground beetle *Pterostichus melanarius*, of European origin, were studied in western Canada. Pitfall trapping showed that the species is one of the most abundant carabids in the city of Edmonton, and is also common up to ca. 70 km from the city. The proportion of macropterous individuals of this dimorphic species increased from ca. 20% in Edmonton to 60-70% in the most distant populations. Contrary to previous studies in anthropogenic habitats, *P. melanarius* did not show negative pairwise associations with any of the abundant native species.

We also used a four-year field experiment to examine potential adverse effects of this species on a native carabid assemblage in an aspen-poplar forest. Three enclosures were each divided into six 4 × 4 m compartments, and the following treatments (with two replicates in each enclosure) were used: (1) *P. melanarius* alone, (2) six abundant native species alone, and (3) *P. melanarius* together with the six native species. *P. melanarius* maintained breeding populations in all compartments where introduced, but it had no negative effect on population size or body mass of the native species. However, the two most abundant native species (*Pterostichus adstrictus* and *P. pensylvanicus*) appeared to be more active in compartments where they co-occurred with *P. melanarius*. Although the enclosures were just a few meters apart, a strong enclosure effect was detected with one of the three enclosures yielding the highest numbers of both the native species and of *P. melanarius*. This difference was correlated with high abundance of earthworms and low litter accumulation in that enclosure. Low densities of *P. melanarius* in forests may explain the lack of negative interspecific interactions in our experiments, though these are suggested in data from urban and agricultural environments where *P. melanarius* is more abundant.

10-146

EVIDENCE FOR INTERPLANT COMMUNICATION OF WOODY PLANTS IN THE FIELD - EFFECTS ON THE HERBIVORE GUILD OF *ALNUS GLUTINOSA*

R. Dolch, T. Tschamtkke

Fachgebiet Agrarökologie, Georg-August-Universität, Göttingen, Germany

Consequences of manual defoliation on the herbivore guild of alders (*Alnus glutinosa*) were studied in the field. One tree in each of 10 alder stands was damaged in spring by manually removing approximately 20% of total leaf area. After resprout, subsequent leaf damage by alder leaf beetle (*Agelastica alni*) and abundance of other herbivores was assessed on 10 trees differing in distance to the defoliated alder until the end of the vegetation period. Stem diameter and infestation with gall mites proved to be minor factors influencing leaf damage caused by the beetles. Effects of manual defoliation explained leaf damage best, which significantly increased with distance to the defoliated tree. Abundance of phytophagous insects rose likewise. Accordingly, induced resistance caused by manual defoliation not only reduced herbivore performance on the defoliated tree itself, but also on its neighbours. These results show strong evidence for interplant communication in *A. glutinosa*, and could be supported by laboratory tests.

10-147

AN ANALYSIS OF POPULATION SYSTEM SPATIAL STRUCTURE OF THE BEET WEBWORM *LOXOSTEGE STICTICALIS* L.

A.N. Bashev

Group of System Modeling, Computer Center, Novosibirsk, Russia

In this paper a local population of *L. sticticalis* survival at the variation of photo - thermal conditions are studied using the space of concordance of inner (physiological) and external (astronomic) times, where inner time is determined as a sum of efficient temperatures. For the beet webworm the sum of efficient temperatures of development stages and their combination are thermal constants. The inner time of a sensitive phase -- the third, fourth, and fifth age of larvae stage is also constant. We fix its respective values on the axis of inner time.

On the axis of external time a value of photo threshold is considered, the value is determined by only the geographic latitude of a local population. The population is described by a set of temporal stratum in external time. Thus, if the sensitive phase of certain stratum develops after threshold and has a necessary sum of efficient temperatures for the survival in accordance it the LCj - type life cycle than the percentage of diapausing individuals will be greater than zero.

This paper shows that at the absence of migrations in the system the trajectory variety of temporal stratum in the space of concordance of inner and external can be divided only into four types. Respectively, the population system range consists of four types: survival region of LCj - type life cycle, "overheating" region, degradation region, and region of disharmony. A detailed spatial structure of British - Ob population system also is described here.

10-148

DRIFT OF RESPONSE OF THE BEET WEBWORM
LOXOSTEGE STICTICALIS L. (LEPIDOPTERA, PYRALIDAE) ON
VARIATION OF ITS POPULATION DENSITY

I.B. Knorr**, A.N. Bashev***, A.A. Alekscev*, E.N. Naumova**
*Division of Optimal Pesticide Application, Institute of Chemical Kinetics, Novosibirsk, Russia - ** Zoological Museum, Institute of Biology, Novosibirsk, Russia. - ***Group of System Modeling, Computer Center , Novosibirsk, Russia

At present abundance dynamics of *L. sticticalis* is considered only as a passive reaction to a change of modifying factors. However, the result of our recent research have shown that there is non - trivial modulation of external effects by means of a set of endogenous transformations having certain inertia. The inertia is disclosed itself as a dependence of internal population state on its previous history.

Effect of density on the abundance dynamics of the beet webworm at various stages of gradation cycle has been studied. Comparison of results obtained in 1991 and 1994 explicitly shows the drift of the following parameters: mortality, structure of larvae color morphs, weight structure of population and female fecundity. Direct influence of previous history on the structure larvae color morphs also has been studied. It has appeared that the morph structure determined as by current density as population density of the preceding generation.

Thus, the obtained results allow to conclude that abundance dynamics of species is determined not only by environmental parameter changes but also by dynamics of endogenous parameters.

10-150

EFFECT OF DENSITY ON PHOTOPERIODIC REACTION OF BEET
WEBWORM *LOXOSTEGE STICTICALIS* L. (LEPIDOPTERA:
PYRALIDAE)

I. Knorr**, A. Alekscev*, E. Naumova**
Division of Optimal Pesticide Application, Institute of Chemical Kinetics, Novosibirsk, Russia - ** Zoological Museum, Institute of Biology, Novosibirsk, Russia.

The density is one of the main population characteristics. Its change causes a cascade of transformations of the population structures. However, there are comparatively few records about effects of population density on diapause and photoperiodic reaction (PhPR) of insects. Such data for beet webworm are absent. The study was conducted on a first generation larvae. Imago were collected on the south of Novosibirsk region (South of Western Siberia). In each variant of photoperiod (12, 13, 14.5, 16 hours) were 3 variants of density - 5, 10 and 50 larvae per glass container (volume 0.5 l). Larvae have finished development on August 3-5. After 45 days (on September 15) the account of diapaused pronymphs was conducted. Larvae developed at $t=26 \pm 1^{\circ}\text{C}$. PhPR of beet webworm was in detail studied by Saulich et al.(Zool. Zh., 1983,) on populations from European part of Russia. Our data (Tabl.1) suggested that the increase of population density causes significant decrease in percent of diapausing pronymphs. Low percent of diapausing pronymphs is marked at shortday photoperiod (12 and 13 hours). Following data of Saulich et al. beet webworm is a species with a thermostable PhPR of long day type and without geographical variability of its parameters. The contradiction between our data and results of Saulich's et al. studies gives evidence of insufficient studying of a beet webworm PhPR. We have found out the drift of such important parameters as fecundity and structure of color morphs (unpublished data), that allows to speak about population cycle of beet webworm. Quite probably, that the character of PhPR can differ in different phases of population cycle.

Tabl.1. Effect of density on PhPR of beet webworm. Numbers are percentage of diapausing pronymphs $\pm Cl_{0.95}$ (confidence interval)

Photoperiod Density	12 hs	13 hs	14.5 hs	16hs
5 larvae/0.5l	53.8 \pm 13.1	23.0 \pm 11.0	67.0 \pm 21.2	0
10	58.0 \pm 15.8	20.0 \pm 11.9	55.0 \pm 18.7	0
50	13.0 \pm 4.0	4.0 \pm 3.6	16.0 \pm 8.6	0

10-149

A STUDY OF MIGRATIONS OF THE BEET WEBWORM
LOXOSTEGE STICTICALIS L.: A QUANTITATIVE APPROACH
A.N. Bashev

Group of System Modeling, Computer Center , Novosibirsk, Russia

It is well known that the migrations result in a change of spatial structure of the population systems. The region of degradation are reduced for account of the arising of migrant survival region. The effect is explained by that the migrant inner (physiological) time is compound and determined by photo - thermal conditions of the respective compartment set. At availability of migrations in the system the trajectory variety of temporal stratus in the space of concordance of external (astronomic) and inner times can be divided into five types. Respectively, population system range consists of five types: survival region of LCj - type life cycle, region of migrant survival, "overheating" region, degradation region, and region of disharmony of inner and external times. The first and second regions can be sources of migrations if the local population density execs threshold value. Migrational induction in the system results in a significant expansion of the effective range territory where processes of reproduction and dispersal occur. As a result outbreak of *L. sticticalis* appear.

Thus, using space of concordance of inner and external times permits: 1) to define a detailed spatial structure of population system at each stage of gradation cycle, 2)to explain a phenomenon of extension of effective territory of the range by migrations, 3) to calculate ecological consequences of all possible migrations in the population system of *L. sticticalis*.

10-151

THE TRANSPLANTING AFFECTS THE SPATIAL
EXPANSION OF A NEWLY COLONIZED INSECT, RICE
WATER WEEVIL, *LISSORHOPTRUS ORYZOPHILUS*
(COLEOPTERA, CURCULIONIDAE) IN JAPAN.

NOBUO MORIMOTO (Division of Entomology, National Institute of Agro-Environmental Sciences, Tsukuba, Ibaraki, Japan

The Rice water weevil (RWW) *Lissorhoptrus oryzophilus*, which is likely to have invaded from California, is currently one of the major pests of rice in Japan. In most of Japan, RWW has one generation a year, and overwinters as adult in grass leaf litter near paddy fields.

In spring, adults feed on grass near the overwintering site, and the flight muscle develops. After they disperse to paddy fields, where they feed on the leaves of rice and begin to oviposit.

RWW was newly found in Nagoya, the central part of Japan in 1976. It expanded its distribution across prefectures and distributed all over Japan in 1986. While they were expanding the spatial expansion rate in each prefecture was greatly different. The ratio was negatively correlated with the sum of effective temperature till transplanting date of rice in each prefecture.

The oviposition of RWW depends on the transplanting of rice, because the development of the ovary of the adults needs feeding of the rice leaf and eggs must be oviposited in the stems of rice transplanted in a paddy field. The development of flight muscle, the development of ovary and the process of oviposition depend on the sum of effective temperature.

In the aria where the sum of effective temperature till transplanting date of rice is large, transplanting is later than when the sum of effect temperature enough for ovary development is attained. As the result, RWW can not feed for the development of ovary which results in reducing the population growth. This may be the reason for the smaller expansion rate in the preference where the effective temperature is large and vice versa.

10-152

PREDACIOUS MITES (ACARI: MACROCHELIDAE) AND SYNANTHROPIC FLIES (DIPTERA: MUSCIDAE AND FANNIDAE) ATTRACTED TO ACCUMULATED POULTRY MANURE FROM FARMS OF ARGENTINA.

A. Perotti & M. Brasesco

Departamento de Biología, Universidad Nacional de Mar del Plata, Funes 3250 3° piso, 7600-Mar del Plata, Argentina.

Many species of synanthropic flies and mites predators of fly eggs and first instar larvae are the most frequent organisms in the manure from poultry farms using caged-layers.

The present work was undertaken to know the variety of flies (Muscidae and Fanniidae) and mites predators associated to poultry manure accumulations in production systems from the South East of Argentina.

During 1994, 1995, samples of accumulated manure were collected at monthly intervals, in barns from three farms from the South-East of Buenos Aires province, Argentina.

Mites of the genus *Macrocheles*, *Fuscouropoda*, *Parasitus*, *Eugamasus*, *Poecilochirus*, *Hypoaspis*, *Proctolaelaps*, *Arctoseius*, *Sejus*, and fly-larvae of the genus *Musca*, *Fannia*, *Ophyra* and *Muscina* were extracted from the manure by illuminated tullgren funnels and identified. Although twelve mite species not previously recorded to the site were counted, *Macrocheles muscaedomesticae* was predominant followed by *Fuscouropoda* sp. Fly larvae of *Musca domestica*, *Fannia canicularis*, *Ophyra aenescens* and *Muscina stabulans* were encountered in that order of abundance. The population numbers of the predators *M. muscaedomesticae* and *Fuscouropoda* sp. coincided seasonally with *M. domestica*, *O. aenescens* and *F. canicularis*.

10-154

POPULATION DYNAMICS OF SAN JOSE SCALE *Quadraspidiotus perniciosus* COMSTOCK, 1881 (HOMOPTERA: DIASPIDIDAE) IN PEACH ORCHARD, IN JACUÍ, MINAS GERAIS STATE - BRAZIL.

L. de C. Diniz¹, V.H.P. Bueno¹, A.M. Aua¹

¹ Departamento de Fitossanidade, Universidade Federal de Lavras, Minas Gerais - Brasil

The population dynamics of San Jose Scale, *Quadraspidiotus perniciosus* on peach orchard in Jacuí, Minas Gerais - Brazil was studied. The natural enemies and weather effects were evaluated. The samples were made on branches of peach tree in two areas, being one treated and the other untreated from August/1994 to July/1995. Adult females occurred all over the year, and presented population peaks in August, October, January and March. Crawlers emerged early in August with increasing of the climatic factors. It showed three peaks in August, January and February. The natural enemies, principally, parasitoids and the fungus *Fusarium coccophillum* (Desm.) showed a high effect on *Q. perniciosus* in untreated area, with 9.5% of parasitized scales and 29.4% of infected scales. In treated area, 5% of parasitized scales and 15% infected scales resulted. The weather (temperature, relative humidity and precipitation) showed more effect on the pest in treated area. Temperature and precipitation had a greater influence on the stages of scales at 30 days before the samplings. In this study, *Q. perniciosus* presented higher population in treated area than in untreated area. The untreated area showed more equilibrium, that is to say, maintenance of *Q. perniciosus* population to lower levels because of the action of their natural enemies and also for climatic effects. The insecticides sprayed in treated area showed to be more harmful than the natural enemies.

10-153

LONG-TERM EFFECTS OF PEAT-CUTTING ON BEETLE (INSECTA: COLEOPTERA) COMMUNITIES OF A DAMAGED CENTRAL-EUROPEAN MOOR

J. Frisch

Institut für Allgemeine und Spezielle Zoologie, Bereich Tierökologie, Justus-Liebig-Universität Giessen, Germany

The coleopteran communities of the moor 'Rotes Moor' and the surrounding areas were investigated in 1993 and 1994. The study sites are situated in the Rhoeun-mountains (Germany), about 810m above sea level. The peat-bog has been damaged by drainage and commercial peat-cutting until 1984. Northern-palaeartic-boreal and Central-European-mountainous species dominated the coleopteran communities. Typical associations between various beetle species and characteristic vegetation types (moor, cut-over area, swamp, surrounding *Betula-carpatica*-wood and *Picea abies*-forest) could be established.

It is shown that the long-lasting alteration of vegetational patterns towards heath following drainage and peat-cutting is the most striking factor, causing a dramatic change of the original beetle community. Tyrphobiontic species were nevertheless found in small relicts of growing moor-areas. The wet cut-over areas, in contrast, were colonized by beetle-communities similar to those of the swamps surrounding the moor in which tyrphobiontic species have completely vanished. The results are discussed in the context of the effect of peat-cutting and drainage on niche-choice behavior of some abundant species. In addition, it is demonstrated that differences in phenological patterns lead to niche separation between closely related, syntopic species of Staphylinidae (*Liogluta* spp.).

10-155

POPULATIONAL DYNAMICS OF THE PEACH APHID *Brachycaudus* (*Appelia*) *schwartzi* (HOMOPTERA: APHIDIDAE) IN JACUI-MINAS GERAIS STATE, BRAZIL.

A. M. Aua¹, V. H. P. Bueno¹

Departamento de Fitossanidade, Universidade Federal de Lavras, Minas Gerais, Brasil.

One of the factors which contributes to low yield of the peach tree in Minas Gerais, state-Brazil, is the occurrence of *Brachycaudus* (*Appelia*) *schwartzi*, which causes leaf and shoot rolling and leads to side sproutings, harming the plant architecture.

This research had the objective of studying the population dynamics of the peach aphid *Brachycaudus* (*Appelia*) *schwartzi*. The weather effects on this aphid population were evaluated, as well as the distribution of first to fourth instar nymphs both apterous and alate and also apterous and winged adults.

Three apical branches approximately 25 cm long per plant on 10 plants giving preference to branches which had shown greatest aphid colonies, were sampled fortnightly, from August, 1994 to July, 1995. All over the survey period, the presence of *Brachycaudus* (*Appelia*) *schwartzi* was found, where its population proved to be positively correlated with temperature and negatively with relative humidity. The highest populational peak was achieved on September, 1994, where the temperature and relative humidity accumulated seven days before the samples were 24.3 °C and 55.8% respectively.

The occurrence of first and second instar nymphs was greatest relative to the other stages, standing for 62.68% of the total of sampled individuals. The occurrence of apterous third and fourth instar nymphs was 17.07%, value which is superior to that found for alate third and fourth instar nymphs which was 2.78%. The percentages of apterous and winged adults were 16.64% and 0.83%, respectively.

10-156

INVASION ECOLOGY OF *SOPHONIA RUFOFASCIA* (HOMOPTERA: CICADELLIDAE), THE HAWAIIAN GOURMAND

Vince Jones & Peter Follett, Department of Entomology, University of Hawaii at Manoa, USA

The two-spotted leafhopper, *Sophonia rufofascia*, is a recently introduced insect that feeds on over 300 species of plants and is changing the landscape of Hawaiian forests and watersheds. Particularly hard-hit plants include the false staghorn fern (uluhe), Hawaiian tree fern (hapuu), *Metrosideros polymorpha* (ohia lehua), and *Myrica faya* (firetree). Studies are underway to better understand plant response to *Sophonia* feeding; patterns of uluhe dieback and dead patch revegetation; *Sophonia* ecology relative to patterns of plant host attack, and the diversity and impact of natural enemies (principally egg parasitoids); and the possibility that *Sophonia* may threaten the health of rare endangered Hawaiian plants.

10-158

ANALYSIS OF ORIBATID MITES (ACARI: ORIBATIDA) COMMUNITIES IN MT. JUMBONG IN KOREA

Joon-Ho Lee, Bang Hun Kang
Div. of Entomology, Dept. of Agricultural Biology, College of Agriculture and Life Sciences, Seoul National University, Suwon, 441-744, Korea
Analysis of oribatid mites communities was conducted at 4 sites (the plantation of Korean pine in alt. 900m; the mixed forest in alt. 1100m; the north-facing slope where lower vegetations were annual herbaceous, and the south-facing slope where lower vegetation was perennial sasa in alt. 1000m, and these slopes were adjacent to each other) in Mt. Jumbong which is a nature reserve area in Korea. Also, organization of oribatid mites communities in the decomposition process of litter was investigated at north- and south-facing slope. The study was conducted from June 1994 to Oct. 1995. In total, 52 families, 81 genus, and 143 species of oribatid mites were collected. Species composition, densities, and dominant species were significantly different between north- and south-facing slopes. About 70% of total species and density were found in less than 5cm depth of soil. *O. nova* was common dominant species at 4 sampling sites. *P. duplicata nipponica* was a dominant species at south-facing slope but was not found at north-facing slope. *Boreozetes donghaksensis* was a dominant species at mixed forest in alt. 1100m, but a rare species at other sites. Species diversity (H') was higher at south-facing slope ($H' = 3.06$) than at north-facing slope ($H' = 2.67$). The proportion of influent species was very low at alt. 900m site compared to other sites. The values of similarity index among sites or sampling dates were higher than 0.6. Results of MGP analysis indicated that M-type and G-type species were dominant groups in Mt. Jumbong.

10-157

NATURAL HISTORY OF A GALL-FORMING WEEVIL, *COLLABISMUS CLITELLAE* (CURCULIONIDAE), ON *SOLANUM LYCOCARPUM* (SOLANACEAE) IN SOUTHEASTERN BRAZIL.

A.L.T. Souza¹, G.W. Fernandes²

1 - Curso de Pós-graduação em Ecologia - Universidade Estadual de Campinas-Bolsista do CNPq - Brasil (processo 141318/95-3)

2 - Departamento de Biologia Geral da Universidade Federal de Minas Gerais, Brasil.

Collabismus clitellae promotes gall formation in branches of *Solanum lycocarpum* (Solanaceae), an invading species in areas of economic value with antropic influence. *C. clitellae* individuals are distributed in variable-sized galls (which are determined by the number of chambers present in each gall), occurring preferentially on the basal part of smaller-sized plants. The adult weevils have a great variation in size (range 4 - 10mm). In this study we relate the main causes of mortality in individuals of *C. clitellae* and describe the development stages and weight variation of the pupes in relation to the gall characteristics and the distribution in the host plants. We collected 376 galls randomly in a population of *S. lycocarpum*, located at Serra do Cipó in southeastern Brazil.

The number of eggs laid by *C. clitellae* females increases with the branch diameter, decreasing with the host plant size. The gall volume increases with the number of chambers until a well defined limit. Therefore, very crowded galls are formed, leading to a decrease on the mean weight of pupae.

The *Penicillium* sp fungus and the woodpecker *Colaptes campestris* were the main external factors affecting the mortality of galls. The fungus occurrence was higher on shorter plants and bigger galls, but was independent of the position of gall on the host plant. Larger galls positioned on the higher parts of the host plants were more often attacked by woodpeckers. We suggest that the survival probabilities and the body size of *C. clitellae* individuals increases with the choice of oviposition sites and the clutch size. This choice is related to mechanical and biochemical differences between different-sized plants and by different mortality agents. Moreover, the fungus and bird attacks must be important factors regulating the population size of this gall species.

10-159

SEQUENTIAL SEED PREDATION ON *PITHECELLOBIUM TORTUM* MART. (LEGUMINOSAE)

M. V. Macêdo^{1,2,*}, M. C. P. Pimentel², & T.M. Lewinsohn¹

¹ Lab. Interações Insetos-Plantas, Depto Zoologia, Universidade Estadual de Campinas, Campinas, SP, Brasil. *Pós-Graduação em Ecologia, Bolsista CAPES.

² Lab. Ecologia de Insetos, Depto Ecologia, Universidade Federal do Rio de Janeiro, Rio de Janeiro, RJ, Brasil

In the Restinga de Barra de Maricá, Maricá, Rio de Janeiro, Brasil, *Pithecellobium tortum* immature seeds are attacked by larvae of *Allorhogas dispistus* (Braconidae) and maturing seeds by larvae of *Merobruchus boucheri* (Bruchidae). In order to investigate whether predation by braconids affects subsequent resource utilization by bruchids we collected 400 fruits from 8 trees in 1992 and 291 pods from 10 trees in 1995. All pods and seeds were dissected and insects or their damage recorded to ascertain predation rates from different agents.

In 1992 *Allorhogas dispistus* was relatively scarce, attacking 31% of the examined pods (range 0 - 86% per tree) and 12% of the seeds (0 - 33%). In 1995, the braconid infested 76% (34 - 100%) of the pods and 54% (7 - 99%) of the seeds. Bruchid attack varied less between years: 71% of the pods and 20% of seeds were infested in 1992, 46% of the pods and 14% of the seeds in 1995. Among-tree comparisons indicated no effect of the braconid infestation on bruchids in 1992, but in 1995 both pod and seed infestation rates by the two predators were negatively correlated ($r = -0.82$ and $r = -0.88$ respectively). Nonetheless, though bruchid larvae were more numerous in trees less attacked by braconids, infestation rates were not higher on those trees. Results suggest that firstcomers affect later predators only above a fairly high density and, apart from reducing total resource availability, they do not provoke noticeable change in attack patterns among pods or trees.

10-160

THE EFFECT OF CADMIUM STRESS ON THE INTERACTIONS BETWEEN *PARARGE AEGERIA* AND ITS HOST PLANT.I. Vandevyvere¹, L. De Bruyn¹, R. Blust²

Department of Biology, University of Antwerp (RUCA), Belgium, 1 Evolutionary Biology Group, 2 Ecophysiology and Biochemistry

Since anthropogenic pressure on ecosystems continues to increase, metal pollution will be one of the most important problems in the future. In the soil, heavy metals operate as stress factors causing physiological constraints after absorption by the root system. This often results in a decreased vigour of the plants and retardation of plant growth.

Insects are dominant components in many terrestrial food webs. They play an essential role as primary consumers of plants and in turn are an important source of food for the higher trophic levels. Consequently, the changes caused by pollution are not restricted to the plants themselves, but may also affect other parts of ecosystems. However, the behaviour and physiological impact of heavy metals on the different trophic levels of terrestrial food chains are poorly understood.

In this study, attention is focused on the impact of cadmium intoxication on *Holcus lanatus* and its herbivore *Pararge aegeria*. To assess cadmium concentration along the food chain more accurately we carried out laboratory studies. Of primary importance is the regulation of the levels of soluble and plant available Cd in soils. Therefore bioavailability was studied using soils with a range of Cd treatments. Dose-response experiments with moderate to excess metal supply to *Holcus lanatus* seedlings gave data on the direct impact of Cd on the plant fitness. We measured growth, biomass production, photosynthetic characteristics and the nutritive value as host plant. Grasses grown on soils with different cadmium treatments were offered to the herbivore larvae. Growth rate, final size and consumption efficiency were measured. The results are explained based on the nutritive host plant characteristics.

10-162

THE INFLUENCE OF PLANT STRESS ON HOST SELECTION AND PERFORMANCE OF THE GRASS MINER *CHROMATOMYIA MILII* (DIPTERA; AGROMYZIDAE)

J. Scheirs, I. Vandevyvere & L. De Bruyn (University of Antwerp (RUCA), Department of Biology, Evolutionary Biology Grp, Groenenborgerlaan 171, B-2020 Antwerpen, Belgium, e-mail: scheirs@ruca.ua.ac.be)

Environmental stresses such as water deficit, or nutrient imbalances, have been hypothesized to change plant quality in nature. Two major hypotheses were formulated. The plant stress hypothesis proposes that physiologically stressed plants become more susceptible to herbivores. On the contrary, the plant vigour hypothesis proposes that plants that are growing vigorously are favourable to herbivores. Recent research brought to the light that the result of plant insect relationships is largely dependent on the feeding behaviour of the herbivores studied. Endophytic insects (miners, gall-formers, borers) should prefer and do better on vigorous growing plants.

Environmental stress theories were largely based on insect guilds feeding on woody plants. Compared to more complex plants such as trees, grasses only possess simple plant architecture, relative low protein concentration, and a low diversity of secondary compounds. Therefore we can suppose the host plant will act differently on the herbivore. The aim of this study was to test the plant stress / plant vigour hypothesis for an internal feeding herbivore living on grasses. We selected for this purpose *Chromatomyia milii*, an oligophagous grass miner (Diptera; Agromyzidae).

In a greenhouse, under controlled conditions, we tested female host plant selection, larval mortality, larval growth rate and final adult size on grasses growing under different levels of nutrient and water stress.

Our results show that low egg densities and low larval performances occurred on grasses under low and high nutrient stresses. High egg densities and high larval performances occurred on grasses under medium nutrient stress. High egg densities and high larval performances occurred on grasses under high water treatment. Differences in food plant quality are responsible for the observed differences in female ovipositional preference and larval performance.

10-161

A COMPARISON OF DIRECT AND INDIRECT METHODS TO ESTIMATE THE POPULATION STRUCTURE IN A DAMSELFLY

R. Stoks^{1,2}, M. Santens², L. De Bruyn², E. Matthysen¹

1 Laboratory for Animal Ecology, Department of Biology, University of Antwerp, Belgium - 2 Evolutionary Biology Group, Department of Biology, University of Antwerp, Belgium

Traditionally population size and lifespan are estimated with indirect methods such as the Jolly-Seber (JS) method and the Manly-Parr (MP) method; lifespan with the method of Scott. An in odonatology scarcely used direct method to determine the population size is the Minimum Number Alive (MNA) method, developed by Krebs (1966) for capture-recapture studies of mice. A simple direct estimate of lifespan is the residence time in the population. We compare these methods, using field data on the damselfly *Lestes sponsa*.

The capture probability influences the accuracy of the population size estimates. The three methods give very similar estimates for the male population sizes. In females however capture probabilities are low. This reduces the number of days that MP and JS give accurate estimates. MNA underestimates absolute population size, but gives the opportunity to know the evolution in population numbers on all days. Estimates of lifespan by the method of Cook and directly by the residence time were the same for males. This last method, however, underestimates female lifespan due to the long interval length between two successive visits in females.

10-163

SURVIVAL AND NON-LINEAR TEMPERATURE-DEPENDENT DEVELOPMENT MODEL OF IMMATURE *AUBEONYMUS MARIAEFRANCISCAE* ROUDIER (COLEOPTERA: CURCULIONIDAE).

V. Marco, A. Taberner, P. Castañera

Centro de Investigaciones Biológicas, CSIC, Madrid, Spain

The sugar beet weevil *Aubeonymus mariaefranciscae* Roudier is a new key pest of sugar beet in Southern Spain. Survival and development of immature stages were studied by rearing them, on artificial diet, at seven constant temperatures ranging from 15° to 33°C.

Eggs development occurred over the whole range of temperatures tested, though a large decrease in the hatching percentage was observed above 30°C.

First, second and third-instar larvae were able to develop at low temperatures but failed to do so above 30°C. Conversely, fourth-instar larvae did not develop below 18°C, and their developmental time at 20°C was longer than 50% of the total immature developmental time.

A non-linear function, Logan type III, rather than a linear one, provided a reliable fit of developmental rates (reciprocal of mean time for development) versus temperature for all immature stages, specially in the high and low-temperature range. The percentages of mortality vs. temperature are also showed.

Implications of these results in predicting *A. mariaefranciscae* phenology, under field conditions, are discussed.

10-164

PRELIMINARY STUDY OF ANT DIETARY-HABITS IN BORNEAN RAIN FOREST - Do ants play as primary consumers in tropical ecosystems ? -

HASHIMOTO, Yoshikai¹ and YAMANE, Seiki²

Museum of Nature and Human Activities, Hyogo, Yayoigaoka Sunda Hyogo, Japan - 1 Department of Biology, Kagoshima University, Kagoshima, Japan - 2

Ants are among the most abundant animals in tropical forests. Although the ant-predation should be considered to have a major impact on the composition of tropical invertebrate biodiversity, the dietary habits have not been studied for large majority of tropical ant-groups. In Sarawak, Borneo, we conducted food preference tests of 19 species (*Dolichoderus*, *Camponotus*, *Polyrhachis*, *Crematogaster*, *Leptogenys*, *Aenictus* ssp. etc.) and continuous observations of 5 species at trails near the nest to find captured prey.

Results

1. All species tested here accepted soil protein foods (cheese and dead insects).
2. *Aenictus* and *Leptogenys* ssp. accepted honey-solutions eagerly in food tests.
3. Continuous observation of *Dolichoderus cuspidatus senipennis* (Nomad ant) for 31hr. showed that only 2 workers carried dead arthropod (Total number of workers returning to the nest = 19,305).
4. In the observation of *Polyrhachis bihamata*, single worker carried dead arthropod (Total observation time = 4hr. Total number of workers returning to the nest = 1,488).
5. The observations of *Camponotus saundersi* and *Crematogaster inflata* showed that no workers carried soil protein foods to the nests.

10-166

POPULATION OF TERRESTRIAL CARABIDAE FROM DIFFERENT ZONES OF CENTRAL SIBERIA.

L. B. Rybalov,

Institute of Ecology and Evolution, Russian Academy of Sciences, Leninsky prospekt, 93, Moscow 117071, Russia.

The study of the Carabidae population in the natural ecosystems of Central Siberia was carried out in 1988-1995. The region of research is located on Asian transect (along Yenisei River) from the Sibiryakov Island in the north (73° N) up to the Predvinsk in the south (57° N) and covers eight subzones: arctic, typical and southern tundra, forest-tundra, northern, middle, southern taiga and subtaiga.

In our material were found out more than 100 species of the Carabidae family, large part from which concerns to the genus *Pterostichus*, *Carabus*, *Agonum*, *Bembidion*. The poorest communities of the ground-beetles is registered in arctic tundra (4 species). The most diverse ones was described in some southern subzones from the middle taiga up to the subtaiga (50-65 species).

In the ecosystems of arctic tundra only one species of the ground-beetle was dominant in most part of communities. For example, *Pterostichus brevicornis* was dominant in all sites on the Sibiryakov Island. 3-5 ground-beetle species inhabit each community in typical tundra and in the intrazonal coastal localities singly the widespread species were marked, for example, *Elaphrus riparius*, *Bembidion lunatum*. In the southern tundra there are some forest species in the *Alnus* association, for example *Trechus mortcowitschi*. In forest-tundra the complex of forest species is represented by many species, however concrete forest and tundra communities have a few similar species. Northern tundra species, for example *Pterostichus brevicornis*, penetrate rather far to the south up to the middle taiga, but in small quantity.

Boreal zonal ecosystems have rather a few number of species (5-10), in comparison with intrazonal communities of bogs and flood-plain, where the number of species is much more (25-30). In all kinds of a taiga in zonal interfluvial ecosystems only three species (*Pterostichus delutipes*, *P. ehnborgi*, *Calathus micropterus*) were basically dominant. In subtaiga zone to these three species is added *P. magus*.

10-165

DISTRIBUTION AND APPEARANCE OF THE SILVER Y MOTH, *AUTOGRAPHA GAMMA* (LEPIDOPTERA, NOCTUIDAE), IN JAPAN, AND SEASONAL CHANGE OF CHARACTERISTICS CONCERNING WITH MIGRATION

Osamu Saito

National Institute of Agro-Environmental Science, Kannondai, Tsukuba, Japan

The silver Y moth, *Autographa gamma* (L.), is a famous migrant insect pest in Europe. This species hibernate in Mediterranean area that has warm winter, and the moth migrate to north way in summer. Distribution of the silver Y moth in Japan recorded at first in 1960s and nowadays there are many records in all area of Japan. The species produce big population in Hokkaido Is. which has long, cold and snowy winter, although the species is few or rare in southern part, Honshu, Shikoku or Kyushu Is..

The moth appear 3 times, May-June, August, and September-October in Hokkaido. They have not obligatory diapause stage but they hibernate in middle larval stages. Dry weight of the male moth captured by pheromone trap in Memuro, Eastern Hokkaido, are light in order of first> second> third appearance. On the other hand fore wing length of the male moth elongate in order of first< second< third appearance. Hence, the weight-wing index (dry weight / fore wing length) become small in order of first> second> third appearance. The same results are taken in the data from four other places in Hokkaido. Dry weight and fore wing length of the female and the male moths captured by a light trap have the same results. Ratio of the mated female captured by a light trap are 90, 65 and 25% in the first, the second and the third appearance respectively. Seasonal changes of characteristics of the silver Y moth in Hokkaido indicate that the adults in third appearance physiologically and morphologically suit for migration.

10-167

INDIVIDUAL SEX PHEROMONE RESPONSE DIFFERENCES IN MALE *AGROTIS SEGETUM* MOTHS (LEPIDOPTERA: NOCTUIDAE)

Mats Svensson

Department of Ecology, University of Lund, S-223 62 LUND, Sweden

Several studies of insect mating systems have identified male traits, such as age and body size, that influence pairing success in the field. In moths is pheromone response also important. Here I show that male moths differ in their mate-finding capabilities and it is related to both pheromone response and morphological correlates. Male turnip moths *Agrotis segetum* (Dennis & Schiff.) were caught alive in pheromone traps in the field and tested the consecutive night in a wind tunnel. Males caught with high release rate baits in the field were responding significantly less in a wind tunnel to a low release rate bait, compared to males caught with a low release rate bait. No differences were found between males caught with a pheromone bait with a distorted ratio and males caught with a high release rate bait. The response time, i.e. time to induced behavioural response, also differed, but not the flight time, i.e. time to reach pheromone source from take-off. The morphological measurements revealed no differences in wing span, wing area or wing symmetry, but the weight differed between males typed low release-responding and males typed high release-responding. The last group was significantly heavier.

10-168

MILKWEEDS AND MONARCH BUTTERFLIES AND THE PARADOX OF PLANT CHEMICAL DEFENCES THAT BENEFIT SEQUESTERING SPECIALISTS

S.B. Malcolm¹, M.P. Zalucki²¹Dept. of Biological Sciences, Western Michigan University, Kalamazoo, Michigan, USA - ²Dept. of Entomology, University of Queensland, Brisbane, Queensland, Australia.

Toxic chemical defences can pose a paradox for plants because many adapted insect specialists benefit from sequestration of these same chemicals for defensive use against their own natural enemies. Thus monarch butterflies, *Danaus plexippus*, increase their defence effectiveness as milkweed host plants increase investment in a group of toxic steroids called cardenolides. However, some highly modular milkweeds have constitutively low levels of cardenolide that can be induced extremely rapidly in a latex delivery system. Here we investigate experimentally the possibility that the latex delivery system helps to resolve this paradox through decreased growth of a specialist, sequestering herbivore. Our results agreed significantly with predictions that plant latex should decrease growth rates and increase mortality of first instar larvae of *D. plexippus*. A second experiment showed that milkweed cardenolides can be induced both quantitatively and qualitatively in ways that may also help to resolve the paradox.

10-169

BUMBLEBEE COMMUNITIES AND FLOWER VISITS IN EASTERN AUSTRIA (HYMENOPTERA: APIDAE)

C. Farnberger, H. F. Paulus

Institute of Zoology, Depart. Evol. Biology, University of Vienna, Austria

Bumblebee communities usually consist of many species coexisting within small areas. Mechanisms of resource partitioning were studied in 7 sites in a nature reserve in Eastern Austria using permanent study transects. Within one investigation period (May-October 1994) 10 bumblebee species (*Bombus* Latr.) and 3 cuckoo bumblebees (*Psithyrus* Lep.) were recorded.

The foraging dynamics of the species and their change in numbers in the frame of available resources were investigated with special reference to phenological patterns of the food plants. The 13 species visited altogether 37 plants from 12 families. The analysis of the food resources showed clear preferences of the *Bombus* and *Psithyrus* species for different flower types, depending mainly on the length of the tongue in relation to the length of the corolla tube.

10-170

SCARAB DUNG BEETLES ASSOCIATED WITH THREE SPECIES OF WILD MAMMALS IN THE QUEEN ELIZABETH NATIONAL PARK (UGANDA)

G.M. Carpaneto, M. Ieradi

Dipartimento di Biologia, Terza Università di Roma

A two-month sampling of dung beetles has been carried out in a savannah ecosystem of the Queen Elizabeth National Park (Uganda) by gathering droppings produced by three wild mammals: African Buffalo (*Syncerus caffer*), Hippopotamus (*Hippopotamus amphibius*) and Warthog (*Phacochoerus africanus*). Two kinds of habitats were considered: (1) dry soil savannah (in Mweya peninsula), and (2) muddy soil savannah (on the shore of Lake Edward).

A number of 2817 scarab beetles has been collected on the whole (71.8% Scarabaeidae, 28.1% Aphodiidae); the first family is more abundant in warthog (49.3%), the second one in buffalo dung (46.3%). Buffalo and warthog dung show both a higher value of beetle species diversity and biomass, respect than hippopotamus dung. As to different kinds of habitat, a lower value of scarab beetle biomass was calculated on muddy soils.

There is not evidence that any of the 26 species of Scarabaeidae will solely occur in one dung types, nevertheless many of them show a clear preference for one kind of food source. Two trophic groups were defined: (1) a group of thirteen species which prefer warthog, and (2) a group of nine species which prefer buffalo dung; none shows a significant preference for hippo dung.

The adults of two K-selected species belonging to two closely related genera of "rollers" (*Sisyphus crispatus* and *Neosisyphus spinipes*) show a phenological displacement. Indeed, the maximum values of density of these two species have been observed at a distance of one month each from the other.

10-171

DIVERSITY AND DYNAMICS OF A DUNG BEETLE COMMUNITY FROM A TYRRHENIAN COASTAL ECOSYSTEM

G. M. Carpaneto, G. Pontuale¹

Dipartimento di Biologia, Terza Università di Roma - 1 Istituto Superiore di Sanità, Roma

The species composition and population dynamics of three different dung beetle communities were investigated in a protected area along the Tyrrhenian coast near Rome (Castelporziano). Dung beetles associated with wild board (*Sus scrofa* L.) have been examined during one year; those with horse and cow dung during two years.

The study area is a grassland surrounded by deciduous forest and evergreen scrub. A monthly sampling of each kind of dung was carried out to assess the seasonal change in both species composition and abundance of the beetle community. The results are discussed in relation with macro- and microclimatic data from the area and a comparison made with other ecological studies in Tyrrhenian coastal zones.

Out of the 51 species collected, 8 were exclusively found in cow, 2 in horse and 1 in wild board dung. According to Shannon-Wiener Index, April shows the highest peak of species diversity in both cow and wild board dung, and May in horse dung. The lowest value was observed in December-February. Concerning the seasonal succession of species and their relative abundance in the pasture, the highest value is in May and the lowest in December.

In the second year's sampling, results show a substantial stability of the community and the few variations may be explained by microclimate difference.

10-172

THE STRUCTURE OF THE ECOTONAL COMPLEXES
OF CARABID BEETLES (COLEOPTERA, CARABIDAE)

Victor GURIN

Institute of Zoology, Academy of Sciences of
Belarus, Skoryna 27, 220072, Minsk, Belarus

The ecotonal complexes of carabid beetles have
been studied in four different ecotones on the
territory of the Berezinsky biosphere reserve
by means of pitfall trapping.

It was found that the ecotonal complex may
include four groups of carabid beetles:

- 1, 2 - species that live mainly in one of the
bordering ecosystems;
- 3 - species that are common for both
ecosystems;
- 4 - species that are found mainly in
ecotone.

The percentage ratio of these groups is not
constant. It differs in various types of
ecotones. In some ecotones one or two of those
groups may be absent.

10-174

COMPARATIVE INVESTIGATIONS ON CARABID FAUNA IN A
INTENSIVELY AND A EXTENSIVELY CULTIVATED VINEYARD
K. Epperlein, R. Schwalbe

Institut für Pflanzenzüchtung und Pflanzenschutz
Martin-Luther-Universität Halle-Wittenberg
Halle/Saale, Germany

1994 in a 0,5ha vineyard which hat been fallow for 2
years was ecological cultivation was established. During
the time of establishment the effects on vegetation and
fauna were investigated and compared with a intensively
used and treated vineyard. Major attention was payed to
the ground beetles (Coleoptera: Carabidae). 12 pitfall
traps were emptied all the year round on both acreages.
On the vineyard under ecological cultivation 43 species
occcured of which 9 were endangered and one species,
(*Acupalpus interstitialis* Reitter) first time recorded
for Germany. The intensively used vineyard was habitat
to only 16 species.

10-173

REPRODUCTIVE AND K-FACTOR LIFE TABLES OF THE
STRAWBERRY BLOSSOM WEEVIL, *ANTHONOMUS RUBI*
(HERBST) (COLEOPTERA: CURCULIONIDAE)

S.Ya. Popov
Department of Entomology, Moscow Agricultural Academy, Moscow,
Russia

Our studies in the population ecology of the strawberry blossom weevil
(SBW) have been developcd since 1977. 3 reproductive and
20 k-factor life tables of natural populations of SBW on strawberry
were constructed. It was found that the rate of development and the rate
of oviposition was greatest at 27°C, but fecundity - at 16°C. The net
reproduction rate (R_0) at 16, 20 and 27°C was 22,2, 19,4 and 11,4
respectively. The approximate intrinsic rate of increase (r_m^*) at optimal
thermal conditions (16 and 20°C) was 0,08-0,09 per day. Its value
depended greatly on mortality of individuals. In general, survival of
males was greater than females.

In 85 % cases females put only one egg in a flower bud, in 13,5 % cases
they put two eggs and in 1,5 % cases - three-five eggs in a bud. Some
females did not cut buds with eggs and the offspring was doomed to be
dead. There was some correlation between the number of double eggs
and population density ($r=0,634$, $n=17$).

K-factor life table studies showed that survival from egg to adult
emergence was very high (about 40-60 %), but total mortality from egg
to new egg was typical for insects (95-99,5 %). At the egg stage the
interruption of stereotype of females behaviour during oviposition was
the main mortality factor ($k=0,08-0,09$). The larval and pupal mortality
was mainly caused by parasitoids *Bracon intercessor* Nees, *Pteromahus*
(*H.*) *grandis* Walker, *Trichomahus* sp., *Lestodiplosis* sp. and sometimes
by invasion of bacteria *Pseudomonas* sp. We could not find proven
method for predicting the success of natural agents. The recognition of
the key factor (or factors) in autumn and winter was also an open
question.

The reproductive strategy of SBW will be discussed.

10-175

RELATIONSHIP BETWEEN NUTRITIONAL AND
THERMAL REQUIREMENTS OF *Trichogramma*
pretiosum RILEY, 1879, REARED ON DIFFERENT
HOSTS.

PÁDUA, L. E. M.¹; PARRA, J. R. P.² and ROSSI, M. M.³

Address:

¹ Departamento de Fitotecnia, CCA/UFPI, Campus da Socopo, 64049-
550, Teresina, PI, Brasil. ² Departamento de Entomologia, ESALQ/USP,
Caixa Postal 9, 13418-900, Piracicaba, SP, Brasil. ³ Bolsista Recém-
Doutor CNPQ-ESALQ/USP, Caixa Postal 9, 13418-900, Piracicaba, SP,
Brasil.

The biology of *Trichogramma pretiosum* was studied
on *Anagasta kuehniella*, *Corcyra cephalonica* and *Sitotroga*
cerealella at six constant temperatures (18, 20, 22, 25, 30 and
32°C), in order to determine the parasitoid thermal
requirements when reared on these hosts. The thermal
requiriments was calculated based on hyperbole method. The
life cycle of this parasitoid increased as the temperature
decrease in all hosts tested. The life cycle of *T. pretiosum* was
shorter when reared on *A. kuehniella* than on *C. cephalonica*
and *S. cerealella*. The thermal constant was higher when the
parasitoid was reared on *C. cephalonica* (159,77 day-degree)
and *S. cerealella* (156,26 day-degree) than on *A. kueniella*
(129,39 day-degree). The lower temperature threshold was
10.05; 10.51 and 11.77°C when the parasitoid was reared on
C. cephalonica, *S. cerealella* and *A. kueniella*, respectively.

10-176

EFFECT OF LINEAR FURANOCOUMARINS AND ULTRAVIOLET LIGHT ON FEEDING BEHAVIOR OF *SPODOPTERA EXIGUA* (HUBNER) LARVAE

M. Berdegué and J.T. Trumble

Department of Entomology, University of California, Riverside, CA, 92521.

Furanocoumarins (benz-2-pyrone compounds with a furan ring) are photoactive secondary substances; restricted in distribution among plants and appear to play a defensive role against herbivores. These compounds, like other allomones, evoke widely varying responses in different species of insects. Several reports indicate that furanocoumarins can act in a defensive role through modification of herbivore behavior.

Spodoptera exigua (Hübner), is an important pest of *Apium graveolens* L. (celery). Studies have shown the toxic effect on *S. exigua* of three linear furanocoumarins (bergapten, xanthotoxin, and psoralen) commonly found in *A. graveolens*. Furthermore, it has been suggested that on *A. graveolens* plants, late instar *S. exigua* larvae may be avoiding photoactivated furanocoumarins present in the more nutritious leaves by feeding within the less nutritious petioles which are exposed to lower ultraviolet light levels. However, there are no available studies documenting the effect of linear furanocoumarins, ultraviolet light (UVA) and their interaction on larval behavior of *S. exigua*.

Low concentrations of psoralen, xanthotoxin, and bergapten commonly present in healthy plants caused avoidance by larvae of *S. exigua* in choice tests with artificial diet. The effect of UVA light on larval feeding behavior and its interaction with furanocoumarins will be discussed.

10-178

STUDY ON ALARM PHEROMONE AND SEX PHEROMONE OF APHIDS

Zhang Zhong-ning, Tu Mei-hua, Fang Yu-ling, Xiangyu Jingong, Geng Wen-jun, Lu Yi

Institute of Zoology, Chinese Academy of Sciences, Beijing 100080, China

Aphids are key pest insects in China with about 1500 species. (E)- β -farnesene (EBF) is the main component as aphid alarm pheromone. There were very different amount of EBF in homogeneous of different aphid species, but there was not found EBF in the bodies of *Brevicorye brassicae*. The primary rhinarium of the antenna of *Myzus persicae* was the main part for response to EBF. EBF possesses coordination effect with insecticide, it may reduce insecticide dose in the plant protection. EBF is stable enough to light, 55°C temperature, air bubble and in the mixture with insecticide, the half life were 13.3, 50.3, 21.3 days and 153 weeks respectively.

Nepetalactol and nepetalactone were two main components of sex pheromone in some species of Aphids. The attractiveness of the ratio 1:1 and 2:1 mixture were better in field traps to *Myzus persicae*. Some other species of aphids (including wheat ones) were also attracted and the attractiveness to some species of parasitoids was also observed.

10-177

LIRIOMYZA TRIFOLII (BURGESS) (DIPTERA: AGROMYZIDAE) PROBING, OVIPOSITION, DEVELOPMENT AND MORTALITY RATES AS AFFECTED BY COMMERCIAL COS LETTUCE (*LACTUCA SATIVA* L.) CULTIVARS

G. S. Nuessly, R. T. Nagata

Department of Entomology and Nematology, Department of Horticultural Sciences, University of Florida, IFAS, Everglades Research & Education Center, Belle Glade, FL USA

The cultivar 'Tall Guzmaine' (TG) was preferred by *L. trifolii* adult females in choice tests 2.2:1 to 5.5:1 over other cultivars based on stipple counts (puncture wounds in the leaf surface). Preference for TG was maintained in no-choice tests. More probing occurred on all cultivars on the most recently fully expanded leaves in the middle of the plants than on leaves toward the bottom or top of the plants. Adult longevity and oviposition rates were greater on TG than on other cultivars in no-choice exposures. Development rates for egg through larval, prepupal through pupal and egg through pupal development periods were affected by cultivar. Females (342.3 ± 0.8 h) took slightly longer to develop from egg to adult than did males (339.5 ± 0.8 h). While cultivar did not affect egg and larval mortality rates, prepupal plus pupal mortality on 'Parris Island Cos' (24.3%) was 2.5 times greater than rates observed on other cultivars. Differences among cultivars in all the tested parameters appears to closely follow the pedigrees of the tested cultivars. Probing preferences, shorter development and lower mortality rates for *L. trifolii* on cos lettuce were associated with 'Paris White' in the cultivar's pedigree.

10-179

ISOZYME ANALYSIS OF ESTERASE, ALKALINE PHOSPHATASE, LEUCINEAMINOPEPTIDASE, ALCOHOL AND OCTANOL DEHYDROGENASE DURING LARVAL DEVELOPMENT OF *Anastrepha fraterculus* (DIPTERA: TEPHRITIDAE).

J.C. Nascimento, M. Taufer, A.K. Oliveira, I.B.M. Da Cruz

Departamento de Genética, Universidade Federal do Rio Grande do Sul, Brasil

The fruit fly *Anastrepha fraterculus* is a major pest of native and exotic tree fruits in Brasil. Ecological, ethological and evolutionary aspects has been well studied. However, developmental biologic aspects studies are still incipient. In this work, we characterized the isoenzyme patterns of esterase (EST), Alkaline phosphatase (APH), Leucinoaminopeptidase (LAP), Alcohol and octanol dehydrogenases (ADH, ODH) in larval development in polyacrilamide gel. The samples analysed were rearing under laboratory conditions (14L:10D, 25°C, 70%RH) in papaya fruit. The results showed a dynamic variation of isoenzymes expression. We observed five EST eletromorphs, four APH eletromorphs and 12 eletromorphs to ADH and ODH dehydrogenases. Probably studies in *A. fraterculus* geographic populations using isoenzymes related with insect development can help to elucidated the speciation question because this species is considered as complex of criptical species that explore wide range of hosts in several environmental conditions. Grants and Fellowships: CNPq, ABPM.

10-180

Drone Flight Time of Tropical Honeybees and the Influence of Light on the Drone Flight Behaviour

by

Makhdzir Mardan and Noor Azhar Zainal

Plant Protection Department, Faculty of Bioresources and Environment
Universiti Pertanian Malaysia, Serdang 43400, Selangor D. E., MALAYSIA

Abstract

The time occurrence of drone flight activity of the AsianTropical honeybees (*Apis cerana*, *Apis andreniformis* and *Apis dorsata*) colonies were monitored at several locations in Malaysia and Indonesia to investigate the factors influencing drone flight or mating flight activity

There were distinct differences on the occurrence of peak times and duration span of drone flight activities between the honeybee species at different locations. The drone flight activity is very much linked to the local azimuth. There is also the influence of light as the experimental on-off manipulation of a fluorescent light bulb (one-sided illumination) on the colony of the open-nesting *Apis dorsata* suppressed drone flight activity.

10-182

STUDIES ON THE POPULATION DYNAMICS OF *CHORTHIPPUS BUBIUS* (ZUBOVSKY)

C. Z. Liu, G. H. Feng

Department of Plant Protection, Department of Pratacultural Engineering, Gansu Agricultural University, Lanzhou, China

Based on data from systematic investigation on the alpine prairie, Xiahe County, Gansu Province, the simulation equation of the growth and decline of numbers of *Chorthippus dubius* (Zubovsky) was established. The spatial pattern and dynamics of the population were analysed by calculating five indices of aggregation, parameters of Taylor model and Iwao model. The results showed that the spatial pattern of 1-2 instars belonged to an aggregated distribution, but that of 3-5 instars and adults became random or uniform. The theoretical formula for determination of the sampling number was given. The sequential sampling was analysed. It is better to combine Iwao's sequential sampling method with Kuno's one.

By using the average density, the index of patchiness, and the frequency of plot existing insects, the population dynamic of *Chorthippus dubius* was studied by the method of fuzzy cluster analysis and then divided into the initial stage of the hatching and last stage of the adults, the low instar stage of the nymphs, the mixed stage of the nymphs and adults, the adult stage.

COMMUNITY ORGANISATION AND DIVERSITY PATTERNS OF THE GALL-FORMER COMMUNITY ON COMMON REED

L. De Bruyn, University of Antwerp (RUCA), Department of Biology, Antwerpen, Belgium, debruyn@ruca.ua.ac.be

Internally feeding herbivore insects are strongly dependent on the growth characteristics of their host plants. Moreover, insect induced plant galls usually form a base for a complex community of parasitoids and predators. Therefore, they are ideal objects to study the mechanisms of community organisation along several trophic levels. The flies of the genus *Lipara* Meigen (Diptera: Chloropidae) are strict monophagous parasites of the common reed, *Phragmites australis*, upon which they induce typical cigar- or spike-like galls. Dependant on the growing conditions, a reedbed can comprise shoots from a wide diameter range. Previous results showed that the diameter of a particular reedshoot is very important for the success of the *Lipara* herbivores. When *Lipara* galls are opened, several larvae turn out to be parasitized by Hymenoptera, while other are killed by predators.

To analyse the interactions between the species of the different levels in the community, a field experiment was carried out. During winter, when all species are in diapause, galls were collected at different localities in Belgium and the Netherlands by means of 0.25 m² quadrat samples. The galls were dissected and the inhabiting species (*Lipara*, parasitoids, predators) were identified. Additionally we measured soil and vegetation characteristics and reedshoot diameter and density. Community structure, species diversity and interaction between the species were analysed with structural equation modelling.

Both the number and the diversity (e.g. Shannon-Wiener) strongly depend on the reedshoot diameter distribution and soil moisture of a reedbed. The mortality due to parasitoids and predators is highest for *L. rufitarsis* and *L. lucens*. However, in many localities, parasitoids are completely absent. The different parasitoids and predators show a specific host spectrum. Parasitoid and predator diversity increase when the overall *Lipara* gall density increase and reedshoots are thinner. Both are independent of *Lipara* species composition and diversity.

10-183

INTERACTION BETWEEN SEX RATIO AND POPULATION DYNAMICS IN SAWFLIES (HYMENOPTERA: SYMPHYTA) K. Otsuka

Institute for Medical and Dental Engineering, Tokyo Medical and Dental University, Tokyo, Japan

A study of a tenthredinid sawfly, *Strongylogaster osmundae*, revealed that some females deposited eggs without mating first in the field. On the other hand, mated females deposited more female than male eggs. This behavior agreed qualitatively with an ESS (evolutionarily stable strategy) model. Mated females produced offspring with a more female-biased sex ratio than predicted by the model when the population density and proportion of mated females were high. This seemed to be caused by low phenotypic plasticity.

Based on the above observations, a simulation model of sex ratio and population dynamics was devised. It was assumed that sex ratio genes on one locus determine the sex ratio of offspring of a mated female, and that the proportion of mated females is high when the population density is high.

This model suggested that:

- 1) The sawfly (haplo-diploid) population sex ratio becomes female-biased than 1:1 when a population outbreak occurs.
- 2) The probability of extinction is lower and probability of a population outbreak is higher in a haplo-diploid than in a diploid population.

10-184

ON INTERFERENCE BETWEEN INSECT PARASITIDS IN A PATCHY ENVIRONMENT

Marcel E. Visser, T. Hefin Jones¹ & Gerard Driessen²Netherlands Institute of Ecology, Heteren, The Netherlands, ¹ NERC Centre for Population Biology, Imperial College, Ascot, UK, and ² Institute of Evolutionary and Ecological Sciences, Leiden University, Leiden, The Netherlands.

Interference between insect parasitoids can be viewed as the consequence of changes in behaviour in response to increasing levels of intra-specific competition. It can serve as a stepping stone from individual behaviour to population dynamics. We present an expression for the overall search rate for a habitat where hosts have a patchy distribution and where there is intra-generation travelling between patches by the parasitoids. We describe two well-known forms of interference: mutual interference and pseudo-interference, and also a more recently proposed form, indirect mutual interference. This type of interference is caused by changes in behaviour at different parasitoid densities that affect the time budgets of the parasitoids or the distribution of parasitoid effort over patches. We present some general methods to distinguish between the different forms of interference and discuss the difficulties in applying these methods to multi-patch laboratory experiments and field data. Next, these methods are applied to a multi-patch experiment using the parasitoid *Trybliographa rapae*. In these experiments, either 1, 5, 10, 15 or 20 parasitoids are released in an arena with 5 patches. Hosts are either distributed evenly (12 each) or aggregated (2, 4, 8, 16 & 32) over these patches. All arrivals and departures are registered over the 8 hours the experiments ran. Overall search rate decreased with parasitoid density for both host distributions. With an increasing number of parasitoids in the arena, a linear increase in the mean and a decrease in the coefficient of variation (CV) of the distribution of patch times over patches was found. Thus, pseudo-interference and indirect mutual interference plays a role.

10-186

STUDIES ON THE ECOLOGY AND BEHAVIOUR OF *Plutella xylostella* (L.) (LEPIDOPTERA: PLUTELLIDAE). MORTALITY AND DISPERSION.

Pedro J. Salinas

Universidad de Los Andes. Mérida. Venezuela.

Plutella xylostella is an important pest of cruciferous crops. Experiments were carried out in controlled environment rooms (20±1°C constant temp., 16 h/day light, rel. hum. not controlled was 44-52% by day, 14% higher at night) to determine development, mortality and dispersion of populations of *P. xylostella* in conditions where all external factors were similar except the initial density of the eggs or larvae and the quality of the host plant. Cabbage plants grown in greenhouse were used. Leaves were from the plant medium region neither senescent nor part grown. The area of the leaves varied from 10 to more than 300 cm². Small transparent plastic cages were used to confine females to selected places where to lay eggs, during one day. Eggs laid anywhere except the upper surface of the leaves were removed. Eggs density varied in different experiments: 1 to 641 per plant, 1 to more than 400 per leaf, 0.5 to 130 per 100 cm²; some were isolated, others in pairs close or separated, or in groups of 10; 35-50; 110-120 per leaf (one or four leaves with eggs per plant). The plant age and the leaves condition (tenderness/toughness) varied. Egg mortality was very low (around 5%), probably due to infertility. Most of the mortality occurred in early stages of the larvae (first and second instars) especially during the first week of life when start to disperse; probably need more space per initial larvae to burrow galleries. Recently hatched larvae disturbed each other and some fell onto the ground or did not established feeding place and die. There was no pupal mortality. There is intra-specific competition of the young larvae at high density (density dependent). The later larval stages did not suffer notable increases in mortality. Intra-specific competition does not affect pupation in terms of survival of adult stages. In tender leaves the distance from egg to first feeding place was 9.5 ± 2.03 mm in eggs laid isolated and 17.6 ± 1.07 mm in eggs laid in groups. The overall pattern of dispersion is affected by the initial density of the larvae and the mortality of the early instars. Higher the density: higher the mutual disturbance and higher the early instar mortality, and the larvae take shorter time to get evenly distributed over the leaves. At lower densities mortality is lower and the larvae (especially early instars) remain longer in their original feeding place, maintaining a similar level of aggregation for longer time. As larvae grow bigger, disperse more evenly throughout the different leaves of the plant. There is little movement from plant to plant. The larvae tend to remain in that even distribution up to the end of the larval stage when tend to aggregate before pupation. This is also shown by aggregation indices.

10-185

COMPARATIVE STUDY OF BEHAVIOR IN ITALIAN AND AFRICANIZED *APIS MELLIFERA* SUBSPECIES : GROOMING AND REMOVAL BEHAVIOR AS AN ELEMENT TO EXPLAIN THE DIFFERENTIAL POPULATION DYNAMICS OF *VARROA JACOBSONI* MITER. VANDAME^{1,2}, M.-E. COLIN¹, G. OTERO-COLINA²¹ Institut National de la Recherche Agronomique, Station de Phytopharmacie, 84143 Avignon, France² Colegio de Postgraduados, Instituto de Fitosanidad, Campus Córdoba, 94500 Córdoba, VER., Mexico

In tropical climate of South Mexico, the africanized *Apis mellifera* honey bee subspecies was found as resistant to *Varroa jacobsoni* parasite, whereas italian honey bee was found as susceptible.

Following the descriptions of Peng (1987), a study of grooming behavior in these subspecies revealed that both types of bees had a high level of auto- and allo-grooming behavior. However, the result of such a behavior staid very poor, since less than 20% of observed mites changed bees and less than 10% failed from bees.

Consequently, the mutilation rate of naturally dead mites was very low, about 15% in africanized colonies, and 10% in italian colonies. A study of removal behavior of infested brood showed that between fifth and seventh day of capping stage, africanized bees removed more than 30% of parasitized brood, while italian bees removed only 10% of parasitized brood. Such a difference could be an important element to explain the differential population dynamics of the mite between resistant and susceptible honey bee colonies.

10-187

COPING WITH COLD: ARE UPLAND POPULATIONS OF THE CRANE FLY *TIPULA MONTANA* CURTIS (DIPTERA: TIPULIDAE) BETTER ADAPTED THAN LOWLAND COUNTERPARTS?R.M. Smith¹ and C.M. Todd²¹ Department of Zoology, University of Aberdeen, Aberdeen, UK. ² British Antarctic Survey, Cambridge, UK.

Tipula montana Curtis is adapted to alpine and boreal biotopes and it is freeze tolerant in the overwintering larval stage (instars 2, 3, 4). Aspects of cold tolerance were compared between a mountain population (1000m a.s.l.) and an atypical population in moorland (400m a.s.l.) to test the hypothesis that adaptation to cold declines in less severe winter environments.

Cold tolerance was assessed in each instar by measuring the concentrations of cryoprotectants (with gas chromatography), lower lethal temperatures, and larval survival at different sub-zero temperatures. The effects of cold stress upon adult fitness were investigated by measuring adult body size, female fecundity, and survival.

10-188

HOW INSECTS DIE: DEMOGRAPHIC TRENDS IN FIELD POPULATIONS

B. A. Hawkins, H. V. Cornell¹

Department of Ecology and Evolutionary Biology, University of California, Irvine, CA USA - ¹ Department of Biology, University of Delaware, Newark, DE USA

Quantitative estimates of mortality for 86 phytophagous species of Coleoptera, Diptera, Lepidoptera and Hymenoptera were extracted from published field life tables and tested for differences associated with the developmental stage and five ecological characteristics of pre-adult herbivores (feeding biology, invasion status, and the successional stage, cultivation status, and latitudinal zone of the habitat). Mortality rates were most strongly associated with the developmental stage and feeding biology of herbivores. The remaining variables showed little or no relationship with mortality. Across all species and life stages, natural enemies kill the most herbivores and competition the least.

10-190

INFLUENCE OF PHYSIOLOGICAL, ENVIRONMENTAL AND GENETIC FACTORS ON LONG DISTANCE FLIGHTS OF *CYDIA POMONELLA* L. (LEPIDOPTERA: TORTRICIDAE) MEASURED BY A FLIGHT MILL

P. Schumacher, D.W. Weber and S. Dorn
Institute of Plant Sciences, Applied Entomology, Swiss Federal Institute of Technology (ETH), Zurich, Switzerland

Cydia pomonella L. (Lepidoptera: Tortricidae) is a global pest of apples. Long distance flights of *C. pomonella* are believed to be important for its colonisation of new habitats, and may also help to maintain genetic variability within the population. In the field, long distance flights up to 11 km have been reported for male codling moths. More knowledge of the factors that influence this behaviour is particularly important for the implementation of the pheromone confusion technique. In this study the flight capacity of *C. pomonella* was measured in the laboratory by using computer linked flight mills. The ability to undertake long flights (defined as continuous flights longer than 5 km) was uniform amongst different populations within northern Switzerland, but significantly reduced for moths of our laboratory colony. We found only small differences between the sexes in the distances that they would fly. The distance flown increased during the first 3 days after emergence (20°C) and then decreased continuously until death (around age 20 days). This decrease was stronger for mated than for virgin moths of both sexes. The ambient temperature was one of the most important environmental factors influencing flight distance. The strongest decrease occurred at 20°C to 15°C. Part of the variation in flight distance was found to be genetically determined. We suggest that there may be a genetic trade-off between flight distance and fecundity.

10-189

THE CONSEQUENCE OF THERMOREGULATION FOR LIFE HISTORY AND POPULATION DYNAMICS OF THE GRASSHOPPER *STENOBOTHRUS LINEATUS* (PANZER) (CAELIFERA: ACRIDIDAE)

J. Samietz, G. Köhler

Institute of Ecology, University of Jena, Germany

Between 1992 and 1995 the population dynamics of *S. lineatus* was investigated on a semi-arid calcareous grassland in Thuringia/Germany. A key factor analysis indicated the time interval between reproduction of the females and hatching of the first instar nymphs as decisive for the observed population dynamics. To analyse the causality of dynamics, the habitat structure, the microclimate and its effects on the species were investigated.

The body temperature of females was recorded in field studies between 1993 and 1995. The results show significant differences between the ambient air temperature and the thoracic temperature of the grasshoppers, depending on the solar radiation energy. Some females of *S. lineatus* achieved differences up to 20 degrees by basking in the sun.

To investigate the consequence of this heat-up for life history, a field experiment to oviposition frequency and pre-oviposition period of *S. lineatus* was conducted. Furthermore, comparative laboratory experiments were conducted by single keeping of *S. lineatus*-couples on standardized conditions of diet, temperature, light and radiation energy.

In the field a mean oviposition frequency of 0.4 pods per day was recorded at an ambient temperature of about 21°C and a radiation energy of 700-900 W/m². In the laboratory at cold light (below 200 W/m²) the same value of oviposition frequency was not achieved until a mean daily air temperature of 35°C. Due to the heat-up, a multiple increase of oviposition frequency could be proved. Thus, at Central European temperate climate the solar radiation energy in the habitat structure and the behaviour of thermoregulation allow the reproduction of the species at all and have a decisive consequence for the population density in the following generation. Furthermore, as an important contribution to life history data and a detailed key factor analysis, the results of the experiments allow to calibrate the oviposition frequency to the actual weather conditions between 1992 and 1995 and to re-estimate the number of laid eggs within four generations of *S. lineatus*.

10-191

SIZE OF EGG CLUSTER, FEMALE SURVIVAL AND LIFE-TIME EGG PRODUCTION, IN THE HERBIVORE BEETLE *GALERICUCELLA SAGITTARIAE* (CHRYSMELIDAE) IN NATAL AND NOVEL HOST PLANT *POTENTILLA PALUSTRIS*.

J. Suhonen

University of Jyväskylä, Department of Biological and Environmental Science, P.O. Box 35, FIN-40351 Jyväskylä, Finland

I conducted a laboratory experiment to investigate several life-history parameters of a herbivore-beetle, *Galericucella sagittariae*, in natal and novel *Potentilla palustris* plants. In the experiment I compared number of egg clusters, number of eggs per cluster, total number of eggs laid per female and adult survival in the two different localities. No significant differences were found between natal and novel plants. However, an inverse relationship between cluster size and female longevity were found. This experiment does not seem to support the generally accepted hypothesis that herbivores are adapted to natal plants but maladapted to colonize novel conspecific plants (deme-formation hypothesis).

10-192

ECOSYSTEM IMMUNITY OF A BIOTIC COMMUNITY AGAINST PEST INSECTS

F. Takahashi

Osaka University of Commerce, Higashi-Osaka, Osaka, Japan

Populations of insect pest sometimes grow up to the high level of economic problem, but usually they are maintained at low level below the economic injury in nature.

Living bodies have a system of immunity against pest invasion, such as macrophages etc. in human body to suppress pest organisms below the level to become illness. In this case, macrophages are selfperpetuating in human body at an expense of blood and body fluid. Analogically crop populations have a defense mechanism in the biotic community against pests by means of natural enemies as like as an immunity in a total system. However, natural enemies, parasites and predators, must be maintained themselves without any support of agroecosystem.

Many years ago I proposed a model 'Reproduction curve with two equilibrium points' to consider the fluctuation of insect population (Takahashi, 1964). The lower equilibrium point in the model can be regarded as a latent period and another higher one as an outbreak level. This model is based on a S-shaped functional response of predator to prey density and is applicable in a biotic community where polyphagous predators predominate.

To keep stable population of natural enemies in the biotic community, it is necessary to maintain their food stability in the fields. In the monophagous predators such as parasitoids, their populations fluctuate in response to prey or host populations sometimes inducing violent fluctuation of pests over the economic injury level. On the other hand, in the case of polyphagous predator, they can find ordinary organisms as alternate foods and keep their population stable even when a pest population, a target food, decreases to low level. This model will be discussed with respect to the diversity of biotic community.

10-194

HETEROGENEITY AND DENSITY DEPENDENCE IN A FIELD STUDY OF A TEPHRITID-PARASITOID INTERACTION

T.H.Jones

NERC Centre for Population Biology, Imperial College at Silwood Park, Ascot, United Kingdom

The spatial distribution of tephritid flies attacking thistle flower heads and the levels of parasitism from the associated parasitoid guilds were studied over a number of years.

Recent developments in population ecology have shown how the effects of spatial heterogeneity of parasitism in a wide variety of discrete-generation host-parasitoid models can be assessed using a simple rule. Specifically, this states that the coefficient of variation squared ($CV^2 = [\text{variance}/\text{mean}^2]$) of the density of searching parasitoids in the vicinity of each host must typically exceed unity for the heterogeneity in parasitism to be a sufficient cause of stability in the interacting populations.

This data set provides a rare opportunity to use the methods of analysis outlined above to seek both temporal, density dependent relationships between average levels of parasitism and host density per generation, and also any spatial patterns of parasitism contributing to stability that may be operating within the same field system.

10-193

REPLICATED, LONG TERM, HOST-PARASITOID POPULATION DYNAMICS

M.B. Bonsall

Department of Biology, Imperial College of Science, Technology & Medicine, University of London, Silwood Park, Ascot, United Kingdom

Replicated, long term population studies provide the foundations against which hypotheses on the mechanisms of regulation can be accepted or refuted. In this study, data from replicated, host-parasitoid laboratory interactions (*Plodia interpunctella* - *Venturia canescens*) are analysed using various methodologies. The study identifies the underlying dynamics and explores the relative roles of density dependent and density independent processes within the interaction.

10-195

INDIRECT EFFECTS IN HOST-PARASITOID ASSEMBLAGES

M.B. Bonsall

Department of Biology, Imperial College of Science, Technology & Medicine, University of London, Silwood Park, Ascot, United Kingdom

Hosts which share a common natural enemy may experience indirect (apparent) competition. Theory predicts that this effect should lead to the elimination of one of the host species. On the other hand, various mechanisms such as density dependent factors, predator switching and temporal refuges, have been suggested as mechanisms promoting coexistence between hosts sharing a common natural enemy.

In this study, apparent competition is explored, both empirically and theoretically, as a factor influencing coexistence in host-parasitoid assemblages.

10-196

MODELLING INSECT NATALITY USING SPLINES FOR POTATO LEAFHOPPER

Zhang Hai Song
Hangzhou Agricultural School, Xi Xi Lu 160,
Zhejiang, 310023, China

We present methodology for analyzing age-specific birth rate, with particular emphasis on describing variability within a cohort of like-aged individuals. We use a model structure appropriate for natality in insects natality and other arthropod species. Our approach separates natality into a baseline rate representative of the effects of the environment for the population and a factor that represents the unique effect of each individual in the cohort. We employ something splines with the penalized likelihood methodology for estimation. We illustrate the methodology by applying it to data on leafhopper egg-laying rates.

10-198

FACTORS AFFECTING THE PERFORMANCE OF PHEROMONE TRAPS FOR *SPODOPTERA LITTORALIS* (BOISD.), *PECTINOPHORA GOSSYPIELLA* (SAUNDERS) AND *EARIAS INSULANA* (BOIS) IN KAFR EL-SHEIKH, EGYPT

G.A. El-Mezayyen¹, M.M. Abou-Khala² and M.S. Tadros³
¹ & ² Agric. Res. Center, Plant Protect. Res. Inst., Dokki, Giza, Egypt
³ Econ. Entomol. Dept., Fac. of Agric., Tanta Univ., Kafr El-Sheikh, Egypt

ABSTRACT

The present work was conducted at the experimental farm of the Agricultural Research Station, Sakha, Kafr El-Sheikh Governorate, Egypt, and lasted for two complete years. Its objectives were to record the populations of three insects infesting cotton "*Gossypium barbadense* (L.) and the Egyptian clover "*Trifolium alexandrinum* (L.). The pheromone trap was the main tool for capturing *S. littoralis* (Boisd.), *Pectinophora gossypiella* (Saunders) and *Earias insulana* (Bois). The effect of 3 main weather factors, max., min. temperature and R.H.% on the density of those pests was also under control. Annual generations for every pest was estimated after the recorded device by Audemard and Milaire (1975) and Iacob (1977). Results indicated the occurrence of 3 peaks per year for *S. littoralis*. Two peaks were recorded for *P. gossypiella* in 1994 and only one in 1993, while three peaks were clear per year for *E. insulana* in either 1993 or 1994. A clear relationship was recorded between numbers of *P. gossypiella* happening in autumn and infestation in the following cotton season and that phenomenon could be used as a prediction. Simple correlation between the 3 tested weather factors and pest catch were recorded, plus the effect of the 3 weather factors and determination of coefficient value. The number of estimated generations was 7/*S. littoralis*, 5/*P. gossypiella* and 5/*E. insulana*.

10-197

INTRODUCTION OF A NEW WHITEFLY TRAP

C. C. Chu, T. J. Henneberry, and A. C. Cohen
USDA-ARS, Western Cotton Research Laboratory,
4135 E. Broadway Rd., Phoenix, AZ
Kai Umeda
University of Arizona Maricopa Coop. Ext.,
4341 E. Broadway, Phoenix, AZ

We designed a adult whitefly trap based on behavior observations that showed: 1) flight response toward light, 2) yellow color attractiveness, and 3) landing behavior on hosts followed by walking to undersides of leaves. Studies to evaluate the efficacy of the trap were conducted in the southwestern irrigated desert crop growing areas of the United States. The traps studies were conducted in five *Bemisia argentifolii* Bellows and Perring chemical control projects on cotton, *Gossypium hirsutum* L. and one chemical control project on cantaloupe *Cucumis melo* L., var. cantalupensis. The 1995 experimental plots were located at USDA-ARS Irrigated Desert Research Station at Brawley, CA and the University of Arizona Maricopa Research Center, Maricopa, AZ. Results showed that the new whitefly trap catch data reflect seasonal dispersal, population variations induced by chemical control, and seasonal population changes on cotton and melon. The numbers caught were comparable to numbers caught with a commercial trap designed for fruitflies using a bait. The new whitefly trap is a non-overloading, non-sticky, no bait trap. The new whitefly trap may be a useful detection, survey and monitoring tool.

AUTOMATED MONITORING OF FREE-FLYING INSECTS USING WINGBEAT WAVEFORMS

A. Moore, J.W. Brown¹
Northern Marianas College, Saipan, Northern Mariana
Islands - ¹ University of Guam, Guam, USA

A computer-based field instrumentation system uses an optical sensor to measure rapid changes in the intensity of light reflected from the wings of individual flying insects. Output from the sensor contains species-specific wingbeat waveforms that are automatically classified using artificial neural networks that have been trained to identify species of interest. The system can monitor many species within a given habitat. Potential applications in the areas of medical entomology and integrated pest management are discussed.

10-200

SIMULATION OF THE WHITEFLY-ENCARSIA FORMOSA INTERACTION, BASED ON FORAGING BEHAVIOUR OF INDIVIDUAL PARASITOIDS

H.J.W. van Roermund, J.C. van Lenteren

Department of Entomology, C.T. de Wit Graduate School Production Ecology, Wageningen Agricultural University, The Netherlands

Greenhouse and sweet potato whitefly (*Trialeurodes vaporariorum* and *Bemisia tabaci*) are very common, highly polyphagous pest insects all over the world. Biological control of greenhouse whitefly with the parasitoid *Encarsia formosa* has been applied with great commercial success during the past 20 years, while natural enemies for sweet potato whitefly are now evaluated. Modelling has always played an important role in the process of selecting and improving the efficacy of releases of natural enemies, but often biologically unrealistic simplifications were part of these models which strongly limited their predictive value.

We have developed a model which is unique in that it is individual based and simulates the local searching and parasitization behaviour of individual parasitoids in a whitefly-infested crop. The model includes stochasticity and spatial structure based on location coordinates of plants and leaves. This model comprises several submodels for (a) the parasitoid's foraging behaviour, (b) the whitefly and parasitoid population development, (c) the spatial distribution of whitefly and parasitoid within and between plants in the crop, and for (d) leaf production. With the model we can simulate temporal and spatial dynamics of pest and natural enemy. The model will allow us (1) to explain why the parasitoid can control whiteflies on some crops and not on others in large commercial greenhouses, (2) to improve introduction schemes of parasitoids for crops where control was difficult, and (3) to predict effects of changes in cropping practices (e.g. greenhouse climate, choice of cultivars) on the reliability of biological control, and finally (4) to develop criteria for the selection of natural enemies.

10-202

DETERMINISTIC AND STOCHASTIC MODELS OF THE SHEEP BLOWFLY, *LUCILIA SERICATA*

A. FENTON & R. WALL

School of Biological Sciences, University of Bristol, Bristol, BS8 1UG, U.K.

Deterministic and stochastic simulation models have been constructed to predict the seasonal pattern of abundance of the ectoparasitic blowfly, *Lucilia sericata* in sheep pastures. These models use empirically derived relationships between temperature and development rate. The number of day degrees accumulated each day by a cohort is calculated from the daily temperature pattern and the base temperature threshold for that stage. The stochastic model uses a Monte-Carlo simulation technique to assign random development rates to each life-cycle stage generated from a Weibull distribution fitted to observed variation in development rate for each stage. Sensitivity analysis has been carried out on the life history parameters in the models in order to determine the importance of the factors affecting the dynamics of the sheep-blowfly system. The results of this work and extension of the models to include farm management factors will be discussed.

10-201

MODELS OF STOCHASTIC DEVELOPMENT IN INSECT POPULATIONSG. Di Cola, G. Gilioli, A. Cossu¹

Dipartimento di Matematica, Università degli Studi di Parma, Italy - 1 Servizio Agrometeorologico Regionale, Sassari, Italy

Stochastic simulation models of single species insect population dynamics are proposed as basic components in pest prediction, management and decision making systems. The models describe the development process of an age-structured population taking into account recruitment, death, environmental and biological variability.

In these models the insect development process, as function of temperature history, is represented by a Brownian motion process with drift, described by a stochastic differential equation in terms of thermal units and other environmental and biological parameters. Random fluctuations due to the variable environment are introduced as stochastic element in the death rate. Since environmental changes are due to many factors, they are approximated with a stochastic differential equation describing the mortality in the population.

The numerical simulation of these processes is performed by means of the fractional step method in which, for every small time step, the random walk principle is used to model the diffusion term (related to the biological variability) combined with other development, recruitment and death mechanisms. At each time step, according to the position of individuals, represented by particle with mass (i.e. computational elements), the developmental level increases, in relation to the drift, of a certain quantity modified by an amount drawn from a continuous probability distribution. These processes are combined with the mortality which is modelled by destruction of computational elements with a given probability depending on death rate. The recruitment is described as an inward flux and leads to the creation of new computational elements on the boundary.

As a case study numerical simulation of *Bactrocera oleae* (Gmel.) populations development in olive groves has been performed. The results are compared and discussed.

10-203

GENSECT - A GENERIC APPROACH TO CONSTRUCTING POPULATION MODELSG.F. Maywald, R.W. Sutherst, S. M. Richardson and M.P. Zalucki
Co-operative Research Centre for Tropical Pest Management, Gehrman Labs, University of Queensland, Brisbane 4072

Many biologists would like to use population models, either to test hypotheses, or to design management strategies. However, the construction of models is beyond the resources of most ecologists without access to a computer programmer. GENSECT provides a research, management and teaching tool that can be used to construct a model of any species without the need for programming.

A major consideration in the design of GENSECT was the provision of a user-friendly interface to make the process of constructing a model easy and enjoyable, with concepts being presented in language familiar to biologists. Different lifecycles are assembled from a 'toolbox' of components by attaching properties like development or survival rates to lifestage objects such as eggs, larvae or plant growth stages. Other components, such as microclimate models or data file readers, are also available as modules, and can be easily coupled to the lifecycle. All internal model variables are available for output as graphs or tables, thus simplifying the construction and error-checking of a new model. Models of different species can be saved as files, which will serve as an important means of summarising and exchanging information about a species' population dynamics. After the model is constructed, GENSECT provides a user-friendly environment in which to run the model, and display selected results.

10-204

CONSEQUENCES OF OBLIGATE KILLING ON THE POPULATION DYNAMICS OF ODNATES AND THEIR MOSQUITO PREY IN TROPICAL TREE HOLES

O.M. Fincke and S. Yanoviak, Department of Zoology, University of Oklahoma, Norman, OK, USA

Water-filled tree holes in the neotropics are a poorly known, but important habitat for a diversity of aquatic macrofauna. In a seasonal Panamanian forest, the larvae of four odonate species are top predators in this unique community. Experiments with *Megaloprepus coerulatus*, a giant damselfly, revealed that larvae kill conspecifics even when well-fed. Under field conditions where prey are scarce, cannibalism and intraguild predation reduces predator density to only 1-2 larvae/liter. Such regulation permits maximal larval growth, increasing the chance that the surviving larvae emerge before the habitat dries out seasonally. Given that the odonates reduce their own numbers to such low levels, what, if any, effect does this guild of predators have on the populations of tree hole mosquitos, their most ubiquitous prey?

In a field experiment using 0.4 l artificial holes seeded with a natural level of detritus, odonates reduced both the total number of mosquito larvae and those surviving to pupation, relative to controls. With high initial nutrient input (a small fruit), the total number of mosquito larvae did not differ between controls and holes containing an odonate predator. Surprisingly, in the treatment with *M. coerulatus*, the number of mosquito larvae actually increased, suggesting that this predator may chemically attract ovipositing mosquitos. Nevertheless, in all predator treatments, the number of mosquitos surviving to pupation was significantly reduced relative to controls. This result is explained by the finding that odonates preferentially ate the largest mosquito larvae. Our work suggests that the ultimate size as well as the behavior of the prey species determine the impact tree hole odonates have on these sylvan mosquitos.

LOCAL DYNAMICS OF TROPHIC INTERACTIONS IN ACARINE SYSTEMS

G. Buffoni, G. Di Cola¹, & J. Baumgärtner²

ENEA CREA, La Spezia, Italy - 1 Dipartimento di Matematica, Università di Parma, Parma, Italy - 2 Agricultural Bureau of the Grisons, Chur, Switzerland

A lumped parameter model representing the dynamics of interacting species is presented: the model is described by a system of O.D.E. in terms of biomass with few observable parameters, with the aim of reducing the complexity of the system and of supporting the practical use.

Methods are proposed for estimating demographic and physiological parameters related to birth, growth and death processes as well as to food consumption and conversion. For this purpose numerical simulations with single-species age-structured models have been carried out.

The dynamics of the system is characterized by the growth function of the prey, the functional response of the predator, and death functions for both populations; these functions depend on both ecophysiological and behavioural parameters.

Basic model properties are studied with particular reference to functional response functions. The model is used to study the dynamics of acarine systems, relevant to poultry houses and protected crops.

EVOLUTION OF PATERNAL BROODING IN THE GIANT WATER BUGS
(HETEROPTERA: BELOSTOMATIDAE)

R.L. Smith

Department of Entomology, University of Arizona, Tucson, AZ, USA

Unilateral post-zygotic paternal care is extremely rare among animals. The giant water bug family Belostomatidae contains most of the arthropod species known to exhibit this unusual behavior. In the subfamily Lethocerinae, males brood eggs laid on emergent vegetation. Brooding in this group involves watering eggs, shading them, and defending them against predation. In the subfamily Belostomatinae, males employ a variety of behavior patterns to aerate eggs attached to their backs by their mates. Brooding is obligatory in all belostomatid species studied, unattended eggs invariably die if left in open air or submersed. This paper explores the biology, phylogeny, and fossil record of the Belostomatidae and related taxa in an attempt to discern the selection forces, constraints, and the sequence of historical events responsible for the evolution of this unusual behavior and its subsequent diversification. Selection for large bug size, in order to take advantage of vertebrate prey, together with the dual phylogenetic constraints of Dyar's Law and the apparent inability of heteropterans to add molts, coupled egg size to body size. Thus selection for large bugs also produced large eggs--too large to develop unattended submersed in water. A past history of eggs being laid in water left these larger eggs lacking the necessary adaptations to survive desiccation when laid unattended in open air. Consequently, large eggs created selection for an innovation to lift egg-size limitations on imago size. Ergo, emergent brooding evolved. The initial costs of emergent brooding were minimal for males who required less food than females, possessed a perfected anti-cuckoldry mechanism, and who were able to obtain multiple mates and brood multiple clutches of eggs. Females in contrast, would have sacrificed substantial future fitness in order to brood eggs and were therefore selected to abandon. Transitions from non-brooding to emergent-brooding and back-brooding are inferred under different assumptions about the behavior of members of the enigmatic genus *Horvathinia*. The evolution of back-brooding was followed by an adaptive radiation. Water bugs in the fossil genus *Mesobelostomum* from the Upper Jurassic probably brooded their eggs more than 150 million years before present. Giant water bug brooding, although complex as expressed in extant species, may have represented a modest innovation at the time of its origin. However, this behavioral innovation lifted constraints, and thus permitted the evolution of larger bugs able to prey on larger aquatic vertebrates, shifting the lineage to new adaptive peaks. Although existing general theory on parental care could not have predicted brooding in the Belostomatidae, much of the theory on unilateral postzygotic paternal care, fits giant water bugs very well. The term "ancillary selection" may usefully distinguish natural selection which produces characters supportive of primary traits. Brooding in the Belostomatidae is deemed to be a product of ancillary selection which supports primary selection for large bug size to facilitate the use of vertebrate prey.

11-003

EVOLUTION OF SECRETION-GROOMING AND
RESPIRATORY HAIR STRUCTURES IN NEPOMORPHA

D. Kovac

Forschungsinstitut Senckenberg, Frankfurt a. M., Germany

Some water bugs from time to time crawl onto land to spread the secretion of their metathoracic scent glands over their water-repellent pubescence („secretion-grooming“). The pubescence is enclosed by an air sheath when submerged and has a respiratory or hydrostatic function. Experimental prevention of secretion-grooming leads to the loss of the respiratory bubble and a significant increase in mortality. The antimicrobial secretion probably keeps the pubescence free of bacterial contamination and thus hydrophobous and functional.

The secretion-grooming behaviour can be released experimentally by an increase in water temperature or light intensity. This method was used for a comparative study of the secretion-grooming patterns and to test, whether secretion-grooming occurs in all families of Nepomorpha. In all, 45 species (28 genera) from Europe, Central America, Southeast Asia, Australia and New Zealand were studied.

It was found that the occurrence of secretion-grooming is correlated with the architecture of the hydrofuge hairs and their presence or absence, respectively. Secretion-grooming with different grooming patterns occurred in five out of nine families: Corixidae, Naucoridae, Notonectidae, Pleidae and Helotrephidae. A model is presented on how secretion-grooming may have evolved in Nepomorpha.

11-001

THE EVOLUTION OF MATING SYSTEMS AND SEXUAL
DIMORPHISM IN WATER STRIDERS (HETEROPTERA,
GERRIDAE)

N. Møller Andersen

Zoological Museum, University of Copenhagen, Denmark

Water striders are conspicuously adapted for life on the water surface and their two-dimensional habitats make them ideal objects for behavioral studies. Matings in water striders can be divided into two distinct types. In type I matings, males search actively for mates and when females are encountered, males initiate matings by simply lunging at females, without prior courtship. Typically, females struggle vigorously before allowing intromission. On the other hand, males usually exhibit post-copulatory mate guarding. In type II matings, males are typically territorial, defending suitable oviposition sites, and "court" females by producing surface ripple signals.

Sexual dimorphism is usually very pronounced in water striders. Several authors have proposed that, given sexual conflicts over mating, male and female genitalia and other structures may be involved in a coevolutionary arms race. This hypothesis predicts that males should evolve structures to cope with female resistance and that females should evolve structures to resist male harassment and gain increased control over matings.

So far, studies of insect mating systems and sexual selection have chiefly been focused on single species or on comparisons among species without attention to their phylogenetic relationships. However, phylogenetic data can contribute significantly to studies of insect ecology and behavior by permitting inferences about the evolutionary history of traits. Here, this approach is applied to the monophyletic group Gerridae, focusing on the evolution of sexual dimorphism in relation to mating systems and the coevolution of male clasping devices and female antilasper devices.

11-004

AQUARIUS REMIGOIDES: A NEWLY-DESCRIBED, LARGE AND ABUNDANT WATER STRIDER FROM THE SOUTHEASTERN UNITED STATES.

D. J. Fairbairn and S. L. Gallant
Department of Biology, Concordia University, Montreal, Canada

The taxonomic status of the common, stream-dwelling water strider, *Aquarius remigis* (Say) (Hemiptera:Gerridae) has been poorly understood. This species occurs throughout temperate and subtropical North America, and shows strong genetic and morphological variation across this broad geographic range. We present evidence from genetic, morphometric and breeding studies that populations previously identified as *A. remigis* in the southeastern USA constitute a new and separate species, *A. remigoides* (Gallant and Fairbairn). An analysis of genetic variation at 13 allozyme loci in 63 populations from across North America reveals significant genetic differentiation of populations in this region. Detailed analysis of a broad transect containing 43 populations from Georgia to Quebec reveals a narrow transition (hybrid) zone, with a genetic distance of 0.30 between the two species. UPGMA cluster analysis based on genetic distances among 11 species in the genera *Aquarius*, *Gerris*, and *Limnoporus*, reveals a greater genetic distance between *A. remigoides* and *A. remigis* than among any of the species in the other two genera. Significant deficiencies of heterozygotes and female-biased sex ratios in transition zone populations indicate strong barriers to gene flow. This is confirmed by laboratory crossing experiments which reveal severely reduced hatching success, reduced nymphal survivorship, and a strongly female-biased sex ratio in F1 hybrids. *A. remigis* and *A. remigoides* differ significantly in both size and shape, and can be reliably distinguished morphometrically through characteristics of the male genitalia. *A. remigoides* appears to be restricted to the eastern drainage of the Appalachian mountains, but further sampling is required to determine the western and southern range limits.

11-006

PHYLOGENETIC RELATIONSHIP OF JAPANESE MACROGERRIS SPECIES (HETEROPTERA: GERRIDAE), INFERRED FROM MITOCHONDRIAL DNA SEQUENCES.

Shuji TACHIKAWA² and Masahiko MURAJI¹
¹Laboratory of Entomology, Faculty of Agriculture, Tokyo University of Agriculture, Sakuragaoka, Setagaya, Tokyo 156, Japan. ²National Institute of Sericultural and Entomological Science, Owashi, Tsukuba, Ibaraki 305, Japan.

In spite of several excellent works on the phylogeny and taxonomy of the Gerridae, relationship among species in several genera and subgenera remains uncertain.

Phylogenetic relationship among species belonging to the subgenus *Macrogerris* of *Gerris* is difficult to analyse by external and other biological characters. In this paper, we inferred the phylogeny of Japanese water striders in this subgenus by analysis of nucleotide sequences of portions of two mitochondrial DNA regions (Cytochrome b and 16S ribosomal RNA).

Phylogenetic analysis showed that three Japanese *Macrogerris* species diverged into two clusters, i.e. *Gerris* (*M.*) *gracilicornis* and *G.* (*M.*) *yezoensis* are one group and *G.* (*M.*) *insularis* is the other. However, mtDNA sequences could not distinguish *G.* (*M.*) *yezoensis* from strains of *G.* (*M.*) *gracilicornis*. The analysis also showed that *G.* (*M.*) *insularis* diverged into two distinctly separated groups and that there is a relatively large evolutionary distance between them.

In order to see the evolutionary history of the subgenus *Macrogerris*, we also analysed genetic variability within and between *Macrogerris* species and compared with that of several species of other related genus and subgenus (*Gerris* and *Aquarius*).

11-005

PHALLIC PHYLOGENY - THE RELATIONSHIPS OF TREPOBATINE WATER STRIDERS (GERRIDAE) BASED ON DEEP GENITALIC STRUCTURES

John. T. Polhemus, Dan A. Polhemus¹
Colorado Entomological Museum, Englewood, Colorado, USA
- I. Smithsonian Institution, Washington, D. C., USA

Water striders of the subfamily Trepobatinae are widely distributed in the New World, but have a more scattered distribution in the Old World, occurring only in Africa, southeast Asia, Melanesia and Australia. Our phylogenetic and zoogeographical analysis of this subfamily strongly indicates a Gondwanan origin, with subsequent radiation northward. Here we present the phylogeny of the tribe Trepobatini, which has one widespread genus in the Americas, and seven genera with much more restricted distributions in Australia and Melanesia. The morphology of the male genitalia show a linear pattern of modification along the zoogeographical progression of genera in western Melanesia, in particular a progressive reduction in the complement of endosomal selerites coupled with strong sclerotization and sculpturing of the phallosome, the latter a phenomenon unknown elsewhere in the Trepobatinae.

11-007

VARIATIONS IN RIBOSOMAL AND MITOCHONDRIAL DNA SEQUENCES AMONG SEMIAQUATIC BUGS (HETEROPTERA, GERROMORPHA).

Masahiko MURAJI¹ and Shuji TACHIKAWA²
¹ Department Insect Breeding and Genetics, National Institute of Sericultural and Entomological Science, Owashi, Tsukuba, Ibaraki 305, Japan. ² Laboratory of Entomology, Tokyo University of Agriculture, Sakuragaoka, Setagaya, Tokyo 156, Japan.

The infraorder Gerromorpha contains more than 1,000 semiaquatic bugs belonging to 8 families. Many groups of Gerromorpha are well known both ecologically and morphologically. Its higher classification and phylogeny are also well studied. However, little is known about genetic diversity and uniformity among gerromorphan families and genera. This paper deals with DNA base sequence variations in genomic ribosomal RNA and mitochondrial genes among gerromorphan families and genera. In this paper, we will discuss about the rate of evolution and phylogenetic application of DNA sequences.

Portions of two mitochondrial genes (16SrRNA and Cytochrome b) and a genomic DNA (28SrDNA) were amplified from individual insects by PCR and sequenced directly from PCR products. In total 27 species representing 14 commonly recognized genera of *Gerridae* and other related families (*Veliidae*, *Mesovelidae* and *Hydrometridae*) were examined.

The preliminary analysis showed that divergence in 28S rDNA sequences among species within *Veliidae* is very much higher than that of gerrid species. The phylogenetic tree generated by UPGMA method suggests that the genus *Microvelia* may be closely related to gerrid insects more than other veliid genera. This tendency was always observed in phylogenies derived from both ribosomal and mitochondrial DNA sequences. Now, we are expanding such analysis to other gerromorphan insect groups.

11-008

THE STATUS OF THE LARGER WATER STRIDERS IN DENMARK (HETEROPTERA, GERRIDAE)

J. Damgaard, N. Møller Andersen

Zoological Museum, University of Copenhagen, Denmark

The three larger water strider species found in Denmark: *Limnoporus rufoscutellatus* (Latreille), *Aquarius najas* (De Geer), and *Aquarius paludum* (Fabricius), differ widely in habitat use, life history, and dispersal strategy. We presents the results of a survey of the past and present distribution and current status of these species in Denmark. Particular attention is paid to potential threats against the survival of these conspicuous insects in the Danish fauna.

11-009

MATE CHOICE AND PARENTAL DECISION-MAKING IN THE WATER BUG *BELOSTOMA FLUMINEUM* SAY (HETEROPTERA: BELOSTOMATIDAE)S.L. Kight, K.C. Kruse¹

Department of Biology, Indiana University, Bloomington, IN USA - ¹ Department of Zoology, Eastern Illinois University Charleston, IL, USA

Female giant water bugs, *Belostoma flumineum* Say, oviposit their eggs upon the backs of male conspecifics. Males subsequently provide care for eggs until they hatch. Bearing eggs is costly to males in terms of increased predation risk, decreased foraging, and minimal polygynous mating. We therefore expect selection to favor males that are "choosy" in terms of mating and parental expenditure. Our findings support this prediction. Males actively terminate care to small egg pads if additional eggs are not received, or if the size of the egg pad is reduced shortly after oviposition. However, if reduction occurs after males have several days experience with eggs, they are unlikely to reject egg pads of any size, indicating that the "value" of eggs increases with age. Courting males prefer to mate with heavily gravid females, thereby reducing the likelihood of receiving a small complement of eggs. The number of eggs retained by a fully gravid female is proportional to the backspace of a male, and gravid females prefer males with no eggs already on their backs. Further study will address seasonal differences in male backspace availability and preference patterns of males that are partially encumbered and females that are partially gravid.

11-010

COMPARATIVE STUDY OF MATING SYSTEMS IN WATER STRIDERS : SEXUAL DIMORPHISM AND POST COPULATORY GUARDING

K. Hayashi

Kyushu junior college, Kinki University, Iizuka, Japan

The mating systems of water striders *Aquarius elongatus*, *A. paludum insularis*, *A. p. amamiensis* and *Gerris lacustris latiabdominis* in Japan were studied.

In *A. elongatus* and *A. p. amamiensis*, males established mating territories suggesting a system of resource defense polygyny. Males of *elongatus* have longer middle legs and *amamiensis* have more incrassate fore legs than females (sexual dimorphism). Non-contact guarding after copulation was seen in *elongatus*, while, males of *amamiensis* guarded females riding on their back after copulation (contact-guarding).

In *A. p. insularis* and *G. l. latiabdominis*, males were non-territorial suggesting a system of scramble competition polygyny. No marked sexual dimorphism in legs. Males of these species usually rode on females' back after copulation (contact-guarding). However the contact guarding was less developed in *G. l. latiabdominis*.

11-011

REVISION OF THE ORIENTAL HALOBATINAE GENUS *VENTIDIUS* DISTANT AND THE ZOOGEOGRAPHIC ANALYSIS INCLUDING ITS ALLIED ORIENTAL GROUPS (HEMIPTERA: HETEROPTERA: GERRIDAE)

P. P. CHEN & H. ZETTEL

Beijing Academy of Agriculture & Forestry Sciences, Beijing 100081, P.R. China.

Naturhistorisches Museum Wien, 2. Abteilung (Insekten), A-1014, Wien, Austria.

The Oriental water strider, genus *Ventidius* Distant (Gerridae: Halobatinae) is one of the habitants of river and the slow current of mountainous stream. Its taxonomical statue was somewhat confusing. This paper presents the taxonomical revision of all the 25 species including 5 new species. Based on its cladistic analysis, the species groups are provided. The difficulties of some taxonomical groups have drawn special attention, especially the *V. modulatus*-group. The phylogenetic reconstruction by the method of cladistic analysis will be also provided. The zoogeographic analysis of the genus and its allied genera in tribe Metrocorini will be discussed.

11-012

POPULATION BIOLOGY OF GIANT WATER BUGS IN ARGENTINA (HETEROPTERA, BELOSTOMATIDAE, BELOSTOMATINAE)

J.A.Schnack

Departamento Científico de Entomología, Museo de La Plata, La Plata, Argentina.

Males of all Belostomatinae species brood eggs that are attached to their backs by conspecific females during the course of mating. This unusual reproductive behavior has made it possible to elucidate some relevant aspects of the population biology of several species from the Province of Buenos Aires for the last two decades. This long term research deals mainly with the most representative species in the study area, *Belostoma oxyurum* (Dufour).

Obtained results include quantitative data on sexual ratio and fecundity seasonal trends, and their effects on intrasexual competition, as well as on the relative and absolute shortage of the sexual resource represented by the male back space. These population traits provide basic information to speculate on which is the main social mating system these water bugs might exhibit.

Detailed information is included concerning the influence of density-dependent and density-independent factors on *B. oxyurum* and on its closest congeneric competitor, *B. elegans* (Mayr) in a permanent pond from the above referred area. Both species adaptive strategies are described based on the r and K demographic parameters.

Reproductive behavior of *B. oxyurum* based upon experimental studies carried out under laboratory conditions is described and include detailed observations of courtship, mating, egg-laying and brooding. These observations are compared to those recorded for North American Belostomatinae (*Abedus herberti* Hidalgo and *Belostoma flumineum* Say).

11-014

FITNESS BENEFITS OF PROLONGED MATE GUARDING IN *AQUARIUS CONFORMIS* (HEMIPTERA, GERRIDAE).

Wilcox, R.S. Binghamton University, Binghamton, New York, USA.

During the mating season in the water strider *Aquarius conformis*, males clasp females continuously for many hours, mate occasionally with them, and guard them from takeovers during foraging, copulation and oviposition. Females lay eggs in batches on the underside of objects such as grass stems floating or fixed at the water surface, making egg counts convenient and accurate. Laboratory experiments showed, significantly, that females lay more eggs if fed more food, and that guarded females capture more food and lay more eggs unguarded females. Females thus increase their fitness by allowing males to clasp them for prolonged periods. Given the high likelihood of sperm precedence in this species, male fitness is concomitantly likely to be increased.

11-013

LIFE HISTORY DEPENDENT BEHAVIOURAL VARIATION IN WATER STRIDERS (*AQUARIUS REMIGIS*; HETEROPTERA: GERRIDAE)

W. U. Blanckenhorn, D. Perner¹

Biology Department, Concordia University, Montréal, Québec, Canada — ¹ Department of Biological Sciences, University at Albany, New York, USA

We investigated behavioural consequences of life history states in *Aquarius (Gerris) remigis*, a hemipteran surface predator and scavenger of small North American streams. A repeated-measures field study comparing reproductive (R) and non-reproductive (NR) first summer generation females (F) and males (M) during the same time in summer showed that NRM and NRF, which are foraging to survive the winter, behaved essentially alike, often being territorial. In contrast, RF and RM were more mobile than NR, RM being much more mobile than RF, always in search of and attacking potential mates. This resulted in RM showing little territoriality and having lower foraging success than all other categories, while RF had higher foraging success than NRF or NRM, thus likely increasing their fecundity. Many behavioural variables did not change with time. Exceptions were a decrease in the mating activity of R of both sexes, the number of mating attempts, mobility, and the stride rate of RM, and an increase in overall foraging activity of all individuals. This indicates that the behaviour of RM converged towards that of NRM as the season progressed. Individuals were assigned to either state post-hoc according to whether they had been seen mating at least once during the study period (July and August). Females were further tested to ascertain if they laid eggs. These results support the hypothesis that diapause and reproductive state to some degree predetermine behaviour, thus constraining behavioural flexibility. Attributing behavioural variation to various proximate causes can be central to the interpretation of alternative strategies and tactics.

11-015

WHERE THE TEXTBOOK MEETS THE POND: LIFE HISTORY VARIATION OF WATER STRIDERS IN NATURE

Christian Peter Klingenberg and John R. Spence

Department of Biological Sciences, University of Alberta, Edmonton, Alberta T6G 2E9, Canada

Current theory on the evolution of life histories is based in part on *a priori* assumptions about the traits involved. For instance, most models assume that adult size is an increasing function of development time, and that size determines fecundity. These assumptions imply a trade-off, and an intermediate optimum can be found where the fecundity benefits of larger size are compensated by the cost of a prolonged development time. We tested these assumptions in a natural population of the water strider *Gerris buenoi* (Heteroptera: Gerridae).

In a large field experiment with individually reared bugs, repeated in the spring and summer generations over three years, we consistently found a negative correlation between development time and adult size instead of a positive one. The estimated genetic correlation was negative, and an additional experiment with different rearing conditions produced similar results as well. Variation in overall vigor dominates in our study population, rather than a trade-off between development time and adult size.

We examined if protozoan gut parasites, which have been shown to affect physiological condition of gerrids adversely, might be a cause of this variation in vigor. Only trypanosomatid flagellates showed significant effects on gerrid life history traits, but they were rare in our study population, and therefore cannot substantially influence population processes.

Several measures of female reproductive performance were uncorrelated with body size: lifetime fecundity, reproductive lifespan, the volume of eggs, and the proportion of eggs hatched. An experiment under food limitation did not show any benefits of larger size.

Despite our replicated and unusually large field experiments, we did not find the associations between life history traits commonly assumed by current theory. Our results, together with those of some earlier studies, challenge the generality of optimality models assuming particular trade-offs. We propose that the range of models in life history theory should be expanded to accommodate stochastic and neutral models.

11-016

SEASONAL DYNAMICS OF STAGE-STRUCTURED POPULATIONS OF THE WATERSTRIDER SPECIES *GERRIS LACUSTRIS* AND *GERRIS ASPER* (HEMIPTERA: GERRIDAE)

M. Zimmermann, A. Luginbühl, S. Minder

Institute of Zoology, Department of Population Biology, University of Berne, Baltzerstrasse 3, CH-3012 Berne, Switzerland

The seasonal dynamics of *G. lacustris* and *G. asper* was studied in two markedly different habitats. The first (near Berne) is a typical habitat of *G. lacustris*, whereas the second (near Thun) is a cool shadowy pond, the only habitat type from which *G. asper* has been recorded on the Swiss Plateau. To sample waterstriders we used a square wooden frame (50 x 50 cm). 49 and 31 samples were taken every three or four days from early May to late October 1994. 24 and 20 sampling units per date were sampled on the two ponds. Species and stage of the captured waterstriders were determined in the field, if possible, and the sampled individuals were released immediately after counting. The sampling area in both populations was less than ca 3% of the total water surface.

The populations in the two habitats showed marked phenological differences. First instars of *G. lacustris* emerged in the second week of May in the population near Berne, and one month later near Thun. Emergence of summer adults near Thun was also delayed for one month compared with the Berne population where first summer adults emerged by the end of June. Despite this difference, *G. lacustris* was partially bivoltine in both locations. *G. asper* occurred only on the pond near Thun where it was univoltine. Maximum densities of all postembryonic stages of *G. asper* were much lower than those of *G. lacustris* in the same habitat. We used the index of dispersion to evaluate the spacing pattern of waterstrider nymphs and adults. As a rule *G. lacustris* showed a clumped spatial distribution. When densities were low, as was the case for most samples of *G. asper* and some of *G. lacustris*, the distribution pattern could not be discriminated from a Poisson distribution.

We used the Kiritani-Nakasuji-Manly (KNM) method to estimate stage specific survival rates, stage durations and numbers entering the six postembryonic stages. The KNM-estimates will be compared with those of another model and also with the results of a simulation approach. The reliability of the different estimators will then be discussed with special emphasis on the assumptions of the different methods.

11-017

UPS 'N DOWNS OF A 12-YEAR BUG COUNT: THE TALE OF TWO POND SKATERS

John R. Spence

Department of Biological Sciences, CW405A Biological Sciences Bldg, University of Alberta, Edmonton, Canada T6G 2E9

Populations of adult waterstriders were studied by marking and weekly census on a small pond in northcentral Alberta, Canada. Individuals of 5 species colonized the pond shortly after ice-off in mid-April. Disappearance of adults from the surface varied more between years, occurring early-September to mid-October, and was associated with late spring conditions that affected the extent of a second generation. Of the 5 species of colonists, only *Gerris buenoi* and *Limnoporus dissortis* were regularly successful; their performance has been remarkably and positively correlated. In recent years populations of *G. comatus* have recruited more strongly although rates of colonization have not increased significantly for this species. Neither *G. pingreensis* nor *Aquarius remigis* have ever recruited significantly, despite regular colonization. These data suggest that associations between species and pond-type depend more on factors affecting recruitment than on those determining colonization. Study of yearly recruitment:colonization ratios and weekly records of the arrival and disappearance of bugs establish a pattern of large-scale colonization and departure over 8-10 week periods each spring. The research emphasizes the importance of flight for these waterstriders and shows that local populations are regularly linked by interpond movement both within and between breeding seasons.

11-018

MIGRATORY SYNDROME IN OVERWINTERING ADULTS OF TWO WATER STRIDERS, *AQUARIUS PALUDUM* (F.) AND *GERRIS LATIABDOMINIS* MIYAMOTO (HETEROPTERA: GERRIDAE).

T. Harada

Biological Laboratory, Faculty of Education, Kochi University, Kochi, Japan.

Most of overwintering macropterous adults histolyzed their mesothoracic indirect flight muscles before the middle of May in a wing dimorphic species *Aquarius paludum* (F.), whereas most adults of monomorphic (macropterous) species, *Gerris latiabdominis* MIYAMOTO kept their flight muscles and showed high flight propensity until late spring in Kochi, Japan. Macropterous adults of *A. paludum* had more mature eggs than those of *G. latiabdominis* in the middle of May. The loss of water surface and following starvation induced histolysis of the flight muscles and elongated surviving period in *A. paludum*, while adult *G. latiabdominis* under these conditions kept their flight muscles and survived for no longer period than the adults provided with sufficient foods and water surface. When macropterous adults fed on sufficient foods, loss of water surface made some adults of *A. paludum* stop laying eggs, although it can only reduce the number of eggs in *G. latiabdominis*.

If the loss of water surface occurs in the field, *A. paludum* may enter diapause and wait for rainfall and *G. latiabdominis* may move onto another water surface by flight.

11-019

DISPERSAL IN *ARCTOCORISA CARINATA* (SAHLB.) AND *CALLICORIXA PRODUCTA* (REUT.): THE EFFECT OF POPULATION DENSITY AND RESOURCE AVAILABILITY (HETEROPTERA: CORIXIDAE)V. I. Pajunen, I. Pajunen¹

Department of Ecology and Systematics, University of Helsinki, Helsinki, Finland - ¹ Department of Animal Science, University of Helsinki, Helsinki, Finland
Dispersal of colour-marked *Arctocoris carinata* (Sahlb.) and *Callicorixa producta* (Reut.) adults in a rock pool environment was monitored for most of the reproductive season. The average daily dispersal was 10-30 %, *C. producta* being more active. Differences between experimental rock pools from which larvae had been removed and control pools were small. Only during short periods when resources in control pools were overused, more intense dispersal was observed.

The results suggest that in both species there exists a strong innate tendency to disperse, and local population density and food availability are factors of minor importance. Although intraquild predation lowers the reproduction success in rock pools with high larval density, preference for patches with low population density could not be demonstrated.

11-020

A LONG TERM MARK-RECAPTURE STUDY OF THE
COMMON EUROPEAN WATERSTRIDER
GERRIS LACUSTRIS (HEMIPTERA: GERRIDAE)

M. Zimmermann

Institute of Zoology, Department of Population Biology, University of Berne,
Baltzerstrasse 3, CH-3012 Berne, Switzerland

The seasonal dynamics of a small population of the wing-polymorphic waterstrider *Gerris lacustris* was studied from 1986 to 1996 using the stochastic Jolly-Seber mark-recapture model. Adult gerrids were sampled weekly, and on their first capture they were marked individually with a simple code. Since the start of this study more than 12'000 individuals were marked. Sampling fraction was high (0.88 ± 0.095). Adult summer emergence ranged from 500 to 2000 individuals, and in eight out of ten years adult production was between 800 and 1400 individuals. The proportion of longwinged (LW) individuals was variable. In spring generations the proportion of LW ranged from 0.30 to 0.53, with a mean of 0.37 (summer: 0.37 to 0.53, mean: 0.44). The absolute number of both LW and shortwinged (SW) individuals of the summer generation was directly proportional to the number of LW and SW spring breeders with a proportionality factor of 4.5 ± 0.43 . The population was partially bivoltine, and the proportion of nondiapauses females was negatively related to the Julian date when the first 10% of the summer adults had been marked. The partial second generation accounted for less than 20% of the yearly production. Its absolute size was dependent on the number of nondiapauses females. Early start of adult moulting in summer, however, did not influence total adult production. LW and SW individuals differ in their observed residence times: LW individuals have shorter mean residence times (2 weeks) than SW individuals (3 weeks), and, furthermore, nondiapauses SW individuals show much longer mean residence times than diapauses SW individuals (6 weeks vs. 3 weeks). Overwinter mortality of SW adults varied from 0.64 to 0.92 (mean: 0.80). LW individuals do not as a rule hibernate in the pond area but disperse by flight in late summer / early fall, and their disappearance rates were correspondingly high (0.93 to 0.99, mean: 0.97). A simple model will be presented to partition the mortality of SW adults between first capture in summer and reappearance in spring into 1) mortality on the water surface and 2) mortality during hibernation on land.

MARINE INSECTS - INTRODUCTORY REMARKS
SYMPOSIUM ON ECOLOGY OF MARINE INSECTS

Lanna Cheng

Scripps Institution of Oceanography, University of
California, La Jolla, CA. USA

Insects are the most abundant animals on land but relatively few species are known in marine environments. Although there are no known physiological barriers for a marine existence, evolutionary history coupled with special adaptations necessary for dealing with harsh physico-chemical conditions in the sea may be chiefly responsible for this paucity. However, at least 20 insect orders have marine species which spend one or more of their developmental stages in a marine habitat.

Most marine insects are wingless, flightless or weak fliers. Some 75% are in the orders Hemiptera, Homoptera, Coleoptera and Diptera. The most ubiquitous genus is perhaps *Halobates* (Hemiptera: Gerridae), the only known insect in the open ocean. The majority of *Halobates* species occur nearshore as do members of the Veliidae and Hermatobatidae (both Hemiptera). Marine Diptera include mosquitoes and biting-midges of economic importance, as well as beach flies and midges that may be mere nuisances. Both *Pontomyia* and *Clunio* (Diptera: Chironomidae) have truly submarine larvae and life cycles closely synchronised with the lunar or tidal rhythms. Most marine beetles occur in the intertidal but there are no truly marine families. The Chathamidae (Trichoptera), with 2 genera and 4 spp., are exclusively marine.

These are but a few examples of the variety of marine insects that one may encounter on beaches, salt marshes, mangrove swamps, coral reefs and the open sea.

11-021

ORIGINS OF EXTREME STRUCTURAL DIVERSITY IN THE
TWO BASAL CLADES OF THE HETEROPTERA

P. Štys

Department of Zoology, Charles University
Prague, Czech Republic

The advanced Heteroptera are rather monotonous structurally while two basal clades, Enicocephalomorpha and Dipsocoromorpha (monophyletic ?) show great structural plasticity. It concerns the basic architecture of labium, pterothorax, forewings, coxal articulation, posttarsus, male abdomen and terminalia (sexual counter-trends: the more complex the male the simpler the female), adult evaporatoria and repugnatorial gland openings (tagmatic shifts from abdominal to modal thoracic position). This structural diversity does not fit the allegedly uniform biology (generalized predators) and habitat preferences (inhabitants of interstices in litter, moss and riparian gravel). The following explanations are possible: retention of the results of evolutionary experiments; results of strong sexual selection; adaptive consequences of an unidentified niche micropartitioning; unique SMR systems.

MOONLIGHT AND TIDAL CYCLES AS TIME CUES FOR
METHAMORPHOSIS AND EMERGENCE IN INTERTIDAL
MIDGES (DIPTERA: CHIRONOMIDAE)

D. Neumann

ABSTRACT NOT RECEIVED

11-024

ECOLOGY OF THE FLIGHTLESS MARINE MIDGE *PONTOMYIA* (DIPTERA: CHIRONOMIDAE)K.-F. Chen, C.-S. Chen¹ and K. Soong

Institute of Marine Biology, National Sun Yat-sen University, Kaohsiung, Taiwan, ROC - 1 Department of Biology, Tung-Hai University, Taichung, Taiwan, ROC

Semimonthly emergence cycles were found in *Pontomyia oceana* in south Taiwan. Each bout lasts for about 5 nights with peaks occurred at day 3 and 18 of a lunar cycle, when large numbers of adult males skiing on water surface with modified wings were attracted to light and hooked under-surface vermiform females for mating several hours after sun-set. A negative correlation was found between water temperature of the tide pools and the mean time of occurrence after sun-set from July to December 1992. In *P. natans* only males were found and they occurred every night, with fluctuations in numbers throughout the months. In the Laboratory, fertilized eggs of *P. oceana* were raised in coral fragments, and they hatched in 3-4 days under 25°C. Larvae build tubes made of small pieces of fragments, while first emergence occurred 22 days after hatching. Male *P. oceana* emerged earlier than females. The males remain active for about 2.4 hours, whereas females lay egg strings near surface in about 2.3 hrs. Modification of sun-set time and temperatures resulted in shift in timing of emergence of the day, but not the day after. It seems that sun-set time cues the starting time of the processes leading to eventual emergence, the rate of which controlled by temperature.

11-025

THE EFFECT OF TIDAL VARIATION ON 'GOOD GENES' SEXUAL SELECTION IN SEAWEED FLIES, *COELOPA FRIGIDA* (DIPTERA: COELOPIDAE)

T. H. Day

Department of Genetics, University of Nottingham, Nottingham, U. K.

Female seaweed flies (*Coelopa frigida*) prefer to mate with large males. Mate preferences are thought to have evolved in response to several types of sexual selection: the fitness of offspring is increased as a result of female choice both by the production of attractive sons (the Fisher process), and by the production of offspring with greater survival ('good genes'). There may also be direct benefits to discriminating females in terms of increased longevity. The contribution of good genes sexual selection was estimated by determining the correlation between the pattern of willingness to mate and the predicted mean progeny fitness of each type of male. Mating patterns were measured in pairwise laboratory trials, and offspring fitness by estimating the deviation from Hardy-Weinberg proportions of a large inversion karyotype. A significant relationship was found in samples from British populations, but not in samples from Sweden. It is suggested that the strength of good genes selection depends on ecological factors associated with the tidal variation to which natural populations are exposed. The effect of tides on the evolution of mating behaviour is discussed.

THE CHEMICAL ATTRACTANTS OF MALE *TROCHOPUS* (HEMIPTERA: VELIIDAE): A PRELIMINARY REPORT
V. Roussis and L. Cheng¹.

Division of Pharmacognosy, Department of Pharmacy,
University of Athens, Athens, Greece.
-1 Marine Biology Research Division, Scripps Institution of
Oceanography, University of California, San Diego, La Jolla,
USA

Although marine insect are rarely encountered, several species are frequently found in high densities around tropical island shores. *Trochopus* is a neotropical genus with five known species, confined to central and south American coasts and occupies habitats similar to those of the much better known sea-skaters *Halobates*. During a recent expedition to the Bahamas Islands the small veliid *Trochopus plumbeus* (Uhler) was found in considerable densities in all visited islands.

Large aggregates, with several hundred specimens, encountered at Joe Sound Long Island allowed us to collect significant numbers of that marine insect for field bioassays and laboratory experiments. Adult specimens were sexed and males and females were kept in separate containers. From the field trials it was quite clear that females were attracted to males as well as to male extracts but not the opposite.
Gas Chromatography-Mass Spectrometry analyses performed on the extracts of both males and females revealed the presence of a series of aldehydes and long chain aliphatic acids that are water insoluble and could possibly act as surface-dispersible semiochemicals. The differences in the chemical composition of the two sexes and their potential role in the insect's chemical communication system will be discussed.

11-030

ECOLOGICAL PHYLOGENETICS AND HISTORICAL BIOGEOGRAPHY OF SEA SKATERS, *HALOBATES* (HEMIPTERA, GERRIDAE)

N. Møller Andersen
Zoological Museum, University of Copenhagen, Denmark

The oceanic *Halobates* are remarkable insects with a unique way of life and there has been much speculation about their origin and evolution. The recent discovery of a freshwater relative to sea skaters, *Austrobates*, adds an exciting new piece to the jig-saw puzzle picturing the evolution and diversification of marine water striders. It is suggested that ancestral Halobatini lived in both limnic and marine habitats and that *Austrobates* and *Halobates* evolved from their euryhaline ancestors into species preferring only limnic and marine habitats, respectively. The single known species of *Austrobates* is endemic to Cape York Peninsula while the subgenus *Hilliella*, the sister group of all other *Halobates* species, is distributed along the coasts of tropical northern Australia. It is therefore hypothesized that the sea skaters evolved somewhere in the area which now constitutes the northernmost part of the Australian continent. Fossil suggests that *Halobates* had evolved before the Middle Eocene (45 Mya), when Australia was part of eastern Gondwanaland. The known distribution of *Halobates* covers the whole Indo-Pacific region (only one species has invaded the Atlantic Ocean) and there are endemic, coastal species in such distantly separated places as the Red Sea and the Galapagos Islands.

11-029

REEF-TREADERS: OBSERVATIONS ON THE BIOLOGY OF AN EXCLUSIVELY MARINE INSECT FAMILY (HEMIPTERA: HERMATOBATES).

William A. Foster
Department of Zoology, University of Cambridge, U.K.

The reef-treaders (Hermatobatidae) are an exclusively marine family of insects that occupies a somewhat isolated phylogenetic position within the semi-aquatic bugs (Gerromorpha). Observations in the south-west Pacific show that they can be abundant on shores that provide rocks with cavities that remain air-filled at high tide. The vertical zonation of cavities suitable for the insects is restricted to mid-to-lower regions of the intertidal zone. The behaviour of the insects during the tidal cycle is described. The adults appear to swim further from the shore than do the larvae, and they were observed copulating in tidal pools. The insects are clothed in a layer of micro-hairs of unique design: a short tapering shaft tipped with a sphere. These hairs may act as a plastron: their distribution corresponds precisely to the pattern of the silvery air-layer seen when the insects are submerged.

11-031

HOW OCEANIC SURFACE ENVIRONMENTS AFFECT THE DISTRIBUTION OF PELAGIC *HALOBATES* (HEMIPTERA: GERRIDAE)?

T. Ikawa, H. Okabe¹, L. Cheng²
Department of Liberal Arts and Sciences, Morioka College, Takizawa-mura, Iwate-gun, Japan - 1 National Institute of Material Sciences, Tsukuba, Ibaraki, Japan - 2 Scripps Institution of Oceanography, University of California at San Diego, La Jolla, CA, USA

Only five species of the ocean skater *Halobates* have successfully colonized the open ocean. They occupy a vast area extending from latitudes 40°N to 40°S of the equator. They are totally wingless and live in a two-dimensional world. Confined to the ocean surface they are exposed to various physical forces acting at the sea-air interface. Oceanic diffusion, which acts constantly to disperse them, must be one of the important factors responsible for the distribution and life history of *Halobates*. We estimated its effects on the following aspects of *Halobates* by using oceanic diffusion diagrams constructed by Okubo (1971, 1974), and the mathematical model developed by Kierstead and Slobodkin (1953) and Skellam (1951):-
1) Oceanic diffusion can carry ocean skaters from an initial patch as far as 2,500 km apart in 60 days. This distance is equivalent to ca. one-sixth of the maximum width of the Pacific Ocean where *H. micans* is found.
2) Mutual encounter rates as facilitated by oceanic diffusion could be high (1.5/day) even at very low population densities (1/km²). This suggests that a *Halobates* could find a mate even when an individual had been carried a long distance away. Thus, extensive gene mixing could occur over the whole range of a species' distribution.
3) We calculated the growth rates of *Halobates* as a function of distribution range and diffusivity. The estimated growth rates are rather low (0.0026-0.0079/day) compared with those of other insects. However, they are offset by a relatively long life span and an extended oviposition period (perhaps over 2 months).
Thus, pelagic *Halobates* appears to have adopted a strategy of slow growth and prolonged longevity to cope with living in an unstable and harsh physical environment.

11-032

MITOCHONDRIAL DNA AND *HALOBATES* (HEMIPTERA: GERPIDAE): TECHNIQUES FOR TRACKING TINY TRANS-OCEAN TRAVELERS.A. M. Shedlock, F. A. H. Sperling¹ and L. Cheng²

University of Washington, Seattle, WA USA - 1 University of California, Berkeley, CA USA - 2 Scripps Institution of Oceanography, UCSD, La Jolla, CA USA

Of the 45 described species in the genus *Halobates*, 5 have evolved a remarkable suite of adaptations and are fully pelagic, found mostly on tropical oceans between latitudes 40 degrees N and S. Each species exhibits a distinct zoogeographic pattern. *H. micans* is cosmopolitan and found in all three oceans; it is the only species found in the Atlantic. *H. sericeus* is amphitropical, the northern and southern populations being separated around the Equator by *H. micans*. The other three species are more coastal in habitat: *H. germanus* occurs in the Indian Ocean and the western Pacific while *H. sobrinus* and *H. splendens* are found off the coasts of central and south America.

These fascinating and enigmatic insects occupy one of the largest continuous ecosystems on the Earth and challenge our conventional wisdom about adaptations and speciation in the pelagic marine environment. To help understand the phylogeographic nature of this system and to complement morphological and behavioral investigations, we have initiated a comprehensive molecular genetic study of *Halobates* using PCR, DNA fingerprinting and nucleotide sequence analysis. We present preliminary data on inter- and intra-specific variation of the mtDNA cytochrome oxidase II sequence of several *Halobates* species and outgroup taxa. Results will be discussed within the context of both conventional phylogeny among species as well as prospects for large-scale studies of gene flow in pelagic populations.

11-034

AUSTRALIAN WOOD-MINING CHIRONOMIDS

P. S. Cranston

CSIRO Division of Entomology, ACT 2601, Australia

In 1988, after a postdoctoral year in Canada, I felt able to join Don Oliver in commenting on northern hemisphere aquatic wood-mining chironomids (Cranston and Oliver, 1988). After eight years of study of the Australian chironomid fauna, a substantial wood-mining chironomid fauna, potentially even more diverse than that of the northern hemisphere has been revealed. Some taxa have been recovered and reared from immersed wood, others are recognized by the wood fibers in the gut, combined with some distinctive head capsule morphologies.

For the Holarctic fauna, Don Oliver and I observed that wood-miners are a paraphyletic assemblage, and we speculated on the convergence of mentum morphology amongst the miners belonging to the subfamilies Orthocladiinae and Chironominae. The menta of a variety of Australian wood-miners will be illustrated, showing that these observations are true also for many Australian wood-mining taxa.

Pupal exuvial evidence suggests that among the Chironomini only *Stenochironomus*, *Harrisius* and the recently-described *Imparipecten* are all common. Amongst the Orthocladiinae, *Austrobrillia* is frequent, whereas others, many of which are *Bryophaeocladus*-like, are at most sporadic in occurrence.

11-033

MORPHOLOGICAL ADAPTATIONS OF ADULT TROPICAL CHIRONOMIDS

O. A. Saether

University of Bergen, Museum of Zoology, Muséplass 3, N-5007 Bergen, Norway

Chironomid wing length was used by McLachlan (1985) to describe habitat characteristics. He suggested a negative relationship between wing length of most abundant species and duration or predictability of its habitat.

Tropical chironomids are smaller or of the same size as their closest relatives in temperate areas. Likewise, the anal lobe and the number of setae on squama often are reduced, the VR often higher, the costal extension often longer, the antennal ratio often lower, and the leg ratio often higher, etc. Not all of these changes appear to take place in all species and certainly not always concurrently.

Several of the characters in which changes take place are important in keys and phylogenies, and it is necessary to take the climatic conditions of where the species were collected into consideration when judging whether a character shows homoplasy or not. In order to judge whether a character is caused by adaptation to a tropical climate or a tropical rain forest, it is necessary to compare a species with its closest relative or relatives from more temperate areas.

Certainly the habitat predictability of semiaquatic chironomids is high in a tropical rain forest with available habitats permanently present. When comparing species within a monophyletic group McLachlan's theory thus appears to hold.

11-035

THE CHIRONOMID SPECIES OF THE ITALIAN LAKES: A REVIEW

B. Rossaro

Department of Biology, Section Ecology, University of Milan, Milan, Italy

Many large and important lakes are present in Italy, especially in the northern areas. These lakes are rich in chironomid fauna. Despite intensive research on zoobenthos of some of these lakes in the past, a complete list of chironomid species in any of these lakes is still lacking. In most cases, a list of genera or species groups was published. For example, in Maggiore lake, 72 chironomid taxa were captured, 29 were identified as genera, 17 as species group, and only 26 as species based generally on larval identification (Nocentini, 1989) and not adults. Such numbers of species identified is low when compared with the ones observed in some other lakes. For example, 184 species were identified in the Bodensee lake (Reiss, 1968). A review of the knowledge of chironomids in Italian lakes is now given. High organic discharges in some large lakes, such as Maggiore, Como, Garda, have necessitated lake restoration which is either planned or being implemented in some cases. This may cause a change in chironomid species composition. Therefore, it is necessary to know the present state and baseline information in order to be able to detect changes in species composition in the future. The collected specimens deposited in the Department of Biology, Section Ecology, University of Milan, have been re-examined and the complete list of species is compiled. Starting at the beginning of 1995, samples of adults were collected with a week or 15-day frequency in Maggiore lake (Angera), Varese lake (Schiranna), Como (Onno), Monate and Comabbio lakes. The information gathered will be compared with the existing information from the past and final conclusions about the trophic state of the lakes, as evidenced by chironomid fauna will be presented.

11-036

TROPHIC INTERACTIONS IN MIRE BENTHIC COMMUNITIES DOMINATED BY CHIRONOMID LARVAE

T. Iwakuma, R. Ueno

Environmental Biology Division, National Institute for Environmental Studies, 16-2 Onogawa, Tsukuba, Ibaraki 305, Japan

Chironomid larvae dominated the zoobenthos in springs, streams and pools of Miyatoko Mire, Japan. A total of 32 species of chironomid adults were collected from the mire by rearing larvae, net-sweeping and light trapping. In a spring-fed pool, a detritivorous [*Stictochironomus akizukii* (Tokunaga)] and a carnivorous [*Procladius culiciformis* (L.)] midge were predominant. Both species were semivoltine with overlapping two cohorts emerging during May-August. Since the day-degrees for *S. akizukii* were adequate to complete its development within a year, some nutritional defects might have existed for this species. Annual production of *S. akizukii* larvae ($4.36 \text{ g m}^{-2} \text{ year}^{-1}$) was equivalent to those reported for large-sized chironomids in eutrophic waters. Production of *P. culiciformis* ($2.06 \text{ g m}^{-2} \text{ year}^{-1}$) also ranked high among the values reported for Tanypodinae larvae. Larvae of *S. akizukii* fed on small-sized diatoms and detritus while 3rd and 4th instars of *P. culiciformis* fed on first 3 instars of *S. akizukii* as well as on its own 1st and 2nd instars. Large-sized diatoms and desmids maintain high production of *P. culiciformis* while early-instar larvae of *S. akizukii* seemed to stimulate its larval growth before emergence.

11-038

WHY PROFUNDAL CHIRONOMIDS AND OLIGOCHAETES CAN BE USED AS INDICATOR ORGANISMS IN MONITORING LAKE TROPHY

C. Lindegaard, P. C. Dall, K. Hamburger

Freshwater Biological Laboratory, University of Copenhagen, 51 Helsingorsgade, DK-3400 Hillerod, Denmark

The trophic lake type system established at the beginning of this century has been fruitful in producing discussions of fundamental causal relationships between different aspects of limnology. Chironomids and later oligochaetes proved to be useful as indicator organisms in classifying lakes. The factors determining the faunal assemblages in the profundal zone of regularly stratified lakes are an interaction primarily between the quality and quantity of food and oxygen conditions. The available food originates exclusively from precipitating organic matter produced in the photic zone, except in relatively shallow oligotrophic lakes, which may also have a profundal production of phytobenthos. With increasing lake trophy the amount of food increases while oxygen concentration decreases.

Based on our own research and the literature review, we describe available food quality/quantity, feeding behavior, respiratory adaptations to oxygen depletion, and anoxic survival for a number of chironomids and oligochaetes characteristic for habitats with different trophic state and oxygen regime.

11-037

DROUGHT TOLERANCE OF LARVAE OF *CHIRONOMUS KIIENSIS* TOKUNAGA (DIPTERA: CHIRONOMIDAE) IN THE LABORATORY.

R. Surakam, K. Yano

Laboratory of Insect Management, Faculty of Agriculture, Yamaguchi University, Yoshida, Yamaguchi, Japan

Larvae of *Chironomus kiiensis* Tokunaga, one of the most dominant species in paddy fields of the Yamaguchi area, Japan, were reared under different drought conditions in the laboratory to determine the effects of drought condition in paddy fields.

After making nests, 2nd, 3rd and 4th instar larvae were kept in the substrata of which water content (W.C.) was 40%. Percentage survival of each instar decreased as drought period and all larvae died within 24-30 days. Second and 3rd instar larvae were more resistant to drought condition than 4th instar larvae in the mean survival percentage. Mature larvae, however, recovered better than younger larvae in percentage emergence when reared at 40% W.C. for 7 days.

Adults derived from 4th instar larvae experienced different drought periods (0-10 days) at 40% W.C. showed effects of drought condition. Percentage emergence distinctly decreased as drought period, and it increased as ages of larvae. Number of ovarian eggs showed no difference until 7 days, but decreased when it lasted 10 days. In conclusion, larvae of *C. kiiensis* suffers from drought condition, but its population in paddy fields is supposedly able to continue when the period not longer than 5 days.

11-039

ORDINATION AND CLASSIFICATION OF SUBFOSSIL CHIRONOMID COMMUNITIES IN DANISH LAKES

K. P. Brodersen, C. Lindegaard

Freshwater Biological Laboratory, University of Copenhagen, 51 Helsingorsgade, DK-3400 Hillerod, Denmark

Parametric and nonparametric multivariate methods were used to classify and characterize the variation in subfossil chironomid communities in a wide range of Danish lakes. Canonical correspondence analysis was used to examine the relationship between chironomid assemblages and contemporary water chemistry with special emphasis on concentrations of total phosphorus (TP). A transfer function to infer lake trophic status (TP range 18-1,200 $\mu\text{g P l}^{-1}$) from subfossil chironomid remains was established using weighted averaging (WA) regression and calibration techniques.

11-040

INFESTATION PROBLEMS AND NEW STRATEGIES FOR CONTROL OF *PARATANYTARSUS GRIMMII* (SCHNEIDER). A CHIRONOMID MIDGE (DIPTERA: CHIRONOMIDAE) INFESTING ENCLOSED DRINKING WATER SYSTEMS IN THE U.S.A.

R. W. Merritt¹, M. K. Alexander¹, M. B. Berg²

Department of Entomology, Michigan State University, East Lansing, MI 48824, USA - 1 Department of Biology, Loyola University of Chicago, Chicago, IL 60626, USA - 2

In 1990, a small midwestern USA town water utility began receiving complaints of small worm-like organisms appearing in the municipal drinking water supply. These organisms were identified as the chironomid, *Paratanytarsus grimmii* (Schneider). In this particular system, the town's water is derived from groundwater sources and is pumped directly into a treatment facility. Upon entering the treatment facility, the water is pumped to an elevated storage tower for eventual distribution to consumers. The original midge infestation occurred through a vent in the water tower. Midge population densities circulating in the distribution system ranged from <1 to 40 individuals/100 liters of water. The larvae appeared to feed on dead bacteria from the water column. Because *P. grimmii* is parthenogenetic, it was able to reproduce in the enclosed distribution system. Two chemicals that are currently used in water purification and clarification were tested as control agents: Cat-Floc LS, a water clarifier, and Hydrogen Peroxide (H₂O₂), a water purifier. Both products caused mortality in larvae of *P. grimmii*, however, Cat-Floc was the most effective with a longer application time. The limitations and constraints of these products will be discussed.

11-041

CHIRONOMIDAE CONTROL IN A DRINKING WATER SUPPLY SYSTEM IN ISRAEL

M. Broza¹, M. Halpren¹, R. Porat², B. Teltsch²

University of Haifa, Oranim, Tivon 36006, Israel-1 Mekoroth Water Company, Nazareth Illit 17105, Israel-2

In 1992, chironomid infestations in a drinking water supply system in Tel Aviv were discovered. Continuous monitoring (1992-95) revealed that a majority of the covered storage tanks receiving Lake Kinneret water through the Israel National Water Carrier (INWC) was infested with all life stages of chironomids. Tanks draining and cleaning, sprinkler spraying water in the tank space, midge adult electrocution (traps) and the routine water chlorination (1 ppm) were inadequate measures for the midge control. Laboratory bioassays of 4th-instar midge larvae with monochloramine resulted in 24-h LC₅₀ and LC₉₀ values of 10.4 and 18.0 ppm, respectively. Addition of ammonium sulfate followed by sodium hypochlorite solution for "shock chloramination" of midges in a tank drained down to contain 20 cm deep water and then disconnected, was tested. All dead chironomids were flushed out through the drainage outlet at 5 h post-treatment. The tank was resupplied with water level raised to the operational volume while confirming its chloramine concentration within the legal limit. A second identical treatment of water in the tank is suggested 8-10 days after the first one to kill the midges hatched from eggs, and the adults, surviving the first treatment. Seven commercial treatments were made in 5,000 - 8,000 m³ storage tanks. Pre-treatment larval density at the tank bottom during the first treatment (August 1994) was 8,500 larvae/m², and 17,500 adults/light trap/night. The treatment eliminated all midge larvae and only 23 adults/light trap were taken after 5 days post-treatment.

11-042

INVASION OF ADULT CHIRONOMIDAE IN VENICE, ITALY: ENVIRONMENTAL, CLINICAL AND PREVENTIVE ASPECTS

F. D'Andrea¹, G. Ceretti¹, S. Della Sala¹, C. Giacomini², G. Marcer³

Department of Public Health (ULSS 11), Venice, Italy-1 Department of Pediatrics, Ospedale al Mare, Venice, Italy-2 Institute of Occupational Health, University of Padua, Padua, Italy-3

In the past decade, the city of Venice was "invaded" by dense swarms of adult Chironomidae, causing a variety of nuisance, economic and medical problems. Car, train and boat traffics to and from, and within, the city were severely affected. In August 1985, the safety of airplane traffic and the airplanes at the Marco Polo Airport near Venice were threatened due to massive accumulations of dead midges on the runways as well as entry of adult midges into delicate equipment on the aircraft. Continuing research on Chironomidae since 1983 has revealed that *Chironomus salinarius* inhabiting the lagoon of Venice is the nuisance midge, with larval densities ranging from 1,000 to 10,000/m². On the basis of midge larval and adult data, control has been attempted taking an integrated approach. Chironomidae are considered as environmental and occupational sensitizers contributing to respiratory diseases. The human sensitivity to chironomid allergens, particularly peptides complexed with hemoglobin(s) sub-units may induce asthma and rhinitis. Clinical and epidemiological screening to establish chironomid-related allergies showed that the prevalence of respiratory allergies was low in the general population, but nearly 5% of symptomatic children tested (skin test) with extracts of *C. salinarius* larvae and adults were positive. Among these children, 6 developed bronchial asthma and the rest rhinitis. Atopy plays a relevant role as predisposing factor in the sensitization. Chironomid allergies, at present, are not in the epidemic stage in Venice. However, continuing studies on chironomids and screening new cases of allergic sensitization in the Venice area are important.

11-043

CHIRONOMIDAE (DIPTERA) NUISANCE IN SOME WETLANDS LOCATED NEAR CAGLIARI AND ORISTANO, SARDINIA, ITALY

G. Ceretti¹, F. Grimm², G. Erbi³, G. Marchese¹

ULSS 11, Public Health Office, Dorsoduro 3493 - 30123 Venezia, Italy -1 Department of Biology, University of Trieste, Via Giorgieri 5, 33100 Trieste, Italy - 2 Environmental Protection Department, Regione Sardinia, Via Biagi 7, 09100 Cagliari, Italy - 3

Chironomid nuisance of great magnitude was recently noticed at first in urban areas of Cagliari and then in the cities of Oristano and S. Giusta, Sardinia, Italy. The Environmental Protection Department of Sardinia Region and the Public Health Office of ULSS 11 Venezia, jointly initiated research in May 1993 to determine the nuisance chironomid taxa and their larval distribution. It was also planned to collect data on selected chemical and physical parameters (e.g., depth, transparency, temperature, pH, Eh, salinity, and dissolved oxygen in the waters: and temperature pH, Eh, and % organic matter in the sediments) of the wetlands studied. In the framework of this research, 10 wetlands with different levels of salinity (>60‰ than freshwater) were studied. *Baeotendipes noctivaga* (K.) was the only chironomid species collected in a salt-farm near Cagliari, with mean density higher than 10,000 larva/m². *Chironomus* gr. *salinarius* was mainly present in saline waters near Oristano, while *C* gr. *plumosus* was abundant in freshwater areas

11-044

SIGNIFICANT RECENT ADVANCES IN THE CONTROL OF NUISANCE CHIRONOMIDAE (DIPTERA)

A. Ali

University of Florida, IFAS, Central Florida Research and Education Center, Sanford, FL 32771-9608 USA

In recent years, massive swarms of adult Chironomidae emanating from a variety of natural and artificial habitats distributed worldwide have been reported. These swarms have increasingly posed nuisance and economic problems and in some situations medical problems to waterfront residents, workers, visitors and business and industrial establishments. Among the many organophosphate (OP) insecticides used as midge larvicides, temephos has been the larvicide of choice in many situations. The insect growth regulators (IGRs), methoprene, pyriproxyfen and diflubenzuron are excellent substitutions, especially against temephos- or OP-resistant chironomids. Chemical formulation research has revealed the usefulness of sustained-release formulations of OPs and IGRs in providing satisfactory and more economical immediate as well as long-term control of chironomids. The bacterium, *Bacillus thuringiensis* serovar. *israelensis*, when used at high rates, is effective against some Chironominae. Some species of fish have reduced larval Chironomidae for short durations. Attraction of some adult Chironomidae to light (quantity or quality) can be useful to divert or trap the adults. Physical and chemical ecological changes of chironomid larval environments may result in reducing midge nuisance in some situations.

11-046

LIFE HISTORY OF
CALOPTERYX HAEMORRHOIDALIS
(ODONATA: CALOPTERYGIDAE).

Prof. Dr. Georg Rüppell, Dipl. Biol. Dagmar Hilfert
Zoologisches Institut, -Ökologie-, Technische Universität,
Braunschweig, Germany

C. haemorrhoidalis lives in Southern Europe. Mating behaviour with threatening- and courtship flight (filmed in slow motion up to 500 frames/ second), and copulation as well as a computer animation of the internal processes (sperm removal) are presented. The film shows submerged oviposition, a computer animation of fertilization of the eggs, and the hatching of larvae from eggs. In summer a high density of individuals and high air temperatures are stress factors. How do they influence the population numbers of *C. haemorrhoidalis*? The film shows the results of our working group as well as other ecological aspects of this wide-spread mediterranean species.

11-045

STRATEGIES TO REDUCE THE ENVIRONMENTAL IMPACT OF CURRENT CHIRONOMID MANAGEMENT PRACTICES IN AUSTRALIAN RICE FIELDS

M. M. Stevens

Yanco Agricultural Institute, NSW Agriculture, Yanco, Australia

Chironomid larvae, particularly those of *Chironomus tepperi* Skuse, are important pests of rice in New South Wales, Australia. They are effectively controlled with the organophosphorus insecticides malathion and chlorpyrifos, however, these compounds are currently under close scrutiny by the NSW Environment Protection Agency and other groups concerned with pesticide contamination in drainage water. The allowable drainage limit for chlorpyrifos is set at 1 ng/L, a level which will preclude the continued use of this compound as a larvicide.

Research is currently being directed towards identifying replacement compounds with a narrower spectrum of activity against aquatic organisms. Of those examined, the phenyl pyrazole compound fipronil is particularly promising. Development of rice varieties resistant to chironomid attack represents a possible method of reducing chemical inputs, and screening trials have shown that lines derived from the water weevil resistant variety WC-1403 may be particularly valuable. *C. tepperi*, which has only a single generation in rice fields, strongly avoids ovipositing into water conditioned by the presence of chironomid larvae, conspecific or otherwise. Identification of the semiochemical responsible may lead to the development of an oviposition deterrent that will allow further reductions in the use of synthetic insecticides.

11-047

FEEDING MECHANISM AND PATTERNS OF ADVANCED INSTAR LARVAE OF *UROTHEMIS ASSIGNATA* (SELYS) (ODONATA: LIBELLULIDAE)

S. S. OGBOGU, A. T. HASSAN'
Department of Zoology, Obafemi Awolowo University, Ile-Ife, Nigeria. 1, Entomology Research Laboratory Department of Zoology, University of Ibadan, Ibadan, Nigeria.

Under laboratory condition, 9th 10th and 11th instar larvae of *Urothemis assignata* (Selys) kept still on detecting prey, waiting for it to encroach on the strike range before it was captured. Stalking of prey was not common and grasping of prey was efficient, especially with small-sized prey. Ingestion followed successful capture of prey, interspaced by a brief period of rest.

The compound eye was the main organ for detecting the presence of prey while antennae and tarsi served as auxilliary organs. The movement pattern of prey significantly affected the ability of larva to detect and capture prey (ANOVA, $P < 0.05$). Larvae exhibited increased food intake as deprivation time increased, and got satiated at 48.88 min.

11-048

ODONATA IN TROPICAL FORESTS: DO THEY INDICATE THE CONSERVATION VALUE? THE ANALYSIS OF THE ODONATA-FAUNA IN FORESTS OF EASTERN IVORY COAST:

M. Mühlenberg¹, J. Slowik¹, W. Schneider²

1- Zentrum für Naturschutz der Universität Göttingen, D - 37075 Göttingen, Germany.

2- Hessisches Landesmuseum, Zoologische Abteilung, D - 64283 Darmstadt, Germany.

Seven „Forêts classées“ in the Eastern Ivory Coast, Westafrica, are the subject of an extensive rehabilitation programme from the GTZ (Gesellschaft für Technische Zusammenarbeit, Eschborn, German ODA). The forests are in different state of degradation. To ensure a rehabilitation „réserves biologiques“ are excluded from further management. In Europe the use of the Odonata group in the implementation of conservation goals is quite common. There are no experiences in tropical countries.

We compared the Odonata fauna between different forest types and between small woodland rivers and open streams. Although the fauna of Odonata in the Ivory Coast has been already studied, serious problems of determination of the adults arised. We could identify at least 50 species, about 160 species are expectet in the Ivory Coast. The species can be classified to species of stagnant and flowing waters. Most of the year the forest rivers have running water. In the dry season the small rivers are divided in many small ponds for a period of about three months. The Odonata of running water bridge this period as adults. The point diversity of the Odonata fauna is high due to the diverse natural conditions in the tropical forest. The Odonata-community in the forest differs strongly from the species assemblage of the open stream. The quality of rivers is influenced by the whole watershed. A lot of species of Odonata are confined to primeval conditions so that their occurence indicates river- and forest-quality of high conservation value. In that way the study of Odonata is a useful tool for the evaluation of a very complex ecosystem.

11-050

COMPARATIVE MORPHOLOGY OF THE SECONDARY MALE GENITALIA OF SELECTED LIBELLULOID DRAGONFLIES (ODONATA: LIBELLULOIDEA)

M. May

Department of Entomology, Rutgers University, New Brunswick, NJ USA

Internal and external cuticular morphology and musculature of the secondary genitalia, i.e., the penis and associated structures on the 2nd and 3rd abdominal segments, are described in male *Zoraena diastatops* Selys (Cordulegastridae), *Gomphomacromia paradoxa* Brauer (Gomphomacromiidae), *Oxygastra curtisii* (Dale) (Corduliidae*), *Didymops transversa* (Say) (Corduliidae*), *Cordulia shurtleffi* Scudder (Corduliidae*), *Macrodiplax balteata* (Hagen) (Libellulidae), and *Libellula incesta* Hagen (Libellulidae). *Zoraena* and *Gomphomacromia* retain symplesiomorphic penile morphology (4th segment symmetrical, sperm pump emptied upon compression of the sperm vesicle), while *Oxygastra*, *Didymops*, and *Cordulia* exhibit distinct torsion of the 4th penis segment and a sperm pump that fills upon vesicle compression; the Libellulidae s.s. have symmetrical penes (possibly apomorphically so) and a sperm pump that fills on compression. *Zoraena*, *Oxygastra*, and *Didymops* all have a well developed anterior hamular depressor muscle (M9a_{II}), whereas this is lost independently in *Gomphomacromia* and the libellulids. Libellulidae share the unique apomorphies of M9b_{II} being lost and M4_{II} and M6_{II} (both well developed) originating near the anterior margin of segment 2 rather than near midlength.

*Conventional family designations are used for convenience, although recent evidence suggests that the Corduliidae, even with Gomphomacromiidae s.s. excluded, are paraphyletic.

11-049

THE WARMING UP STRATEGY OF IMMATURE *AESHNA MIXTA* (ANISOPTERA: AESHNIDAE)

R. Stoks^{1,2}, M. Santens², L. De Bruyn², and E. Matthysen¹

1 Laboratory for Animal Ecology, Department of Biology, University of Antwerp, Belgium - 2 Evolutionary Biology Group, Department of Biology, University of Antwerp, Belgium

In dragonflies, as in most other flying insects, the thoracic temperature has to reach a certain level before flight is possible. Dragonflies can warm up both ectothermically or endothermically (by shivering). This has already been shown in adults of the genus *Aeshna* and is thought to be absent in immatures. Because shivering increases the thoracic temperature, it is expected that this also reduces the duration of the pre-flight period. Since the rate of increase in thoracic temperature is related to ambient temperature, we also expected a negative relation between shivering and the ambient temperature.

We tested the presence of endothermic warming up and the effects of ambient temperature and shivering on the duration of the pre-flight period on 27 immature *Aeshna mixta*.

We show that also maturing *A. mixta* can use shivering. The duration of shivering was negatively, but just not significantly, correlated with the ambient temperature. The duration of shivering and the ambient temperature did not affect the duration of the pre-flight period. Shivering intensity however significantly reduced the time prior to take-off. Our results further suggest that abdominal shivering may be part of an endothermic strategy. We discuss our findings in the light of eocrepuscular flight, that until now has only been observed in mature dragonflies.

11-051

INTRASPECIFIC INTERACTIONS OF LARVAL ODNATES G.I. Ryazanova

Department of Entomology, Faculty of Biology, Moscow State University, Moscow, Russia

The spatial behaviour of dragonfly larvae was studied in the laboratory. Methods of direct observations and filming and video were used. Only significant quantitative results were discussed. The subjects were F - F-3 larvae of 14 zygopteran and anisopteran species.

Territorial competition has been found to characterize all the studied species. In middle and older instars territorial competition is not associated with person's age and sex. It is an adaptive species-specific and plastic behaviour. That territorial competition is one of the mechanisms for spatial organization of larval communities, regulating their distribution. It is determined by relative population density. That form of behaviour can be substituted by another form (aggregation or accidental distribution) in stress condition.

Cannibalism and the deficit of the refuges was been the factors of evolution of dragonfly larvae territorial competition.

The special form of territorial competition is shown by larvae of the last instar several days before emergence. That form is associated with the larval sex. That behaviour can be regarded as a precursor of the imaginal one in these hemimetabolic insects.

The investigation demonstrated the sample of the intraspecific interactions of watching predatory insects as exemplified by dragonflies.

11-052

THE MATING SYSTEM OF THE DAMSELFLY *LESTES SPONSA* (ZYGOPTERA: LESTIDAE)

R.Stoks^{1,2}, M.Santens², L.De Bruyn², E.Matthysen¹
1 Laboratory for Animal Ecology, Department of Biology, University of Antwerp, Belgium - 2 Evolutionary Biology Group, Department of Biology, University of Antwerp, Belgium

We studied a population of the damselfly *Lestes sponsa* which shows extreme contact mate guarding at a small shallow pond from 17 July till 11 August 1994. Every animal in the population was individually marked with a number written on its wings with a permanent marker, which made it possible to recognize animals without capturing them. Each day we walked around the pond every half hour recording every animal with its code, sex, position at the pond and reproductive state (solitary, tandem, copula or ovipositing). Males did not defend territories, instead there was intense interference competition with tandem pairs. We discuss how the adaptation of the genus *Lestes* to live in temporary ponds may have impeded the evolution of territoriality. Mate choice is thought to be very limited. Species recognition by males is reduced and thought to be unadaptive in this species. The mating system can best be described as 'female control' with encounter-limited mating by the males. This is the first description of a combination of two mating strategies sensu Conrad and Pritchard (1992) in one species. We discuss the predictions made by Conrad and Pritchard for the female-control mating system and make predictions about the occurrence of the combined mating type.

11-054

TAXONOMIC REVISION AND PHYLOGENETIC ANALYSIS OF THE GENUS *OREODYTES* SEIDLITZ (COLEOPTERA: DYTISCIDAE: HYDROPORINAE) BASED ON LARVAL MORPHOLOGY.

Y. Alarie
Department of Biology, Laurentian University, Ramsey Lake Road, Sudbury, Ontario, Canada, P3E 2C6

The larval morphology of the dytiscid genus *Oreodytes* Seidlitz is investigated through a detailed analysis of 16 Nearctic and two Palearctic species. Many structural features, especially those of chaetotaxy and porotaxy of head capsule, head appendages, legs, last abdominal segment, and urogomphi were found to be useful for taxonomic and phylogenetic comparisons. Within the tribe Hydroporini, it is proposed that *Oreodytes* shares a monophyletic origin with the genera *Deronectes* Sharp, *Scarodytes* Gozis, *Nebrioporus* Régimbart, and *Stictotarsus* Zimmermann. The classification of members of *Oreodytes* indicated by larvae reveals to be only partly reconcilable with the one indicated by adults. Once subdivided into three species-group, *Oreodytes* is now comprised of four species-groups: the *O. picturatus*, the *O. obesus*, the *O. scitulus*, and the *O. quadrimaculatus* species-groups. *Oreodytes quadrimaculatus* was found to be more closely related phylogenetically to members of the *O. picturatus* and *O. scitulus* species-group which share a monophyletic origin. The genus-name *Neonectes* J. Balfour-Browne is suggested as a junior synonym of *Oreodytes* as it is hypothesized that their members are closely related phylogenetically with those of the *O. scitulus* species-group.

11-053

PHREATOBIONTIC BEETLES OF JAPAN (COLEOPTERA: PHREATODYTIDAE AND DYTISCIDAE)

S.-I. Uéno
Department of Zoology, National Science Museum (Nat. Hist.), Shinjuku, Tokyo, Japan

Ten species with a subspecies of phreatobiontic beetles are now known in Japan, all from the western parts of the main islands, though only three of them were previously described. They are: 6 species of *Phreatodytes* of the Phreatodytidae, 3 species and 1 subspecies of *Morimotoa* of the dytiscid tribe Hydroporini, and 1 species of a new genus of the dytiscid tribe Hyphydrini. The six species of *Phreatodytes* are classified into 3 species-groups, which show every step of reduction of the marginal furrows of the prothorax and elytra. Most archaic is a new species endemic to southeastern Kyushu, which looks like a miniature of *Metrius*. On the contrary, the type of the genus, *P. relictus*, and its new relative are most derivative as they have lost most parts of the furrows. This can be regarded as a positive proof that the Phreatodytidae is more primitive than the Noteridae and is independent from the latter. The three known species of *Morimotoa* form a rather compact group, which is evidently different from epigeal genera, while the hyphydrine new species is relatively similar in general conformation to epigeal species, with the obvious exception of the absence of eyes and the depigmentation. Other new species of phreatobiontic beetles should occur in the Japanese Islands, but after the 1950's, it has become extremely difficult to obtain new material because of rapid disappearance of driven wells.

11-055

MORTALITY FACTORS AFFECTING THE ARID DIAPAUSING DYTISCID *AGABUS DISINTEGRATUS* IN CALIFORNIA

R. Garcia, W. G. Voigt, K. S. Hagen
Center for Biological Control, University of California at Berkeley 94720

The dytiscid *Agabus disintegratus* breeds from fall to spring in seasonal wetlands in California. In the spring, teneral adults move to the water from embankment pupation sites. They feed and develop fat reserves prior to entering aestival diapause. As the habitat dries in the late spring, the adults take refuge at the soil-root interface of wetland plants where they pass the late spring, summer, and early fall in the absence of water. Adults cannot be induced to fly during diapause, but surface movement by some aestivating beetles is common during this dry period. Movement is apparently related to the quest for more optimal conditions. Mating and oviposition commence in the fall after inundation. Larvae develop through the late fall and winter and begin pupation in late February. Observed mortalities include an estimated 20% pupal parasitization by the ichneumonid, *Medophron* sp., and desiccation of adults prior to emergence and after aestival diapause. Mortality of larval populations will also be discussed.

11-056

THE *HYPHYDRUS* SPECIES OF THE ORIENTAL AND AUSTRALIAN ZOOGEOGRAPHICAL REGIONS (COLEOPTERA: DYTISCIDAE)

O. Biström, L. Hendrich & A.H. Kirk-Spriggs

The *Hyphydrus* fauna recorded from the Oriental and Australian zoogeographical regions is reviewed. At present 29 species belonging to five species groups are recognized. The distribution of the species is given on country-level and the origin of the different species groups is briefly discussed. A new *Hyphydrus* species from the Aru Islands in Indonesia is presented. The new species belongs to the species group *H. signatus*.

11-057

A NEW SPECIES OF *LACCOPHILUS* LEACH FROM EAST KALIMANTAN (COLEOPTERA: DYTISCIDAE)

Paolo Mazzoldi

A new *Laccophilus* belonging to the group *javanicus* Régimbart, recently collected in East Kalimantan (Borneo, Indonesia), is described. Habitus and genitalia of the new species are figured and diagnostic characters which differentiate it from the other species of the same group are illustrated.

The new species lives in small springs and in the first stretch of streams originating from them in primary rainforest.

11-058

AN ANALYSIS OF COMMUNITY-STRUCTURE AND HABITAT-PREFERENCE OF ADEPHAGE WATERBEETLES (COLEOPTERA: HALIPLIDAE, NOTERIDAE, DYTISCIDAE) IN CENTRAL EUROPE, USING 17 PHYSICOCHEMICAL PARAMETERS

J. Schmidl

Institut für Zoologie I, Universität Erlangen-Nürnberg, Germany

In a study of 60 random-sampled stagnant waters in Franconia the Hydradeephaga fauna was recorded semiquantitatively and 17 physicochemical parameters were analysed.

Using Canonical Correspondence Analysis TER BRAAK 1986, species data show distinct species assemblages, referring to 3 major types of waters:

- 1: bogs and acid, oligo- to mesotrophic woodpools: *bog-community*, with a sphagnophilic and an umbrophilic aspect;
- 2: polytrophic ponds and pools in open landscape: *pond-community*;
- 3: raw-bottom waters (sand-, claypits etc.): *raw-bottom-community*.

This three types of communities are „connected“ by transitions depending on succession in the waters. On the basis of 12 waters each recorded in spring, summer and autumn, it can be shown that the ordination of waters of the first two types is quite independent of season and therefore reproducible. In contrast raw-bottom pools show great seasonal variety in accordance with quick ecological succession.

In a Monte Carlo permutation test the 17 physicochemical parameters were tested for each parameters contribution to explanation of variation in species data. The test exhibits high significant ($p < 1\%$) or significant ($p < 5\%$) correlation for the parameters pH, conductivity, chloride, oxygene, carbonate hardness, total hardness, nitrite, sulphate, nitrate and temperature (in order of descending correlation).

The results are discussed towards building up an indicator-system for stagnant waters based on adephaga waterbeetles, especially for use in landscape ecology and monitoring.

11-059

WATER BEETLES (COLEOPTERA: ADEPHAGA) FROM EVACUATION ZONE OF CHERNOBYL NUCLEAR POWER STATION

M.D. Moroz, E. Biesiadka¹

Institute of Zoology, Academy of Sciences, Minsk, Belarus - ¹ Teacher Training College, Olsztyn, Poland

Present communication is based on the samples of water Adephaga which were collected during 1991-1995 near the Chernobyl Nuclear Power Station.

78 species of water beetles were found. They belongs to four families: Haliplidae - 7; Noteridae - 2; Dytiscidae - 62 and Gyrinidae - 7 species. Registration of 5 species, which at present period are still not recorded from other regions of Belarus (*Haliplus heydeni* Wehncke, *H. furcatus* Seidlitz, *Coelambus parallelogrammus* (Ahrens), *Agabus bifarius* (Kirby), *Gyrinus suffriani* Scriba) is of particular interest.

According to the results of our investigations one can state that radioactive contamination did not influence significantly beetle species diversity.

11-060

INVERTEBRATES OF THE TERRESTRIAL INTERSTICES IN AN ALPINE FLOODPLAIN
Martin Dieterich
Fachbereich Biologie, Fachgebiet Naturschutz,
Philipps-Universität Marburg, Marburg, Germany.

Sediment baskets and tube-traps were designed to study the terrestrial arthropod community in gravel bar interstices along the Isar river (Bavaria, Germany). Sediment baskets filled with selected substrates were exposed at different depths (25 cm, 50 cm, 75 cm) in the gravel bed to allow for colonization. Tube-traps were installed to continuously collect animals moving through the sediments at 25 and 50 cm below the surface.

Initial results suggest that a specific arthropod community consisting of mites, spiders, springtails, the true bug *Cryptostemma alienum* Herrich-Schäffer (Dipsocoridae), larval Diptera, larval and adult Staphylinidae and Carabidae colonizes gravel bar interstices.

Different species of mainly surface active *Bembidion* use crevices in the gravel bed for hibernation. Hibernating beetles were collected down to a depth of about 1 m, preferably in coarse substrates just above the level of the subsurface flow.

11-062

ANIMAL COMMUNITIES ASSOCIATED WITH BAMBOO PHYTOTELMATA IN PENINSULAR MALAYSIA

D. Kovac¹, B. Streit²

¹ Forschungsinstitut Senckenberg, Frankfurt a. M., Germany
² Zoologisches Institut, J. W. Goethe-Universität, Frankfurt a. M., Germany

In recent years micro-ecosystems, for example, small water bodies held in terrestrial plants (phytotelmata), have increasingly been used to investigate fundamental biological problems. We found that bamboo phytotelmata are particularly suitable for studying the structure and dynamics of tropical animal communities. This ongoing investigation was begun in 1991 at the Ulu Gombak Field Studies Centre, near Kuala Lumpur.

Bamboo phytotelmata are created when the bamboo culm is punctured by insects or otherwise injured and then becomes filled with runoff rainwater. We first took a survey of the aquatic and terrestrial animal taxa inhabiting the internode cavity. Later on, we studied the spatial and temporal patterns of the animal community, the food webs and the life histories of some internode inhabitants. For the observation of the animals we used an endoscope.

We found that the internodes harbour a specialized fauna which mainly consists of arthropods. In the aquatic zone Diptera, especially mosquitoes, form the largest group of inhabitants. In the terrestrial zone a hitherto completely unknown animal community was discovered. Two remarkable features of the internode fauna are that some terrestrial predators, e. g. rove beetles or jumping spiders, are preying upon aquatic Diptera larvae and that representatives of many usually terrestrial taxa have adopted an aquatic mode of life. Furthermore, we found that different types of internodes, e.g., shoot internodes or decaying internodes, harbour different animal communities. In all, several hundred species were found, which makes the bamboo internodes among the most species-rich of all phytotelma-communities.

11-061

ARCTIC INSECTS:
DESICCATION VERSUS CRYOPROTECTION

R.A. Ring

Biology Department, University of Victoria,
Victoria, B.C. V8W 2Y2, Canada

Many adaptations allow insects to survive the extreme conditions of arctic Canada. Some of these adaptations such as overwintering microhabitat selection, blood solute biosynthesis and body water content have been correlated in many ways with cold-hardiness. Such adaptations, however, may also contribute significantly to enhanced desiccation resistance and/or tolerance. The concerns that many of the ecological and physiological adaptations that have hitherto been interpreted as contributing to cold tolerance may also ensure winter survival to insects in cold, dry environments will be discussed.

11-063

FIRE AND WATER: COMPARISON OF THE ENVIRONMENT AND EVOLUTION OF CAVE-ADAPTED INSECTS IN VOLCANIC AND KARSTIC CAVES

F.G. Howarth

Department of Natural Sciences, Bishop Museum, Honolulu, HI, USA

The discovery of cave-adapted insects in volcanic caves provides opportunities to test the evolutionary theories resulting from historic biospeleological studies in limestone caves. Compared to lava caves, limestone caves are usually older, deeper, larger, and more complex three-dimensional mazes, which connect with fewer mesocaverns, and which are often subjected to more complex geologic histories. Despite these major geologic differences, both volcanic and karstic caves harbor specialized insects that display similar adaptations, indicating that their evolution must be similar. Beyond the influence of entrances, the environment in subterranean habitats is similar in both cave types, being perpetually dark, humid, and nearly isothermal; lacking most environmental cues; and often containing lethal or sublethal gas mixtures and wet barren rocky substrates. Food resources differ greatly between lava and limestone caves, but the difficulty in finding food, as well as mates, are similar. The surface over both cave types is often at least partly barren, with food resources sinking into subterranean voids out of reach of surface species. Specialized cave animals evolved to exploit these resources in the harsh environment. Lava and limestone cave communities may accumulate and lose species differently over time. In limestone caves, succession progresses downward, with younger, energy-rich habitats deeper below the surface and relict unsuitable passages nearer the surface. Succession in lava caves is opposite, with younger habitats nearer the surface and older habitats deeper. In volcanically active areas, new lava flows continually rejuvenate aging cave habitats, allowing specialized species to occur in exceptionally young caves.

11-064

PHYLOGENY AND THE STUDY OF TROGLOBITIC TAXA

Laure DESUTTER

EP 90 CNRS, Laboratoire d'Entomologie, Muséum National d'Histoire naturelle, Paris, FRANCE

As in every field of Comparative Biology (1), phylogeny provides an independent reference system in evolutionary studies on cave life to test current theoretical proposals (2, 3). Using phylogeny, sound hypotheses on the ancestral states of characters and their subsequent changes can be made by polarising the characters between related taxa (4, 5). Also hypotheses on evolutionary processes can be tested by comparing the patterns they imply with independently inferred phylogenetic patterns (6).

Two classical assumptions on the evolution toward troglobitic life have been analysed with this methodology : 1/ troglobitic taxa could be defined by troglomorphic characters, and 2/ troglobitic life would be an evolutionary dead-end.

Using phylogenetic analysis, so-called troglomorphic features may or may not occur in troglobitic taxa. These taxa can be characterised only by their behavioural ecology : they live, forage and reproduce exclusively in the subterranean environment. Preadaptations (exaptations) can also be precisely defined.

The evolution toward cave life does not appear to be a dead end. Two patterns subsequent to cave life appearance have been documented : speciation of troglobitic taxa in the subterranean environment, and reversal to an epigeal habitat. Troglobitic life thus appears as one step in clades diversification.

1, Grandcolas, P. & al. 1994. *Acta Oecologica*, 15 : 661-673. 2, Juberthie, C. 1984. *Mém. Biospéol.* 9 : 65-102. 3, Peck, S.B. & Finston, T.L. 1993. *Mém. III, 317 (10): 907-912. 6, Desutter-Grandcolas, L. & Grandcolas, P. 1996. *Mém. Biospéol.* (in press).

11-066

SURFACE AND CAVE SPECIES OF *NOCTICOLA* (NOCTICOLIDAE): EVIDENCE FOR EVOLUTION OF NON-RELICTUAL TROPICAL TROGLOBITES

F. Stone

Hawai'i Community College, Hilo, Hawai'i, USA

Cave-adapted species of *Nocticola* were first discovered in caves of the Philippines in 1890, followed by additional cave and surface species of the family Nocticolidae from Africa, South Asia and Southeast Asia. According to the glacial relict theory of cave species evolution, obligate cave species should not have evolved in the tropics, due to lack of a major isolating mechanism that would have eliminated the troglomorphic parent species. Since the 1970's, many additional cave species of *Nocticola* have been collected from caves of Thailand, Malaysia, Indonesia and Australia. These include several highly cave-adapted species associated with "bad-air" caves. Epigeal relatives of the cave *Nocticola* have been found in Australia using light traps and intensive searches of forest floor. Presence of highly cave-adapted species of *Nocticola* in areas where surface relatives still exist can be explained by bioclimatic and adaptive shift models of cave species evolution.

11-065

THE HAWAIIAN CAVE PLANTHOPPERS (HOMOPTERA CIXIIDAE) - A MODEL FOR RAPID SUBTERRANEAN SPECIATION?

H. Hoch

Institut für Systematische Zoologie, Museum für Naturkunde, Humboldt-Universität Berlin, Berlin, Germany

After the successful colonization of a single ancestral species in the Hawaiian Islands, the cixiid genus *Oliarus* underwent intensive adaptive radiation resulting in 80 described endemic species. *Oliarus* habitats range from montane rain forests to dry coastal biotopes, and to subterranean environments: at least 7 independent evolutionary lines have adapted to lava tubes on Molokai (1), Maui (3), and Hawaii Island (3). Behavioral and morphological studies on one of these evolutionary lines on Hawaii Island, the blind, flight- and pigmentless *Oliarus polyphemus* have provided evidence for the reproductive isolation between allopatric populations which may in fact be separate species. Significant differences in song parameters were observed even between populations from neighbouring lava tubes, although the planthoppers are capable of underground migration through the voids and cracks of the mesocavernous rock system which is extant in young basalt: after a little more than 20 years, lava tubes within the Mauna Ulu 1974 flow had been colonized by *O. "polyphemus"* individuals, most probably originating from a near-by kipuka. Amazingly, this species complex is found on the youngest of the Hawaiian Islands, with probably less than 0.5 m.y., which suggests rapid speciation processes. Field observations have led to the development of an hypothesis to match underground speciation with the dynamics of vegetational succession on the surface of active volcanoes: planthopper range partitioning and geographic separation of populations by young lava flows, founder events and small population size may be important factors involved in rapid divergence. Approaches to test this hypothesis are introduced and discussed.

11-067

CLIMATIC FLUCTUATIONS AND TROPICAL TROGLOBITIC EVOLUTION

P. Gnaspini

Departamento de Zoologia, Instituto de Biociências, Universidade de São Paulo, São Paulo, Brasil

Allopatric speciation of cave organisms requires geographic isolation as a result for instance of local extinction of epigeal populations. A classical model proposed to explain the origin of terrestrial troglobites in temperate zones relates this local extinction to long-term climatic fluctuations, such as Pleistocene glacial cycles. From this model, it is predicted that: 1) Regions subject to more frequent and accentuated fluctuations will present a higher ratio troglobitic/troglophilic species, especially in the case of terrestrial fauna. 2) Dry, arid or semi-arid areas will bear the most specialized troglobites.

This model can be applied to the origin of tropical troglobites as well, especially for terrestrial organisms. Evidences of Quaternary climatic changes in tropical South America are indisputable, indicating drier climates related to glacial periods. Moreover, preliminary comparative data on the composition of Brazilian cave fauna seems to fit those predictions.

For instance, relatively few terrestrial troglobites are found in those areas in Central Brazil which remained covered by a cerrado vegetation similar to that of the present time during the last glacial period.

Highly specialized troglobites and some "relictual" hygrophilic organisms have been found in caves of northeastern Brazil (and in the Argentinian Patagonia). These animals may have colonized the subterranean biotope during the short periods of higher humidity (possibly near the interglacial maxima) and became isolated for long periods since then (including the glacial and part of the interglacials).

Less specialized troglobites are found in areas now covered by humid vegetation but that had dried during glacial periods, as seems to be the case of the southeastern Brazil. It probably happened because the total time of isolation is shorter (all or part of the glacial).

11-068

CARABID BEETLES AND SUBTERRANEAN ENVIRONMENTS

A. Vigna Taglianti, A. Casale¹
Dipartimento di Biologia Animale e dell'Uomo, Università di Roma "La Sapienza", Italy - ¹ Istituto di Zoologia, Università di Sassari, Italy.

Carabid beetles, polyphagous predators and/or omnivores, are a successful, highly diverse group of Coleoptera, represented in a wide range of biomes, from temperate to tropical and boreal regions. Mostly winged, often arboreal in tropical forest communities, they became true "ground beetles" in temperate lands: in these countries, many species are brachypterous, montane, nocturnal, often steno-hygrophilous soil dwellers. These are excellent conditions for a pre-adaptation to the subterranean environment.

With the exclusion of the heliophylous (Cicindelinae) or phytophagous (Harpalinae, and Amarini plus Zabritini among Pterostichinae) elements, several groups of carabid beetles colonise different subterranean compartments (endogean, upper hypogean zone and caves). Large numbers of subterranean species are included in the Clivinini Reicheiina, Anillini, Trechini, Platynini, Sphodrini, Pterostichini and Molopini. A few highly specialised (upper hypogean and/or cave dwelling) species are found also in the tribes Ozaenini, Calleidini, Zuphiini and Brachinini, but the largest number of such specialised elements belong to the tribe Trechini.

Distribution patterns of subterranean carabids are not homogeneous throughout the world. The areas with the highest diversity in specialised elements are the boreal and austral temperate 'mediterranean' zones while tropical lands are particularly rich in endogean species.

11-070

INTRODUCTION TO PHYLOGENY AND EVOLUTION OF SUBTERRANEAN AND ENDOGEAN CHOLEVIDAE (= LEIODIDAE CHOLEVINAE)

Stewart B. Peck, Department of Biology, Carleton University, Ottawa K1S 5B6

This is an introduction to phylogeny and evolution in subterranean and endogean Cholevinae, a group within the Staphylinoid assemblage of beetle families. I review ideas on the monophyly of the family groups and prefer to use an expanded family Leiodidae; containing the subfamilies Camiarinae, Catopocerinae, Leiodinae, Coloninae, Platypsyllinae, and Cholevinae. These groups have very diverse biologies. Most are scavengers or fungal feeders, but some are ectoparasites. Some show clear and ancient "transantarctic" distributions. The Cholevinae represent the world's greatest (after Carabidae) endopterygote insect radiation in soil and cave habitats. I review some of the adaptations, morphologies, and biologies of this interesting fauna, drawing mostly from European and North American examples. Topics of productive future research are suggested.

11-069

HISTORICAL BIOGEOGRAPHY OF JAMAICA: EVIDENCE FROM CAVE INVERTEBRATES

Stewart B. Peck, Department of Biology, Carleton University, Ottawa K1S 5B6

The biogeographic history of the West Indies, and Jamaica in particular, is controversial. This paper examines historical clues in the invertebrate cave fauna of Jamaica. Cave faunas are frequently considered to be archaic and relictual, and thus could provide possible clues to early regional biogeographic history. The troglobitic (cave specialized) fauna contains (1) 12 freshwater-brackish water species (mostly crustaceans) that have invaded from the sea, and (2) 25 species of terrestrial arachnids and insects. Cladistic analyses suggest a closer relationship to Central America than to Cuba-Hispaniola. There is no strong evidence for a vicariance origin of the fauna in a continuously subaerial environment since separating from proto-middle America. Over-water dispersal seems to account for the presence of the ancestors of the troglobitic fauna in Jamaica, and they probably arrived after Jamaica became emergent, about 20 million years ago.

11-071

CONSIDERATIONS ON THE PRESENT KNOWLEDGES ABOUT THE ITALIAN CHOLEVIDAE AND THEIR DISTRIBUTION, WITH PARTICULAR REFERENCE TO THE HYPOGEAN SPECIES (COLEOPTERA)

S. Zoia
Genova, Italy

The Italian Cholevidae fauna includes at present some 265 species (187 of which only belong in Leptodirinae) arranged in 50 genera. An overview of each genus is given showing some of the main aspects of the biology and the distribution both of each genus in its whole and of some more significant species.

Referring to the major groups, it is reported that: - Nemadinae have in Italy only one central-european species; - Ptomaphaginae include some central-european species as well as some W-mediterranean, circumadriatic or endemic ones; - Anemadinae are, in the whole, mediterranean with two endemic species; - Cholevini include principally central-european or european species; also some endemic species are present; - Catopini are represented by several european or central-european species, but also olarctic, palaearctic, mediterranean, S-mediterranean or endemic taxa occur; - Leptodirinae have, in general, endemic genera, being Bathysciola, Parabathyscia and Speonomus only with a wider distribution.

All the Italian Cholevidae are related to the soil fauna; Leptodirinae include a lot of endogean or hypogean species, while only some representatives of other subfamilies occur more or less regularly in cave environment.

Some aspects of the systematic and distribution of the Italian Cholevidae are discussed.

11-072

CLADISTIC BIOGEOGRAPHY OF CAVERNICOLOUS
PTOMAPHAGUS (LEIODIDAE: CHOLEVINAE:
PTOMAPHAGINI) IN THE UNITED STATES

Stewart B. Peck, Department of Biology, Carleton University,
Ottawa K1S 5B6

Cavernicolous species of *Ptomaphagus* occur on three continents; most occur in the southeastern United States. This paper examines the 18 species of the *P. hirtus* species group of troglobites in the southeastern USA. Predictions of the speciation models, cladograms, and area cladograms suggest (1) periods of successive glacial overland dispersal, and (2) cladogenesis by climate induced (vicariant) interglacial isolation in caves. Adjacent and non-overlapping (parapatric) ranges of the species show the possibility of competitive exclusion for the prevention of sympatric distributions.

Vicariance Biogeography is a method of construction of general area cladograms to attempt to learn the histories of regional biotas. *Ptomaphagus* is proposed as a model for use in seeking general-area cladograms of geographic patterns in southeastern US terrestrial cave faunas. Have the terrestrial cave faunas been assembled by climatically coordinated community vicariance events (as predicted when general area cladograms can be found)? Or, have cave faunal assemblages come together in a random (non-coordinate) way, controlled by multiple external physio-geographic barriers? Is the biogeographic history of cave faunas in general that of (1) individualistic random (non-predictive) dispersal events, or (2) coordinated vicariance biogeography? Cladistic analyses of many components of regional cave faunas are necessary to answer such questions. Because of the similar ecological requirements of terrestrial cave faunas, they should be a good model system for testing principles of vicariance biogeography.

11-074

A SYSTEMATIC REVISION OF *ADELOPSIS* AND COMMENTS ON
THE PHYLOGENY OF THE PTOMAPHAGINI
(COLEOPTERA, CHOLEVIDAE)

P. Gnaspini

Departamento de Zoologia, Instituto de Biociências, Universidade de São Paulo, São Paulo, Brasil.

The genus *Adelopsis* was previously defined to include the Neotropical species of the Ptomaphaginae (presently 25 species) with aedeagus different from that of *Ptomaphagus*. Afterwards, it was redefined with the description of 16 species from the Appalachians (USA) in 1978. The recent study of Brazilian cavernicolous species warned about the paraphyletic condition of the genus and the need of a systematic revision. The study of the large collection of S.B. Peck, from Canada, led to the recognition of more than a hundred undescribed species and corroborated the paraphyly of the genus.

A cladistic analysis was made based on characters studied from several species in the genera of the tribe and allied cholevids. The resulting cladogram helped in the definition of four new genera and the redefinition of the previous recognized genera. Some previously described species of *Adelopsis* are transferred to the new genera. The group of Appalachian species of *Adelopsis*, as well as the genera *Echinocoleus* and *Synaulus*, are defined as subgenera of *Ptomaphagus*. The subtribe Ptomaphagina, which includes *Ptomaphagus* and *Proptomaphagus*, resulted to be paraphyletic.

In these new definition, the genus *Ptomaphagus* includes several probably independent lineages with subterranean evolution, including endogean, myrmecophilic and troglitic species, some showing highly evolved related morphology. In the other genera, as in *Adelopsis*, *Proptomaphagus*, and *Ptomaphagus*, some species also colonized the subterranean environment, although only few show eye, wing and/or pigmentation reductions. In *Adelopsis*, these reductions seem to be specially related to litter inhabiting species.

11-073

CAVE AND ROCK DEBRIS DWELLING SPECIES OF THE
CHOLEVA AGILIS SPECIES GROUP FROM CENTRAL
EUROPE (COLEOPTERA: LEIODIDAE: CHOLEVINAE)

Jan Růžička

Department of Ecology, Faculty of Forestry, Czech Agricultural University, Praha, Czech Republic

In central Europe, five (from the total number of 11) species of the *Choleva agilis* species group have been known: widely distributed epigean *C. agilis* (Illiger, 1798); *C. lederiana* Reitter, 1901 (S Finland and NW Russia; epigean as well as cave records); *C. septentrionis* Jeannel, 1923 (S Norway and Sweden, and also Krkonoše Mts., N Bohemia; mostly epigean records, alpine stone fields in Krkonoše Mts.); and two strictly cave dwelling species: *C. holsatica* Benick & Ihssen in Benick, 1937 (Segeberger Höhle cave, N Germany) and *C. gracilentia* Szymczakowski, 1957 (caves in Sokole Góry Mts., SW Poland).

Recently, three other isolated populations with relict distribution have been found (presently undescribed), in: (1) cold taluses of České středohoří Mts., N Bohemia; (2) caves in Pilis Mts., NW Hungary; (3) cave in Bakony Mts., W Hungary.

Multivariate statistical analyses of 15 morphometric characters have been made for samples of all 8 species. The gradient in increasing length of appendages (length of antenna, metatibia and metatarsus) have been found from epigean to rock debris dwelling to cave dwelling species, probably as adaptations to hypogean conditions.

11-075

MAIN QUESTIONS IN PHYLOGENY AND BIOGEOGRAPHY
OF CHOLEVIDAE (COLEOPTERA)

P.M. Giachino, D. Vailati¹, A. Casale²

Museo Regionale di Scienze Naturali, Torino, Italy - 1 Museo Civico di Scienze Naturali, Brescia, Italy - 2 Istituto di Zoologia, Università di Sassari, Italy

A phylogenetical system of Cholevidae (treated as a family) is presented, and relationships of them with other higher taxa of Staphylinoidea are discussed. Characters regarded as phylogenetically meaningful are reinterpreted, and their evolution in the family and in related groups are widely illustrated. Modifications of several features, due to adaptation to different environments and ways of feeding, are also made evident. A preliminary cladistic analysis of subordinate taxa of the family, in which the character state polarity is based on out-group comparison, is attempted. Furthermore, a hypothesis of the origin of different subfamilies, and a zoogeographical history of the Cholevidae as a whole, are proposed.

11-076

PHYLOGENY AND BIOGEOGRAPHY OF CHOLEVIDAE LEPTODIRINAE (COLEOPTERA)

A. Casale, P.M. Giachino¹, D. Vailati²

Istituto di Zoologia, Università di Sassari, Italy - 1 Museo Regionale di Scienze Naturali, Torino, Italy, - 2 Museo Civico di Scienze Naturali, Brescia, Italy

Among the subfamilies of Cholevidae, Leptodirinae present the most specialized and impressive adaptations to the subterranean environment. For that reason, several convergent adaptive features are present in different genera and/or phyletic lines not directly related each other. Apart from some well known characteristics common to other hypogean beetles, such as reduction or loss of eyes, depigmentation, loss of metathoracic wings, elongation of antennae and legs, other peculiar modifications of the body such as pseudophysogastry, elongated and prognathous head, modified mouth parts in relation to the way of feeding in oligotrophic caves, are noticeable. So, it is evident that any phenetical approach is impossible to achieve a phylogeny of the group.

In the present research, characters regarded as phyletical meaningful, their weight and state polarity based on outgroup comparison, are discussed and reinterpreted, for a cladistic analysis and a congruent zoogeography of the subfamily in the Euro-Mediterranean area.

11-078

ZOOGEOGRAPHICAL REVIEW OF THE TROGLOBITIC AND ENDOGEAN CARABIDAE AND CHOLEVIDAE (COLEOPTERA) OF YUGOSLAVIA AND ADJACENT REGIONS

D. Pavićević, G. Nonviller¹, A. Četković²

Proleterskih brigada 15, Belgrade, Yugoslavia; 1 -- Nušićeva 2a, Zemun, Yugoslavia; 2 -- Institute of Zoology, Department of Biology, University of Belgrade, Belgrade, Yugoslavia

An updated zoogeographical review of the most diverse subfamilies of Balkan cavernicole and endogean coleopterans -- Bembidiinae, Trechinae (Carabidae) and Leptodirinae (Cholevidae) is based on the revised literature data, as well as on the abundant new material collected during the last 20 years (from Serbia and Montenegro, mainly unpublished). A synoptic review of the numbers of genera, species and subspecies is presented, as recorded in different countries of the region. The distribution of species was analysed according to their life form and ecological preferences (troglobitic, troglophile and endogean, respectively). For the territory of the former Yugoslavia, distributional patterns of the recorded genera, as well as the types of the species range endemicity are discussed. Within the territory of F.R. Yugoslavia (Serbia and Montenegro), a comprehensive faunistic review is based on 84 described and about 30 new species, with emphasis on the notified local differences in species diversity. The status and significance of the apparent diversity centres were considered in relation to the regional trends of the expected taxonomic richness, with respect to their relevance for the biodiversity conservation.

11-077

PHYLOGENETIC PROBLEMS, CURRENT CLASSIFICATION AND GENERAL CATALOG OF WORLD LEIODIDAE (INCLUDING CHOLEVIDAE)

A.F. Newton Jr., S.B. Peck(1)

Department of Zoology, Field Museum of Natural History, Chicago, IL USA - (1)Department of Biology, Carleton University, Ottawa, ON Canada K1S 5B6

Subterranean and endogean cholevines are placed in the context of a world-wide review of the past and present classification of related Staphylinoidea. Arguments are presented for recognizing a single large monophyletic family, Leiodidae, rather than a series of less well-defined families including Cholevidae, Leptinidae, etc. Six leioidid subfamilies are recognized, all but the first probably being monophyletic: Camiarinae, Catopocerinae, Leiodinae (=Anisotominae), Coloninae, Cholevinae (=Catopinae, Leptodirinae) and Platypsyllinae (=Leptininae). Outstanding phylogenetic problems at the subfamily and tribal levels are discussed.

The Cholevinae contain the greatest diversity in subterranean habitats, with some 140 genera and 600 species in the Leptodirini (=Bathysciini) in the Palaearctic Region.

Keys for identification, diagnoses, and brief summaries of the biology of each subfamily and tribe are given. A complete generic catalog, with indication of genera examined and the distribution and number of named species for each genus, and an appendix of new taxonomic and nomenclatural changes, are also provided.

11-079

TROGLOBITIC ADAPTIONS AND PHYLOGENETIC AGE OF A POST PLEISTOCENE CAVE BEETLE IN NORTHERN GERMANY (CHOLEVA HOLSATICA IHSENSEN & BENICK; CATOPIDAE)

Anne Ipsen

Zoological Institute & Museum
University of Hamburg, Germany

Troglobitic adaptations and ecological basis of Choleva holsatica IHSENSEN & BENICK (Catopidae, Coleoptera) were studied (for example eye-analyses by REM-method and factor-gradient-tests in the laboratory). This species is endemic to a climatically constant cave (9°C, 100 % humidity) in Northern Germany. Its closest surface relative is Choleva septentrionis Latr., which occurs in Norway and from which it was probably separated subsequent to postpleistocene climatic warming.

11-080

IMPACT OF TEMPERATURE CONDITIONS ON THE REPRODUCTION OF AQUATIC BUGS (HETEROPTERA: CORIXIDAE)

N.N. Khmeleva, M.D. Moroz

Institute of Zoology, Academy of Sciences, Minsk, Belarus

Field and experimental works were carried out on 5 species of Corixidae (*Sigara lateralis* (Leach), *S. falleni* (Fieber), *S. striata* (Linnaeus), *S. cocinna* (Fieber), *S. praeusta* (Fieber)).

First eggs were laid when the temperature was between 10° and 12°C. It seems that these temperature interval represents lower ones for egg-laying in Corixidae. During the temperature increase from 12° to 25°C rate of egg-laying grew steadily reaching the maximal values at 25°C.

The study of the impact of temperature on the total fecundity was carried out on 5 species of Corixidae. Total fecundity is relatively conservative reproduction index. It is not affected by the temperature factor and apparently is determined genetically. Of course, optimal temperature conditions (15-25°C) for egg-laying in investigated species of Corixidae are necessary for its realisation.

11-081

EVOLUTION OF THE THORACICO-ABDOMINAL JUNCTION IN THE NOTONECTOIDEA AND PLEOIDEA (HETEROPTERA, NEPOMORPHA)

M. Papáček

Pedagogical Faculty, University of South Bohemia, České Budějovice, Czech Republic

The lateral thoracico-abdominal regions of twenty two species of eleven genera of the superfamilies Notonectoidea and Pleoidea (Notonectidae: *Notonecta*, *Enithraes*, *Aphelonecta*, *Nychia*, *Martarega*, *Anisops*, *Buenoa*; Pleidae: *Plea*; Helotrephidae: *Helotrephes*, *Distotrephes*, *Trephotomas*) were studied.

The morphological features of the pterothorax and base of abdomen are partly influenced by the locomotion, feeding and respiratory strategies, and by the pteropolymorphism too. Nevertheless, these have significant differences on the taxonomic level of tribes, subfamilies and families. Some evolutionary trends of the arrangement of the lateral pterothoracic region and thoracico-abdominal junction were ascertained in the particular taxons. A hypothesis on the origin and homologization of the individual parts of thoracico-abdominal junction was expressed.

11-082

EFFECTS OF GRADUAL INCREASE IN PHOTOPHASE ON DISPERSAL POLYMORPHISM AND REPRODUCTION IN A WATER STRIDER, *AQUARIUS PALUDUM* (F.) (HETEROPTERA: GERRIDAE).T. Inoue and T. Harada¹

Department of Biology, Faculty of Science,

Kochi University, Kochi, Japan - ¹ Biological Laboratory,

Faculty of Education, Kochi University, Kochi, Japan

Constant long-day conditions induce brachypterous form and reproduction, whereas constant short-day conditions cause macropterous form and diapause in *Aquarius paludum* (F.).

The critical daylength for the determination of wing forms is about 13.75 h, and that for reproduction is 13 h in Kochi (33° 33' N, 133° 35' E) (Harada & Numata, 1993). The photophase was increased by 2 or 3 min every 2 days (12.25 h to 13.25 h, or 11.5 h to 12.5 h) during the first to the fourth (penultimate) nymphal instars. The increase had no effects on both wing form and maturation of oocytes. However, it inhibited flight behavior and caused higher proportion of adults which histolyzed their mesothoracic flight muscles before the 30th imaginal day than did a constant daylength of 13.25 h or 12.5 h.

The results suggested a following hypothesis: Increase in photophase is converted to another endocrine pathway excluding juvenile hormone which may induce brachypterous form and reproduction, and the pathway causes the inhibition of flight behavior and histolysis of flight muscles in *A. paludum*.

11-083

Ecological and morphological differentiation of the two closely related species *Gerris asper* and *G. lateralis* (Hemiptera, Gerridae).

Anne Luginbühl, Manfred Zimmermann (Institute of Zoology, Department of Population Biology, University of Berne, Baltzersrasse 3, CH - 3012 Berne, Switzerland).

Although the two closely related species *Gerris* (*Gerriselloides*) *asper* and *G. lateralis* differ in their distribution areas and habitats, they were often confounded among each other and with other *Gerris* species. Up to now the five larval stages of the two species could not be discriminated.

Whereas *G. lateralis* has been reported from the Swiss Jura Mountains some twenty years ago, *G. asper* was only recently recorded on the Swiss Plateau. Investigations were made on the ecological differentiation of *G. asper* and *G. lateralis*. The five larval stages were differentiated morphologically. Our regular samples suggest that the populations of *G. asper* on the Swiss Plateau are generally univoltine. Field experiments on inter- and intraspecific competition in the Swiss Jura Mountains and on the Swiss Plateau show, that under interspecific competition *G. lateralis* is superior to *G. asper* at both locations.

The five larval stages of *G. asper* and *G. lateralis* are described and differentiated by various pigment patterns and also by morphometric features. Larvae of *G. asper* are more delicate than those of *G. lateralis*. In contrast with larvae of *G. asper* the larvae of *G. lateralis* show dark epimeral and episternal lobes and also dark adjacent ventral and lateral areas. Using linear discriminant analysis and stepwise backward elimination the number of morphometric measurements was reduced from eleven to the two measures head width and length of antennal segment 4. Applying a single discriminant function common to all 5 larval stages, 95 % of the larvae can be determined.

11-084

THE INFLUENCE OF ENVIRONMENTAL FACTORS ON THE DISTRIBUTION OF HEMIPTERA OF ACID HEATHLAND FENS
M. Santens, R. Stoks, B. Van De Vijver, L. De Bruyn & R. Verhagen
University of Antwerp (RUCA), Department of Biology, Antwerp, Belgium, santens@ruca.ua.ac.be

Heathlands have become an increasingly scarce habitat. Because they grow on acid and nutrient-poor sandy soils, they impose particular demands to the inhabiting fauna and flora. Until now, only few biocoenological investigations have been undertaken on the species living in acid heathland fens. Here, we investigate the distribution of Hemiptera in relation to environmental parameters. Hemiptera were collected in 31 pools at the "Groot Schietveld" near Brecht (northern Belgium) during the summer of 1993. Several biotic and abiotic habitat characteristics were measured.

In total 26 species were found belonging to seven families: Corixidae (16sp), Gerridae (2sp), Hydrometridae (1sp), Naucoridae (1sp), Nepidae (2sp), Notonectidae (3sp), Veliidae (1sp). Five species, *Corixa dentipes*, *Cymatia bonndorffi*, *Micronecta meridionalis*, *Sigara limitata* and *Microvelia reticulata* are rare and one, *Glaenocoris propinqua*, is very rare in Belgium.

Multivariate techniques (canonical correspondence analysis, CCA, and two-way indicator species analysis, TWINSpan) were applied to examine the impact of environmental variables on the occurrence of species. CCA showed that pH, plant cover, hardness, O₂ and depth explained 92.5% of the total variance of the species distribution. The Hemiptera species richness (number of species) and the diversity (Shannon-Wiener index) decreased with increasing amount of vegetation cover, depth and acidity.

11-086

THE DISTRIBUTION AND ABUNDANCE OF PTERONARCYS CALIFORNICA NEWPORT IN THE MADISON RIVER, MONTANA, USA

D.C. Richards, M. Rolston, F.V. Dunkel

Department of Entomology, Montana State University, Bozeman, MT USA

Despite the importance of *P. californica* to river community ecology, little is known about its distribution and abundance in the Madison River, MT, USA. Larval *P. californica* in the section of the Madison River downstream of the top release dam grow faster and larger but are much less numerous than in the section of the Madison River above the dam. Habitat availability seems to effect their abundance. Other dam-related factors may also contribute to *P. californica* distribution and abundance. Methods used in this study for counting shed exuviae may be used by others to monitor water quality locally.

11-085

SPATIAL DYNAMIC OF THE CADDISFLY (TRICHOPTERA) COMMUNITIES OF A BASIN IN THE NORTH-WEST OF SPAIN

C. Fernández, J. de Soto, M. Fernández

Area de Ecología. Universidad de León, León, Spain

The spatial dynamic of the caddisfly (Trichoptera) communities in the Sil Basin (Spain) was analysed and compared with the structural change of the riparian and channel vegetation. The study was based on the variation of specific diversity (Shannon index) at 40 localities, which were sampled in summer. The structural heterogeneity analysis and the evaluation of the specific composition changes between consecutive sampling sites were also carried out.

The Sil River Basin is an hydrographic network situated in the north-west of the Iberian Peninsula. The basin is characterized by its environmental heterogeneity caused by the strong contrast between altered and unaltered rivers.

The average diversity of caddisfly communities for the different rivers was relatively low, not above 2 bits/individual. We have not found correlation between heterogeneity and geographic distance in the macrophyte and caddisfly communities. The influence of coal mining and urban pollution is shown by important spatial changes in the Trichoptera community structure, and therefore high values of heterogeneity. However, the heterogeneity of the macrophyte communities is basically related with the morphologic variability of the channel and the banks.

11-087

MORPHOLOGY AND COLEOBIOSIS OF TWO SPECIES OF HELICOPSYCHE von Siebold, 1856 PRESENT IN ITALY (INSECTA TRICHOPTERA: HELICOPSYCHIDAE).

F. Gianficoni, G.P. Moretti

Cattedra di Zoogeografia, Facoltà di Scienze MM.FF.NN., Università di Perugia, Italy.

The genus Helicopsyche has a worldwide distribution, most of the species being found in intertropical areas. In Europe, 5 species have been described. In Italy up to now, 2 species have been found: H. sperata in the pre-Alps (including Canton Ticino), the Apennines, Sicily, Elba Island and H. revelieri in Corsica, Sardinia, Capraia Island. The aquatic stages, characterized by snail-like cases of sand grains (diameter up to 5 mm) are found in springs, hygropetries and margins of shallow streams. During the early instars, the larva builds a curved tube-case which later becomes a helical case. At the last instar, the case is coiled three times, around a columella, lined with pillars of vertically-stacked sand grains bordered by silk threads. The sand grains are connected together by a loose irregular silk weave (under scanning electron microscope). An opening on the upper coil facilitates water circulation. The larva, 5-6 mm in length, is coiled inside the case in such a way that the posterior end lies above the head. The dorsal protuberance of the first abdominal segment is larger and more prominent in H. revelieri. Gills are absent and fork-like plates occur on the sides of segment 8. The anal claw has a sclerified comb-like structure. The silk glands are double-folded and symmetrically located in the abdomen. The pupal case is closed by a thick woven silk lamina with a thin transverse opening.

11-088

NEW DATA ON THE TRICHOPTERA OF A FEW SPRINGS OF THE PROVINCE OF BERGAMO - LOMBARDIA.

E. Bertuetti ¹, GP. Moretti ², M. Valle ¹¹ Museo Civico di Storia Naturale "E. Caffi", Bergamo, Italy² Istituto di Zoologia dell'Università di Perugia, Italy

In this report we present the data relative to the Trichoptera found in 15 springs of the Province of Bergamo (Lombardy) from 350 to 1,800 metres of altitude.

This study has been carried out in the period 1993-1995 and has led to the identification of 64 species from 4,000 adult insect specimens examined, that is particularly interesting in consideration of the very few data available related to this area of the Alps.

It is particularly interesting the presence of some species with a not very well characterised distribution such as *Microptila minutissima* Riss for which these are the only data available for Italy. Several specimens of the stenodemite of the Central Alps *Rhyacophila hirticonis orobica* Moretti were also found, confirming the characters of the holotype but requiring a more detailed comparative analysis to establish the exact taxonomic status. For ten other species our findings represent the first description for the Lombardy region. Our data confirm that this, sector of the Alps despite not being well investigated is particularly interesting as it represents the limit of longitudinal distribution of several taxa both from the East and from the West. For instance, we found *Tinodes dives dives* Pict., (a taxon of Central Western Europe) and of *T. d. jeekelii* Bots. (typically from the Eastern Alps and the Balkans), as well as some intermediate forms.

From our data it has been possible to assess the abundance of the different species in the various springs and to perform some quantitative analysis.

The method of Sørensen has allowed the correlation of the trichoptero-coenosis with the altitude of the various sites.

11-089

ZONATION OF HYDROPSYCHIDAE (TRICHOPTERA) IN THE SIMETO RIVER (SICILY)

R. De Pietro

Dipartimento di Biologia Animale, Università degli Studi di Catania, Catania, Italy

The Hydropsychidae species inhabiting the Simeto River, the biggest river in Sicily, and its principal mountain branch, the Saracena Stream, were studied.

The sampling of the aquatic stages was carried out about every two months between 1992 and 1994. In order to obtain comparable data, the sampling time for each site was about 20 minutes.

Seven species of Hydropsychidae were found: *Hydropsyche dinarica* Marinkovic-Gospodnetic, 1979; *H. doehleri* Tobias, 1972; *H. klefbecki* Tjeder, 1946; *H. modesta* Navas, 1925; *H. morettii* De Pietro, 1996; *H. spiritoi* Moretti, 1991; *Cheumatopsyche lepida* (Pictet, 1834). Only three species (*H. morettii*, *H. modesta* and *C. lepida*) were found in the low course of the Simeto River.

Regarding the ecological zonation of Illies and Botosaneanu (1963), the species showed the following preferences: *H. doehleri* for hypocrenal and epirhithral; *H. dinarica* for epirhithral; *H. klefbecki* and *H. spiritoi* for metarhithral and epirhithral; *H. morettii* and *C. lepida* for hyporhithral; *H. modesta* for epipotamal.

The preferences in the ecological zonation, which showed no direct correlation with altitude, were confirmed in the populations of other Sicilian streams.

11-090

PLANT, FUNGAL OR ANIMAL DIETS: DIFFERENT EFFECTS ON LARVAL DEVELOPMENT OF MOSQUITOES (DIPTERA: CULICIDAE)

S. E. Timmermann & H. Briegel

Zoologisches Institut der Universität Zürich, Zürich / Switzerland

Mosquito larvae colonize small shallow freshwater pools with usually unbalanced nutrition, in quantity as well as in quality. Compared with food of microbial or animal origin, plant material is poor in protein, lipid and vitamin content or, such as seeds, largely inaccessible to mosquito larvae. Mosquitoes have evolved into various ecotypes which are adapted for efficient development despite of dietary imbalances.

In the field it is difficult to separate the various nutritional components and their individual significance as dietary requirements. Therefore, we have experimentally selected three diets of plant, fungal, and animal origin. We quantified the effects of nettle powder, brewers yeast, and TetraMin® on larvae from different mosquito species. In contrast to animal food, development was decelerated and population size, body size, and caloric reserves were reduced with plant and fungal food, respectively. In addition, nettle powder affected the metabolism of female mosquitoes as reflected by reduced hatching of their offspring. This effect could largely be compensated by the female through repeated blood meals.

On a higher trophic level, i.e. mosquitoes whose larvae prey upon other larvae, pupal mortality of the predator was higher and fecundity was significantly lower when their food has been raised with plant material. Our data support the role of essential fatty acids in development and reproduction, as reported in the literature.

Supported by the Swiss National Science Foundation.

11-091

NEW DATA AND FAUNISTIC ANALYSIS OF THE HYDRAENIDAE (COLEOPTERA) OF ANDALUCÍA (SOUTHERN SPAIN).(*)

C. E. Sáinz-Cantero, J. Gamido ¹ & L. F. Valladares ²

Dpto. Biología Animal y Ecología. Universidad de Granada. E-18071-Granada.- 1 Dpto. de Recursos Naturales y Medio Ambiente. Universidad de Vigo. E-36200-Vigo (Pontevedra).- 2 Dpto. de Ciencias Agroforestales. Universidad de Valladolid. E-34004-Palencia.

A taxonomic study was carried out on 1243 coleopteran specimens belonging to *Hydraenidae* from several localities of Andalucía (Southern Spain). A total number of 25 species were identified and eight are firstly reported for four provinces. From these results and the reported literature we were able to elaborate an updated *Hydraenidae* species list and to perform faunistic and corological studies for Andalucía.

(*) Founded by the DGICYT, FAUNA IBERICA-III project N° PB92-0121

11-092

INFLUENCE OF ENVIRONMENTAL VARIABLES ON THE DISTRIBUTION OF ELMIDAE AND HYDRAENIDAE IN A RIVER BASIN IMPACTED BY MINING ACTIVITIES (COLEOPTERA)

F. García Criado

Departamento de Biología Animal. Facultad de Biología. Universidad de León, León, Spain.

Fourteen species of Hydraenidae and thirteen of Elmidae were collected from riffles of several rivers in the Sil River basin (NW Spain). The aim of the research was to establish the potential influence of coal mining activities, the main impact in the study area, on the distribution of these species.

Several parameters were analysed by means of Canonical Correspondence Analysis (CCA). The results reveal that distance from the source and mining activities are the most significant factors.

CCA allowed to define groups of species with different degrees of tolerance to pollution derived from mining.

11-093

A CLASSIFICATION AND EVALUATION OF WATER BEETLE ASSEMBLAGES IN THE SIBILLINI NATIONAL PARK (CENTRAL ITALY).

Q. Pirisinu, G. Giangiuliani

Istituto di Zoologia, Università degli Studi di Perugia, via Elce di Sotto 06123 Perugia, Italy

Water beetles were recorded from different sites in the "Pian Grande" inside the Sibillini National Park and assembled for analysis. The main water beetle assemblage were identified by multivariate analysis and then habitats of these assemblages were characterized by measurement of a range of physical and chemical factors. Each taxon is linked with the environmental variables and the ordination of the taxa and variables allows presentation of the more synthetic correspondence between the Coleoptera and their ecological and biological characteristics.

THE GENUS *HYDROCHUS* (COLEOPTERA:HYDROPHILOIDEA:HYDROCHIDAE) IN SOUTH AMERICA

A. Oliva

División Entomología, Museo argentino de Ciencias naturales, Buenos Aires, Argentina

Twenty-three South-American species of the genus *Hydrochus* were examined, seeking for a natural division of the genus. Male genitalia suggests four species-complexes, with a few species which appear to have evolved along independent paths. Most species are exclusive of South America; two range from Central America to Argentina; these belong to the largest complex, which centers around *H. obscurus*. A second complex is made up of the small-sized species found in tropical and subtropical South America. The third comprises *H. secretus* and two similar species; the fourth *H. metallipes* plus *H. ducalis*. For the two last complexes, some external characters had to be taken into account. Use of new characters is becoming necessary for more natural grouping. Examination of the microtrichia on the inner elytral face under Scanning Electron Microscope is suggested as one possibility

NUMBER OF INSTARS IN *SIPHONURUS AESTIVALIS* (EPHEMEROPTERA, SIPHLONURIDAE): TEMPERATURE AND FOOD INFLUENCES

L. RUFFIEUX, M. SARTORI

Museum of Zoology, Lausanne, Switzerland

To determine the precise number of instars in mayflies, a Palmen Body Standard Method was developed, based on the usual techniques applied in histology. This technique is successfully tested on mature larvae of *Siphonurus aestivalis* (Ephemeroptera, Siphonuridae) growing in two biotopes, a pond and a river with different temperature regimes and food availabilities.

The number of larval instars for *S. aestivalis* is included between 10-17 for the specimens coming from the pond and 12-17 for the individuals collected in the river. Considering each intralayer space of the Palmen body as the developmental time of each larval instar, the moulting frequency in the two biotopes is compared. The importance of water temperature and food on the moulting number is discussed.

11-096

DRIFT OF LOTIC MAYFLIES IN STREAMS WITH CONTRASTING PREDATION REGIMES: FIELD PATTERNS AND BEHAVIOURAL INTERACTIONS.

A. Huhta, T. Muotka¹ and P. TikkanenDept. of Biology, University of Oulu, Oulu, Finland -¹Dept. of Biological and Environmental Sciences, University of Jyväskylä, Jyväskylä, Finland

Nocturnally biased drifting of stream invertebrates is often regarded as a behavioral mechanism whereby invertebrates avoid encounters with visually hunting fish predators. To examine this hypothesis, we collected invertebrate (especially mayfly) drift from five streams in northern Finland: one with trout (drift-feeding fish), one with sculpin (benthivore), one with both species, and two fishless streams. Drift of *Baetis* mayflies was aperiodic or slightly diurnal in both fishless streams on all sampling occasions. In streams containing fish, the peak in drift in July occurred during the short crepuscular period around midnight. At other sampling times, drift was clearly nocturnal in streams with trout and, to a lesser extent, also in the stream lacking drift-feeding fish. It thus appears that nocturnally constrained drifting may also arise as a post-contact mechanism: invertebrates enter the water column after being encountered (and possibly attacked) by a benthic-feeding fish. We tested this in laboratory trials where mayflies were exposed to sculpin predation. Sculpin were almost exclusively nocturnal, and their foraging activity resulted in a much higher frequency of drift entries by mayflies at night than during the day. We suggest that nocturnally restricted drifting of stream invertebrates may function either as a pre- (avoidance of visual predators) or a post-contact (flight after encounter) antipredatory mechanism.

11-097

THE DRIFT OF BENTHIC INVERTEBRATES OF THE VERA STREAM (ABRUZZO-CENTRAL ITALY)

P. Tetè, M. Giustini, M. Di Francesco

Dipartimento di Scienze Ambientali - Università degli Studi di L'Aquila, Italy.

The results of pluriennial investigations about invertebrate drift in a small, cold-water stream in Gran Sasso (Abruzzo - central Italy) massif are reported. This study is carrying on benthic invertebrates and especially on four taxa (Plecoptera: *Protonemura*, Ephemeroptera: *Baetis*, Diptera: Chironomidae, Crustacea: Gammaridae), collecting drift and benthos samples. Effects of seasonal fluctuations and carrying-capacity variations on drift of benthic invertebrates are analyzed.

11-098

ON THE SCALE INSECTS FAUNA (HOMOPTERA, COCCINEA) OF THE WHITE SEA INTERTIDAL ZONE

E.M. Danzig, A.A. Przhiboro

Zoological Institute Russian Academy of Sciences, St. Petersburg, Russia

The scale insects fauna of the intertidal zone of the White Sea was investigated for the first time. 4 species were found. *Acanthococcus* sp. and *Trionymus* sp. inhabit above-ground parts of plants and settle on places flooded approximately once a week. *Atrococcus craccens* Will. and *Rhizoecus halophilus* (Hardy) live on roots and can develop successfully in the zone submerged twice almost every day. At the White Sea the rare itself phenomenon of the scale insects inhabitation on flooding sea shore combines with one of the northernmost occurrences of the Coccinea.

11-099

THE FIRST STUDIES ON THE ENTOMOLOGICAL FAUNA OF THE PERSISTENT SNOW-ENVIRONMENTS IN THE DOLOMITES MOUNTAINS: BRACHYPTEROUS INDIVIDUALS OF *DIAMESA STEINBOECKI* GOETGH. (DIPTERA: CHIRONOMIDAE).

S. Vanin, M. Turchetto

Dipartimento di Biologia, Università di Padova, Padova, Italy.

During a study carried out on the entomological fauna of the Dolomites Glaciers we have found the presence of *Diamesa steinboeckii* Goetgh., the glaciers-fly, a dipteran with short underdeveloped wings.

Among the population of these insects a great variability of development degree has been found in their wings both in the sizes and in their shapes. In this study we compare the thorax muscular structure with the different kinds of wing development.

We also made some considerations about the morphological relationships between the body different parts and their adaptation to the life in the extreme environments such as the high altitude glaciers.

11-100

AQUATIC INSECTS OF THE KÖYCEĞİZ-DALYAN NATURE RESERVE AREA WITH THEIR USAGE,EVALUATION OF ENVIRONMENTAL QUALITY OF RUNNING WATERS

N. Kazancı¹, M. Düğcl¹

1 Hacettepe University, Faculty of Science, Department of Biology, Beytepe 06532, Ankara

The Köyceğiz-Dalyan Region is an important aquatic ecosystem in South Western Turkey. From the hydrobiological point of view, the importance of this area is mainly due to the occurrence of a wide variety of aquatic habitats, supporting a number of valuable biotic communities. As a result of special biodiversity value of habitat, species and genetic level this area is among the most attractive scientific and protected site. The centre of the system is the ectogenic, crenogenic meromictic Lake of Köyceğiz. The lake fed by a series ground water and surface water inflows. The streams are the important sources that feed the lake. The benthic macroinvertebrate fauna of running waters which is mainly composed of aquatic insects (the aquatic insects represented by 93 genera among 118 genera of benthic macroinvertebrates) have been identified for future biological monitoring.

In this research, distribution of aquatic insects and other benthic macroinvertebrates of the running waters has been evaluated with physico-chemical parameters. The numerical analyses and a biotic index have been used as biological criteria for the assessment of water quality.

AQUATIC MACROPHYTES AND INVERTEBRATES IN NATURAL CULICIDAE BREEDING SITES OF BARINAS STATE, VENEZUELA.
E. Rojas, J. Velázquez¹, J.V. Scorza, C. Rosas, E. Brown.

Laboratorio de Quimioterapia y Control de Vectores. Centro de Investigaciones Parasitológicas "J.W.T." U.L.A.-N.U.R.R. Trujillo 3102/Venezuela. 1. Laboratorio de Plantas Acuáticas. Inst. de Zoología Tropical. U.C.V. Caracas-Venezuela

We describe changes in the invertebrate fauna from **Anopheles** breeding sites in relation to the aquatic macrophytes and precipitation regime in permanent and temporary pools in a area in which malaria is refractory in western Venezuela. As methodology we used the index of biotic integrity (IBI) (Karr, 1986) and the hypothesis of Habitat Selection (Buchwald, 1989). The data were first computed using a principal components analysis. Ordination of the points indicated changes in invertebrate fauna assemblage from permanent pools and separate from temporary pools. Depending of environmental factors, we found association with aquatic macrophytes and **Anopheles** larvae. Finally, we compared IBI with chemical variables to illustrate how this methodology can be applied for quantify associations factors. This IBI, based on 19 taxa attributes, showed close agreement with the precipitation and validated the hypothesis of habitat selection for **Anopheles** spp. in the study area.

This work received economical support from TDR/OMS Project ID880346.

CALLING AND HEARING PLASTICITY IN THE ENSIFERAN ORTHOPTERA.

W. J. Bailey, A. Mason¹

Department of Zoology, University of Western Australia. 1.
Neurobiology and Behavior, Cornell University, Ithaca, New York,
USA.

Most hearing systems have their threshold sensitivities close to the centre or predominant frequency of the signal used to bring the sexes together: the call frequency matches the sensitivity of the ear. There is increasing evidence of hearing mis-match between sensitivity and call carrier frequency in a range of acoustic insects including the ensiferan Orthoptera. When the predominant frequency of the song and hearing sensitivity are not aligned, or even where there is sexual dimorphism in both hearing structure and the physiology of the receptors in response to sexually distinct calls, the question is raised as to which selective processes produce these changes. The paper briefly reviews auditory mismatching in the ensiferan Orthoptera and focuses on two examples of hearing plasticity in West Australian bushcrickets. First, from the genus *Kawanaphilla* (Zaprochilinae), which has three species showing a range of hearing styles, from males with highly reduced auditory spiracles, rendering them almost deaf and females showing typical ensiferan sensitivity (*K. narree* and *K. mirla*), to a species that shows normal hearing sensitivities in both male and female (*K. yarraga*). We have gathered sufficient behavioural and ecological data to suggest that these systems may have evolved through sexual selection in response to different mating strategies. A second case concerns a sagine tettigoniid, *Scirasaga quadrata*, where sensitivities have thresholds at moderately high frequencies, between 15 - 20 kHz, while the song of the male is at the remarkably low frequency of 5 - 7 kHz. This species is subject to intense predation through an ormine parasitoid fly and its calling and mating strategy may have evolved in part through avoidance of predation.

12-001

FUNCTION IN PHYSICAL PARAMETERS OF ORTHOPTERAN SOUND SIGNALS

G. K. Morris

Dept. of Zoology & Erindale College, University of Toronto,
Mississauga, Ontario, Canada

The sound signals of acoustic Orthoptera include calling, courtship and rivalry songs. And the physical structure of these sounds is characterized by parameters of power, carrier and amplitude modulation pattern (AMP). A subset of these physical parameters is effective in communicating with potential mates and rivals about a sender's location, identity, quality and motivation. And signal morphology has also been shaped by interference from other environmental sounds and in response to eavesdropping exploitation by predators and parasites.

Signal parameter functions are made apparent by their underlying neurophysiology as well as the context in which they occur. Hypotheses of function can be tested by comparing signal parameters between related species, by whether they predict sender and receiver behaviour and by bioassay. This paper is a review of the evidence of adaptiveness in orthopteran signals from the perspective of the physical parameters that comprise the signal.

Power and carrier frequency are important in communicating a sender's quality to potential mates and rivals. But intensity is sometimes subordinated to pattern as animals establish identity. Signal power has been constrained in katydids by eavesdropping predators and interference has affected both carrier and pattern. For crickets, sinusoidal carriers over a limited spectral range provide accurate bearings to a distant male, while in grasshoppers and katydids broad band carriers may function to localize a sender by signal degradation. Calling song patterns, rather than power or carrier frequency, are the principal basis of encoding species identity and distinctive AMPs within the same song can be receiver-specific.

12-003

EVOLUTION OF CHORUSING: PRECEDENCE, RELATIVITY, AND SELECTIVE ATTENTION

M.D. Greenfield

Department of Entomology, University of Kansas,
Lawrence, KS USA

The synchronous and alternating choruses produced by males in many acoustic species are epiphenomena resulting from individuals competing to jam each other's signals. This arises when females disregard all but the leading signal in a sequence, and males who lead are selectively favored. Given this perceptual bias, modeling shows that a resetting of signal rhythm, which generates either synchrony or alternation, is evolutionarily stable provided that resetting includes a relativity adjustment for the velocity of signal transmission and selective attention toward only a subset of competitors. Signaling strategies in chorusing insects and anurans incorporate these predicted features.

12-004

ACOUSTIC SIGNALLING AND CONSTRAINTS ON SEXUAL SELECTION IN SAGEBRUSH CRICKETS (HAGLIDAE).
W. A. Snedden, Department of Entomology, University of Kansas, Lawrence, KS, USA.
Sagebrush crickets (*Cyphoderris strepitans*) breed during early spring in the mountainous regions of western North America. Each evening during the 4 - 6 week mating season, males emerge from the soil litter, climb sagebrush, and call for several hours. Males are able to call at remarkably cold temperatures, as low as -8°C. During copulation, females feed on the male's fleshy hindwings and the resultant flow of hemolymph. As a consequence, it is possible to determine male mating status in the field by direct examination of the hindwings. Further, male lifetime mating success can be determined in the field by mark-recapture and sequential examination of the hindwings of recaptured individuals.
Field and laboratory studies have shown that in this species calling functions both in the attraction of females and in male spacing behaviour. Calling, per se, is important to male mating success; males rendered mute do not get mated. Males are not territorial, but spacing behaviour appears to be mediated through acoustic signalling and the mutual avoidance of rivals.
A two year field study revealed that male lifetime mating success is related to adult longevity and the number of nights during the breeding season spent calling. Most males mated only once, or not at all. The opportunity for sexual selection was low, and differed between years. Virgin males obtained matings at a frequency higher than predicted by a random mating model. This virgin male mating advantage appears to constrain the opportunity for sexual selection in the species.
The mating system of sagebrush crickets resembles that of some anurans. There is an explosive early spring breeding season, intense inter-male competition, and chorus tenure is the major predictor of male mating success. Unlike most anurans however, the opportunity for sexual selection in sagebrush crickets is rather low.

12-006

THE "SHAPE" OF FEMALE MATING PREFERENCES, AND WHAT THIS TELLS US ABOUT THEIR EVOLUTION.

Michael G. Ritchie
Biological & Medical Sciences, University of St Andrews,
St Andrews, Scotland KY16 9TS (mgr@st-andrews.ac.uk).

The "shape" of female mating preferences (or the "preference function") is an important component of models of sexual selection and communication. Whether preferences are directional or stabilising can influence the dynamics of the communication system. The extent of overlap between the shape of preferences and the current distribution of male traits will determine the strength of sexual selection on male traits and indicates the extent to which coevolution, species recognition or arbitrary sensory biases may have influenced the evolution of the communication system. Orthoptera, especially crickets, provide an ideal model system for studying the variation and genetics of this trait. I review how much progress has been made in measuring this, and present new results using a technique developed to measure variability in female preference in the bushcricket *Ephippiger*. Preliminary results suggest that the shape of preferences varies with different structural components of the signal. There is evidence that preferences are genetic and can vary between individuals. Even within *Ephippiger*, some preferences imply coevolution, others "sensory drive", and others are primarily exerting sexual selection.

12-005

TEGMEN ASYMMETRY AND ITS INFLUENCE ON FREQUENCY MODULATION AND SONG PREFERENCES OF FIELD CRICKETS (*GRYLLUS CAMPESTRIS* L.)

L.W. Simmons
Department of Zoology, The University of Western Australia,
Nedlands, WA 6009, Australia

Acoustic signals produced by males are the traits most often subject to sexual selection. The mechanism of song production in crickets is well documented. However, contrary to previous work, I show that cricket songs exhibit frequency modulation to varying degrees, dependent on the degree of asymmetry in the sound resonators or harps. Recent studies of sexually selected traits suggest that size and symmetry may reflect male quality. The harps of crickets exhibit directional asymmetry yet show patterns similar to those of traits that exhibit fluctuating asymmetry; large males have large and relatively symmetrical harps. Females prefer pure tones of low carrier frequency, characteristic of large symmetrical harps. However, small males can partially compensate for their high carrier frequency by producing frequency modulated song. Directional asymmetry in harps may arise because of a selection bias favouring an alternative signalling strategy among males of low quality.

12-007

CHORTHIPPUS PARALLELUS: WHAT DOES IT TELL US ABOUT MATING SIGNAL DIVERGENCE?

T. B. Tregenza and R. K. Butlin, Department of Biology,
The University of Leeds, Leeds, UK

The mating behaviour, including both acoustic and chemical signals and mating preferences, of the grasshopper *Chorthippus parallelus* (Orthoptera: Acrididae) has been studied both in a hybrid zone between parapatric subspecies and more broadly around Europe. Originally focused on the possibility of reinforcement of prezygotic isolation in the hybrid zone, this project has now moved on to consider the interactions between the two signalling channels, the likely processes underlying their divergence, and the selection pressures operating on them. Displacement of clines in the hybrid zone provides the opportunity to study a wide range of signal combinations while background information on the current distribution and colonisation pattern of the grasshopper in Europe allow tests of competing hypotheses about divergence.

12-008

THE BEHAVIORAL ECOLOGY OF FEMALE CHOICE IN TREE CRICKETS

W.D. Brown

Institut de Zoologie et d'Ecologie Animale, Université de Lausanne, Lausanne, Switzerland

Although evidence of mate choice is now well founded, distinguishing among alternative evolutionary models of female choice remains problematic. An approach that has been surprisingly under-utilized is the study of the functional design of preferences. My goal during this talk is to make two points about the value of studying preference design for understanding sexual selection. First, models of sexual selection make fundamentally different predictions about the way in which preferences should be structured. Thus studying the structure of preferences provides a functional (teleonomic) approach to testing alternative models of sexual selection. To illustrate this point, I present work on female preferences in tree crickets that contrasts predictions of indicator models with those based on runaway sexual selection. Indicator models predict that choices should be (1) based on comparisons, (2) directed at elements of sex-limited signals that indicate fecundity benefits and/or heritable benefits, and (3) that these elements should lack susceptibility to cheating. In comparison, runaway models predict that choices are (1) fixed within females and (2) show consistent variability among females. Results of experiments on female choice for song showed that comparisons were necessary for choices, females preferred low-frequency songs, and low frequency was a reliable indicator of both fecundity and putative heritable benefits of mating, supporting all 3 predictions of indicator models. By contrast, female preferences were neither fixed within nor variable among females, falsifying the necessary conditions for runaway selection. My second point is that understanding the design of preference can also elucidate social and environmental factors influencing the direction and intensity of sexual selection. To illustrate this second point, I present a study that shows that both the relative coyness of females and the degree to which they differentially mate with larger males depends on the benefits of mating, which in turn depends on food quality. Thus I predict that the intensity of sexual selection and possibly even the criteria of female choice will vary with the environment.

12-009

THE FUNCTION OF LENGTHY COPULATIONS IN A BUSH CRICKET

N. Wedell

Department of Zoology, University of Stockholm, S-106 91 Stockholm, Sweden

Copulation duration varies dramatically in insects, ranging from a few seconds in certain chironomid flies to several days in some butterflies and bugs. Variation in copulation duration can be related to sperm transfer (including manipulation of previous males' ejaculates), mate guarding and/or mate assessment. Males of the Australian bushcricket *Coptaspis sp 2* mate for several hours. Unlike most bushcricket species, males of this species remain attached to the female for up to 6 hours after transfer of the sperm containing ampulla, which he attaches externally to the female's genitalia. Females mate multiply and males are capable of re-mating soon after a copulation has ended. The function of these lengthy copulations was examined experimentally. The number of sperm present in the ampulla in relation to varying copulation durations was determined, and the influence of female mating status on the number of sperm transferred and copulation duration was assessed. Finally, male fertilization success in relation to copulation duration was examined in an attempt to determine the main function of these lengthy copulations.

12-010

THE BUSHCRICKET SPERMATOPHORE: A FEMALE PERSPECTIVE

K.-G. Heller

Department of Zoology, University of Erlangen-Nürnberg, Erlangen, Germany

During mating, many male bushcrickets transfer a large gelatinous mass, the spermatophylax, attached to the sperm containing ampulla. Immediately after mating, the female consumes first the spermatophylax and thereafter starts to eat the ampulla. Concerning the function of the spermatophylax, there are a number of recent papers discussing whether this nuptial gift represents male mating effort or male parental investment. In many species, the spermatophylax seems to be exactly the size to secure sperm transfer from the ampulla to the female spermatheca. Since the duration of this process can be influenced by the female - at least on an evolutionary time scale -, the female should control also the size of the spermatophore. Little attention, however, has been paid to the question which factors should influence the female "decision". Possible advantages the female might receive by eating a large spermatophore have rarely been discussed or measured, apart from effects of increasing egg number or size after mating. By examining the behaviour of females of *Poecilimon* species which have a relatively high mating frequency (mating every day or every second day) I try to understand and quantify the direct benefits for the female. Spermatophore size per se gives only limited information. More important aspects are (1) the period of time the female does not need to look for food after receiving a spermatophore, and (2) reduced predation pressure during this period due to reduced motility and mortality. To know how spermatophylax size affects female survival may be important in order to understand the evolution of spermatophylax size.

12-011

THE ENERGETICS OF MALE MATING BEHAVIORS IN THE HOUSE CRICKET, *ACHETA DOMESTICUS* L. (ORTHOPTERA: GRYLLIDAE), AND THEIR IMPLICATIONS FOR ALTERNATIVE MATING STRATEGIES IN THE GRYLLINAE

M.A. Hack

Population Biology Research Group, Department of Environmental and Evolutionary Biology, University of Liverpool, Liverpool, England.

Knowledge of the costs of alternative behaviors is critical to understanding when and why a particular behavior is observed. Flow-through respirometry of male house crickets revealed that their rates of oxygen consumption during contests over burrows increased by 5-8 times resting rates. During terrestrial locomotion, i.e. walking or running, males consumed oxygen at 3-5 times resting rates. In contrast, acoustic advertisement for mates raised male oxygen consumption by only 10-30% above resting rates, or an order of magnitude less than either combat or locomotion. Similar relative energetic costs for these behaviors in other crickets may explain the appearance of alternative mating strategies with changes in competitor density and adult sex ratio.

12-012

LONGITUDINAL STUDIES OF SELECTION ON THE TEXAS FIELD CRICKET: THE SIGNIFICANCE OF PARASITOID FLIES.
A-M. Murray, W.H. Cade.
Dept. of Biological Sciences, Brock University, Ontario, Canada.

Acoustic signalling in *Gryllus integer* is important in attracting conspecific females for mating. Callers, however, also attract acoustically-orienting females of the tachinid parasitoid, *Ormia ochracea*. Fly females larviposit on and around males and infested males die in 7-10 days. Males are under opposing selective pressures; calling is important for reproductive success, but may result in premature death. Fly numbers, however, vary seasonally and so selection pressure from *Ormia* may change across the year. Longitudinal studies were carried out to examine the relationships between calling activity, searching, mating success and longevity. Individually marked groups of 10 male and 10 female *G. integer* were released into large 30m² outdoor arenas and observed for 2-3 weeks. The arenas were covered by fine netting to control fly access to the experimental animals. Gravid *Ormia* females, captured locally, were used in some of the arenas and not in others. Replicates were carried out both in the presence and absence of the ormine parasitoid. Flies were found to be phonotactically active throughout the scotophase except when the temperature dropped below 12 °C. Flies within the arenas oriented to calling song but also, to a lesser degree, to courtship and aggressive stridulation. Infestation rates in the fly-present arenas was high; 40 -70% for males and 24-30% for females. Females were infected as a consequence of responding to male calls. Parasitized males had significantly longer mean nightly calling durations than unparasitized males, suggesting that prolonged calling activity carries a heavy cost in terms of attracting parasitoid flies. Increased calling activity was, however, positively correlated with relative male mating success. Selection gradients and selection differentials were calculated and indicated significant positive selection for calling in *G. integer* males, even with flies present.

12-014

CALLING BEHAVIOUR, AGE AND SURVIVAL IN BUSHCRICKETS: THE ROLE OF SOUND LOCATING PARASITIC FLIES?

Geoff R. Allen
Department of Zoology, University of Western Australia, Nedlands WA 6907 Australia.

During the summer months in south-western Australia adult males of the univoltine bushcricket *Sciarasaga quadrata* (Tettigoniidae: Austrosaginae) call to attract mates. However, calling males also attract the acoustically orienting parasitic fly *Homotrixa alleni* (Tachinidae: Ormiini). Parasitised male *S. quadrata* will only live for a further 2 weeks whereas unparasitised males live and continue to call for up to 4 months. Parasitism rates among surviving males steadily increase during the calling season and may be as high as 87% by the season's end. An experiment was conducted to compare the calling behaviour of males that had escaped parasitism throughout the entire calling season to that of all males at the season's beginning (prior to the commencement of parasitism) and to that of surviving males at intervals throughout the calling season. Males were also tested for age related changes in calling behaviour. Calling parameters measured included the onset, duration and temporal pattern of calling. Results are discussed in relation to estimated risks of parasitism and the flight activity periods of gravid female *H. alleni*.

12-013

PHONOTACTIC PARASITIDS AND CALLING BEHAVIOR IN THE FIELD CRICKET *TELEOGRYLLUS OCEANICUS*
M. Zuk, L. Simmons¹, J.T. Rotenberry
Department of Biology, University of California, Riverside CA 92521 USA – ¹ Department of Zoology, University of Western Australia, Nedlands 6009 Australia

Acoustically-orienting parasitoids take advantage of male mating advertisement calls to locate hosts, putting the male simultaneously at risk of being parasitized by calling and of losing potential mates by remaining silent. A particularly intriguing example of such a host-parasitoid relationship is seen in the field cricket *Teleogryllus oceanicus*, an Australasian species introduced to Hawaii. In Hawaii, but nowhere else, it is subject to parasitization by the phonotactic parasitoid fly *Ormia ochracea* (Tachinidae: Ormiini). Other studies of such cricket-fly systems have suggested the existence of a silent satellite class of males, presumed to avoid detection by the parasitoid and intercept females as they move toward calling males. In contrast, noncalling *T. oceanicus* males occurred with callers in all locations, and silent males were actually more heavily parasitized than callers. Parasitized populations of crickets from several locations in Hawaii differed from non-parasitized populations from Australia and the Pacific in call structure, the diel distribution of calling, and the sex-specific age structure. Dawn and dusk calling is curtailed in parasitized populations, and males from Hawaii are younger than males from uninfected populations. Variation in parasite prevalence helps explain variation in temporal structure of the calling song, although other factors also influence this variable. This system presents an excellent opportunity to examine conflicts between natural and sexual selection.

12-015

A MATING HISTORY OF KATYDIDS, CRICKETS AND WETA (ENSIFERA)
D. T. Gwynne

Department of Biology, Erindale Campus, University of Toronto, Mississauga, Ontario, Canada
I use recent phylogenies of the Ensifera to trace the evolutionary history of reproductive behaviours that typify many taxa in this orthopteran suborder. These include, calling behaviour by males that precedes pair-formation in many taxa, the mating position, mate feeding by males (on glandular secretions, body parts or nutritious spermatophores) and maternal care of eggs and/or nymphs. Some phylogenies support the hypothesis that male tegminal (and tibial ears) evolved more than once.

12-016

SEXUAL SELECTION AND SPERM COMPETITION
A. Parker (Liverpool-United Kingdom)

ABSTRACT NOT RECEIVED

12-017

A MOLECULAR BASIS FOR SPERM COMPETITION IN *DROSOPHILA* *MELANOGASTER*

L.G. Harshman

School of Biological Sciences
University of Nebraska-Lincoln
Lincoln, NE USA

Sperm competition in *Drosophila melanogaster* has been investigated.

In one study, the hypothesis that males are passing a "spermicide" substance(s) to remating females was tested using interrupted matings and a transgenic line which results in ablation of the accessory gland. Evidence is presented that males pass a substance(s) from the accessory gland that incapacitates or dislodges stored sperm.

In a second study, genetic variation for sperm competition parameters was measured in relationship to accessory gland gene allelic variation. The allelic variation was almost entirely associated with first-male resistance to sperm displacement.

12-018

PLASTICITY IN MALE REPRODUCTIVE STRATEGIES AS ADAPTIVE RESPONSES TO VARIABLE RISKS OF SPERM COMPETITION

Matthew J.G. Gage
Dept. of Zoology, University of Western Australia and D.E.E.B.,
University of Liverpool, UK

Reproductive environments are variable but often predictable. Because of this variability, individuals may be selected to be plastic in the strategy they adopt for optimal reproduction. An important factor which determines mating pattern is population structure: at higher densities females may mate more frequently, generating higher risks of sperm competition for males. Males should therefore be selected to be sensitive to population structure in order to tailor a strategy which delivers the greatest reproductive success.

In the semelparous meal moth *Plodia interpunctella* (Lepidoptera: Pyralidae), all resources for the brief period of reproduction are accrued during the larval development stage. Population structure is variable and female mating pattern is positively related to population density. Males therefore emerging into dense populations encounter higher risks of sperm competition. By manipulating larval population structure, but maintaining food levels per capita constant, I demonstrate that developing male *P. interpunctella* are sensitive to population density and tailor a reproductive strategy to fit the predicted adult reproductive environment. I measured the following constituents of a male reproductive strategy: development time, relative gonadal investment, ejaculate sperm numbers, relative head/thorax and abdomen size, and adult longevity. Males from high densities anticipate frequent mate encounter and elevated risks of sperm competition and appear to invest in a strategy for mating and sperm competition competence. At lower densities males anticipate rare mate encounter and low risks of sperm competition, and appear to invest in a strategy of migration and mate searching. Such flexible male responses represent a 'reaction norm' where male strategies vary as a continuous function of the predicted reproductive environment's signal.

12-019

SPERM COMPETITION IN THE BUSHCRICKET *POECILIMON* *HOELZELI* (ORTHOPTERA, TETTIGONIOIDEA) IN RELATION TO THE NUMBER OF INSEMINATING MALES

R. Achmann & K.G. Heller
Department of Zoology, University of Erlangen-Nürnberg, Erlangen,
Germany

Most studies on sperm competition in insects focused for methodological reasons on a situation, in which the sperm of only two males compete for the fertilization of a single female's eggs. In the majority of these cases the second mate gains most fertilizations. In many insect species, however, more than two matings of a female are common in the field. We investigated the outcome of sperm competition in multiple mated females (2 to 5 matings) of the bushcricket *P. hoelzeli*. The paternity of the progeny was determined by DNA microsatellite analysis.

There was no change in the sperm precedence pattern with respect to the number of mating partners of a female. On average the last mate predominated at fertilization. The proportion of offspring sired by the last mating male varied over an extremely wide range (mean = 63%, range = 100% - 0%). It was dependent on male age at copulation and male size. The success of an individual male increased with age at copulation and with body size.

The present study demonstrates that even in a polyandric mating sequence the position of a copulation is important in determining sperm precedence. However, individual variation in the proportion of offspring sired by the last mating male may influence differential reproductive success among males.

12-020

GENITAL MORPHOLOGY, SPERM COMPETITION AND SEXUAL SELECTION IN *ALEOCHARA* SPECIES (COLEOPTERA: STAPHYLINIDAE)

K.Peschke, C.Gack

Institut für Biologie I (Zoologie), Universität Freiburg, Germany
During copulation males of the rove beetle *A.curtula* (Goeze) introduce a flagellum of the endophallus as a guidance for the tube of the spermatophore into the female's spermathecal duct. After separation of the pair, the tube further elongates and passes through a valve at the basis of the sclerotized, U-shaped spermatheca. Here the tube swells to form a balloon filling most of the spermatheca. Sperm of previous copulations are backflushed, indicative of last-male precedence, which could also be established by DNA-fingerprinting. The balloon of the spermatophore is pierced within the spermatheca by tooth like structures releasing large number of small sperm.
Other species of the genus exhibit a whole variety of complicated male and female genital structures. In *A.bilineata*, the spermatheca with two valves forms narrow coilings at its base. The spermatophore tube opens just before, and free sperm of significantly larger size enters the spermatheca. In *A.tristis*, the spermathecal duct is spiral and has double the length of the female's body. Correspondingly, the male's flagellum forms a spiral and is introduced into the spermathecal duct. Here also free sperm of large size enter the spermatheca.
Function and morphology of *Aleochara* genitalia, spermatophore and sperm are discussed in the view of sperm competition and female choice. Additionally, the mating strategies have been investigated behaviorally and ecologically with respect to polygamy, male territoriality, female coiness, mate guarding, pheromonal communication, and sperm precedence by using molecular techniques.

12-022

MATECHOICE AND SPERM TRANSFER IN THE AUSTRALIAN SHEEP BLOWFLY *LUCILIA CUPRINA* (DIPTERA: CALLIPHORIDAE)

D.F.Cook, I.R. Dadour

Entomology Section, Agriculture Western Australia, Perth, Western Australia
Female *L.cuprina* contribute significantly to the production and survival of offspring, whereas males provide no investment in their offspring beyond their sperm. Sexual selection theory predicts that this asymmetry would favour mate choice by females, however evidence of mate choice by females is very limited, with females only appearing to be less willing to mate with previously mated males. Males discriminate against non-virgin females smaller than themselves. As the size of the male increases relative to the size of the female, the male takes longer to make the first mating attempt.

In this study, large and small adults of each sex were paired in four different combinations to look for evidence of mate choice both prior to and during mating. Males were placed into standard mating containers and once the female was introduced, a record was taken of the time from pairing to the first mating attempt, the number of mating attempts and copula duration. The numbers of sperm transferred to small and large females were estimated from spermathecal squashes under a millimetre grid. In addition, large or small females mated by either small or large males were allowed to oviposit freely until death to determine lifetime reproductive success. The fecundity of *L.cuprina* females is strongly and positively correlated with size, so by choosing to mate with females larger than themselves, males would be expected to increase their own reproductive success. The results of this study are discussed in the context of sexual selection and mate choice theory.

12-021

PRE-AND POST MATING FEMALE CHOICE IN GRASSHOPPERS (ORTHOPTERA: ACRIDIDAE)
M. Niedzlek-Feaver

Department of Zoology, North Carolina State University, Raleigh NC USA

Grasshopper mating systems have not received as much attention as those of their close relatives, the katydids and crickets. The relative role of pre and post-mating female choice in shaping the mating behavior of three species of grasshoppers, *Chortophaga viridifasciata* (De Geer), *Dichromorpha viridis* (Scudder), and *Schistocerca americana* (Drury) was examined. In general, females encountered and so chose among males sequentially. Species varied in the degree of pre versus post mating choice exhibited by females. In all species, even in *C.viridifasciata* where females typically exhibited strong mating preferences, there was evidence that females did also choose among males more cryptically by controlling the timing of a second mating, copulation duration or how sperm was stored. Some of the mitigating factors, such as a male's relative ability to deliver nutrients, have also been identified.

12-023

LEK BEHAVIOR OF FRUIT FLIES

T.E. Shelly, T.S. Whittier
Hawaiian Evolutionary Biology Program
University of Hawaii, Honolulu, HI USA

Lek behavior is a relatively common mating system in drosophilid and tephritid fruit flies. Still, detailed quantitative studies have been conducted for only a few species. Here, we focus on the Mediterranean fruit fly (*Ceratitidis capitata*), the best studied species, to examine key questions common to lek-forming species in general.

Several laboratory studies have demonstrated nonrandom mating among males, with a small subset of males accounting for a disproportionately large number of matings. Identifying the factors responsible for this trend is difficult, and only overall indicators of sexual activity were correlated with mating frequency. Male size and fighting success appear unimportant. Recent work has shown that parapheromones may affect male mating success: males given access to trimedlure or a-copaene achieved more matings than unexposed, control males. Despite the apparent operation of female choice, tests regarding the adaptive benefits of female choice were inconclusive. No significant relationship was found in father-son mating success, and data on direct benefits (enhanced fecundity) yielded weak trends, which were difficult to interpret.

In addition to examining mate choice within leks, we will also evaluate hypotheses relating to the evolution of lek behavior, with particular emphasis on the importance of predation on signaling males. The role of male "quality" and number and food resources in affecting female arrivals at leks (hotspot model) will also be addressed.

12-024

MATING SYSTEMS OF SONORAN DESERT DROSOPHILA (DIPTERA:DROSOPHILIDAE)

T.A.Markow, C.M.Breitmeyer

Our ability to evaluate the interplay between phylogeny and recent ecological adaptations in mating system variation is often restricted by limited information on either the systematic or ecological relationships of a specific group of organisms. Phylogenetic relationships of flies of the genus *Drosophila* have been well characterized. Four species of *Drosophila* are endemic to the Sonoran Desert of North America and utilize necroses of specific host cacti to feed and breed. We have found that these cactus species differ significantly in resource availability on both temporal and spatial scales. The four fly species exhibit enormous diversity in their mating system features, raising the question as to whether this variation reflects their long-term evolutionary history or their resource ecology. We employ our expanding ecological data for these *Drosophila* species to examine the influence of resource availability on patterns of allocation to reproduction.

12-025

MATING IN FEMALE *DROSOPHILA MELANOGASTER*: COSTS, BENEFITS AND THE EVOLUTION OF MATING FREQUENCY.

Tracey Chapman and Linda Partridge.

Department of Biology, University College London, London, UK.

Female *Drosophila melanogaster* from both laboratory stocks and field populations can show high frequencies of remating. Why females should mate multiply is the subject of several adaptive explanations and is influenced by a number of environmental factors. Female mating frequency is heritable and shows a bi-directional response to artificial selection, suggesting an evolutionary history of stabilising selection. Too low a frequency of mating may be non-adaptive because females run the risk of running out of sperm and too high a mating frequency is also costly. The cost of mating is caused by the transfer of non-sperm components of male seminal fluid to females at mating, and may represent a side-effect of evolutionary conflict between males. The manipulation of female life histories by these male 'accessory gland' components may have implications in the control of insect pests.

12-026

PATTERNS OF HOST USE BY FEMALE INSECTS AND THEIR SIGNIFICANCE FOR INTERACTIONS BETWEEN THE SEXES

D.R. Papaj and H. Alonso-Pimentel

Department of Ecology and Evolutionary Biology, and Center for Insect Science, University of Arizona, Tucson, Arizona, U.S.A.

Studies of resource defense mating systems to date have generally failed to capture the complexity of resource utilization by females and its consequences for interactions between the sexes. Likewise, the substantial literature on the dynamics of foraging behavior by female insects has largely overlooked the role of males in shaping those dynamics.

We describe an unusual host-defense mating system in walnut-infesting flies in the genus *Rhagoletis*. In two such species native to southern Arizona, *R. juglandis* and *R. boycei*, females show an unusual propensity to add eggs to previously-established egg-laying cavities. Males defend fruit territories and in particular guard egg-laying cavities. The function of the female's behavior remains at issue; by contrast, site preference on the part of the male is associated with clear improvements in male mating success.

Other instances in which male preference in terms of resource defense mirrors female preference in terms of egg-laying are presented. In each case, male preference is expressed even in the absence of females. Finally, ways in which host use is dynamic over the life of individual females are enumerated and early evidence that male behavior is dynamic in parallel fashion presented. We end by discussing how male tracking of female resource preference might itself affect that preference, sometimes in unexpected ways.

PHYSIOLOGICALLY INDUCED CHANGES IN THE MATING BEHAVIOUR OF TSETSE FLIES

R. WALL

School of Biological Sciences, University of Bristol, Bristol, BS8 1UG, UK.

The mode of reproduction of tsetse flies, by adenotrophic viviparity, is unusual among the Diptera and is associated with many unique aspects of the tsetse's mating system. The behavioural repertoire associated with mate location and identification, courtship and copulation is regulated by external physical and chemical stimuli as well as by internal physiological mechanisms. This paper will discuss research designed to elucidate the mating behaviour of tsetse and its regulatory mechanisms.

12-028

MALE DISTRIBUTION AND MATE SEARCHING SUCCESS AT PATCHILY DISTRIBUTED RESOURCES

M. Otronen
Department of Zoology, Uppsala University,
Villavägen 9, S-752 36 Uppsala, Sweden

I will show results on male mate searching success in two fly species where males gather at female oviposition sites. Using the ideal free distribution as basic model, male distribution at oviposition sites and male gain rates in terms of mating success are examined. In both species, short term mating success was positively related to male size. However, even within large males there were differences in movements and mating success. This suggests the importance of identifying individuals and their differences and not assuming, for example, that males with the same phenotypic character have equal gain rates.

12-030

SWARMING IN EMPIDID FLIES

Bo G. Svensson, Erik Petersson

Department of Zoology, Uppsala University, Villavägen 9, S-752 36 Uppsala, Sweden

Dance flies are predacious insects which often form male mating swarms and in many species males collect an insect prey item prior to swarming, which is presented the female at copulation.

In the species *Empis borealis*, females, however, gather to swarm and males carrying prey visit swarms for mating. Males either mated with one of the females (accepted swarms) or left swarms (refused swarms) without mating. Males mated with younger (low wing wear) and relatively larger (wing length) females. Males stayed shorter as females size variation in swarms increased and males more often left smaller than larger swarms without mating. Female mating status (virgin/non-virgin) or proximity to oviposition did not influence her likelihood of copulation. Male visiting rate in swarms and mating rate per female increased with swarm size. We suggest that *E. borealis* males discriminate among females, but found no evidence for male competition or female choice.

The mean swarm size was 4.85 ± 4.54 females (median 4.03). The very same swarm site was used for several years and some swarm sites held larger amount of females than others. Larger experimental swarm-markers attracted both more males and females. The number of females attending a given swarm site is also supposed to be influenced by male arrival pattern, male preference for larger swarms, the inability of males to judge the absolute body size of females, and female polyandry.

Females are polyandrous and females containing more sperm also had more developed eggs. The nuptial gift nutrients provided by the male seem to contribute to egg production and possibly limit female reproductive success, giving rise to the sex role reversed mating system in *E. borealis*.

12-029

COSTS OF SWARMING BY ANOPHELINE MOSQUITOES

B. Yuval
Department of Entomology, Hebrew University, Rehovot, Israel

A cost-benefit analysis of the swarming behavior of male *Anopheles freeborni* in California and *A. sergentii* in Israel will be presented.

The activity of predators affects the timing of copulations in swarms. Dragonflies attack swarms of *A. freeborni* during the early part of the swarming period, and most copulations take place after attacks cease. Conversely, swarms of *A. sergentii* are attacked by insectivorous bats which appear late during the swarming period. In this system most copulations occur before the predators appear. Glucose and glycogen fuel swarming flight. On average the amount of energy used is more than 50% of the reserves available to males- thus success at sugar feeding is linked to reproductive success.

The costs of swarming are energy expenditure and risk of predation, while the obvious benefit is reproductive success. For *A. freeborni* this benefit is not shared equally by all investors- large males copulate significantly more frequently than small ones. Size appears to be the cardinal factor determining initiation of swarming for males. Smaller males are relegated to commence swarming earlier, when predators are active and females relatively scarce.

12-031

ACOUSTIC COMMUNICATION IN THE AUSTRALIAN WHISTLING MOTHS - A CASE OF SENSORY EXPLOITATION.

W. J. Bailey
Department of Zoology, University of Western Australia.

It may be assumed that the ears of moths have evolved primarily to detect the presence of bats and are normally tuned to sonar frequencies most used by bats in prey detection. The behaviour of the moth is usually predictable and, in the presence of bats, the moth will take evasive action. There are a number of cases within the Lepidoptera where sound is used either for aposematic display or sexual attraction and, in the later case, we may presume that ears evolved for prey detection will now be used to detect the social signal. In this case the nervous system must resolve an apparent conflict between the historical situation of prey avoidance and the more recently evolved condition of mate attraction. One solution is for the moth to fly in the absence of bats, either within secluded habitats or during the day when bats are not active.

Two species of whistling moth, *Hecatesia exultans* and *H. thyridion* (Agarastinae: Noctuidae) inhabit different regions of the coastal areas of Western Australia and males of both species use an acoustic display to defend territories and attract females. One species is day flying, and calls from perches within defended territories, while the second calls in the evening and uses an areal acoustic display. This paper examines the hearing sensitivities of both species of moth, their calling and mating strategies in the field, and focuses on the shift in roles between predator detection and avoidance to mate attraction.

12-032

SUBSTRATE TRANSMITTED SIGNALS IN THE
BROWN PLANTHOPPER, *NILAPARVATA LUGENS*
(HOMOPTERA: DELPHACIDAE)

A. J. Trickett and R. K. Butlin, Department of Biology,
The University of Leeds, Leeds, UK.

Brown planthopper males signal to females using vibrations transmitted through plant stems. The pulse repetition frequency of the male signal is known to vary geographically and between host associated races. Here we report on structural complexity in the signals that has not previously been described, on the pattern of female preference for features of the male signal and on correlations between male signals and mating success. There is evidence for sexual selection favouring high pulse repetition frequency, although females respond to a wide range of signals. Pulse frequency modulation has less effect on female response or male mating success. The results are discussed in relation to divergence in signals among populations.

12-034

INTEGRATION OF VISUAL AND CHEMICAL SIGNALS IN
MATE-FINDING OF MOTHS

S.P. Foster, A.J. Howard
Horticulture and Food Research Institute of New Zealand, Mt. Albert
Research Centre, Private Bag 92169, Auckland, New Zealand.

The mate-finding behaviour of moths generally involves an upwind flight response of a male to the volatile sex pheromone of a conspecific female. This response of male moths has been the subject of much work, and is thought to involve the behavioural mechanism of optomotor anemotaxis, the use of visual information to steer a resultant track and groundspeed with respect to the wind, as well as modulation of certain manoeuvres through contact with the fine structure of the pheromone plume. Thus, a male moth continually integrates appropriate chemical and visual stimuli as it progresses upwind.

We have studied the behaviour of flying male lightbrown apple moths, *Epiphyas postvittana* (Walker) as they approach and land on or near pheromone sources. Where the male lands is influenced strongly by both chemical and visual stimuli. The pheromonal stimuli are important because the male must maintain contact with the plume as they influence the manoeuvres of the male, which subsequently affects where he lands. For example, physical objects within the plume create turbulence, thereby changing the fine structure of the plume, and affecting where the male lands. Visual stimuli influence the manoeuvres of male moths. If these stimuli are imbalanced, with respect to the axis of the wind, the male's flight tracks are skewed towards the greater visual stimulus; with a choice of sources, the male tends to fly towards the source(s) on the side with the greater visual stimulus. The landing behaviour, and especially where the male lands with respect to the pheromone source, is also influenced strongly by visual stimuli. These stimuli are, we believe, related to those used by the male during optomotor anemotaxis, rather than any specific visual stimulus relating to the female moth.

12-033

FRUIT FLY PHEROMONES AND FRUIT TREES

J. Sivinski, N. Epsky, R. Heath
Insect Attractants, Behavior and Basic Biology Research Laboratory,
USDA-ARS, Gainesville, FL USA

While participating in leks, male Caribbean fruit flies, *Anastrepha suspensa* (Loew), apply everted anal membranes associated with pheromone glands to the surface of leaf-territories. This dipping coincides with periods of wing fanning which may disperse pheromones in addition to generating an attractive acoustic signal. Some pheromone components remain on the leaf for at least 1 hour. Females are attracted to leaves that have been previously occupied by mature males, presumably because of the chemical cues deposited on their surfaces. The value of a territory may be increased by the accumulation of pheromones and this might contribute to aggression among males and the defense of certain leaves. Pheromone production, the relationship of pheromones to the chemicals present in hosts and possible cases of deposition on substrates in the Tephritidae are reviewed. Advantages of placing pheromones and other attractive signals on objects, such as increasing emission surfaces and misdirecting predators, are considered in a variety of insects.

12-035

MATE LOCATION BY PENTATOMIDS MEDIATED BY
SUBSTRATE-BORNE SIGNALS

A. Čokl, T. Amon, S. Jeram, M. Virant-Doberlet
National Institute of Biology Ljubljana, Večna pot 111, P.O.B. 141,
61001 Ljubljana, R. Slovenia

Pentatomide landbugs emit sound signals by tymbal located at the dorsal side of abdomen. The dominant frequency of their signal emissions lies between 80 and 150 Hz. Males and females of the same species emit songs with similar frequency but significantly different time characteristics. Species specific sound emissions are characteristic for pentatomids; differences are more pronounced in males than in females. Still recent investigations have shown that time parameters of the male and female songs of *Nezara viridula* from different continents are characteristically different. Sound communication in the form of calling, courtship and rival songs plays a vital role in premating behaviour enabling among others also mate location and species recognition. Small diameter of tymbal and low frequency of the emitted signals prevent their effective transmissions via air. Laser vibrometry of songs transmitted as substrate-borne signals as well as behavioural experiments on their host plants have shown that communication via substrate might be effectively performed at distances of at least 1m. Lower frequency components are transmitted on the plant at longer distances than the higher frequency parts. The subgenual organ with just two scolopidia is tuned to frequency characteristics of pentatomide sounds. Leg campaniform sensilla and joint chordotonal organs together with well developed Johnston's organ and campaniform sensilla on antennae might participate in reception of the low frequency parts of their songs transmitted as substrate-borne sound on their host plants.

12-036

LEKS OF PAPER-WASPS:
VISUAL AND CHEMICAL SIGNALS USED IN MATE ATTRACTION

L. Beani
Dipartimento di Biologia Animale e Genetica, Università di Firenze,
Firenze, Italy

A lek is an aggregation of males displaying in a nuptial arena, where they occupy and defend contiguous territories lacking in resources useful to females (in the case of paper-wasps, a few branches of a tree, some stones, a bush, segments of fences or poles, more or less conspicuous landmarks, and so on). Male activity at these potential mate-encounter points, which are species-specific and basically stable in space and time, consists of struggles, pursuits, threats and self-advertisement displays, i.e. flights along fixed patrol routes, marking and attendance at exclusive perches.

Aggregations of flying wasps represent short-range visual cues for conspecifics of both sexes, whereas scent-marking might act as a relatively long-distance attractant and enhance the visual signal. Males of several species of *Polistes* rub the abdomen, face or legs on habitual perches, a behaviour commonly explained as a pheromonal release. On the other hand, *Stenogastrinae* males patrol and defend aerial territories from intruders, without marking or perching on the substrata. Males of this group perform a conspicuous 'stripes-display' by fully stretching the abdomen in flight; this movement reveals three large white stripes on the tergites (a sexually dimorphic trait) and probably elicits a glandular secretion from tegumental cells. Visual and chemical components of male displays in paper-wasps will be discussed in relation to mate attraction.

12-037

RELATIONSHIP BETWEEN VISUAL FIELD STRUCTURE AND
MATE-FINDING TACTICS USED BY MALE BUTTERFLIES

R. L. Rutowski
Department of Zoology, Arizona State University, Tempe, AZ USA

Many male insects use a sit and wait tactic to locate females. This tactic places a number of conflicting demands on males that include (1) the need to be on the best perch and in the best body orientation to detect females, and (2) the need to maintain a body temperature permits a quick response to passing females. We have been studying the nature and resolution of these conflicting demands in the desert hackberry butterfly, *Asterocampa leilia*, in the Sonoran desert of North America. Males in this species occupy and defend perches on or adjacent to the larval foodplant where they sit and await the arrival of females. Males leave their perches to approach and chase females that fly by.

During the morning when males perch, they maintain a body temperature of about 38-40°C through adjustments in body orientation, wing position, and perch substrate preferences. They begin the morning perched on the ground and later switch perches about 1 m above the ground on the larval foodplant. Does this affect their ability to detect visually females passing nearby? Our data suggest that: (1) females fly through male perching areas at an altitude of about 1 m, (2) when perched on the plant the male's visual system is optimally positioned to detect passing females given the structure of the male visual system and his head orientation, and (3) when perched on the ground, males are in a less than optimal location for detecting females. We conclude that on cool mornings a compromise is struck between mate detection and thermoregulation that is in favor of maintaining body temperature in the preferred range.

12-038

MATE-FINDING IN COCKROACHES

William J. Bell
Department of Entomology, University of
Kansas, Lawrence, Kansas 66045 USA

Male cockroaches have diverse orientation mechanisms for locating mates. They are able to employ spatial processing, whereby they compare the inputs to the two antennae in determining in which direction to move. They also employ temporal processing, whereby they sample female sex pheromone over time and use the simple rule of turning if the concentration goes down and moving straight if the concentration continues to increase. When the pheromone is in a wind current, male cockroaches can use zig-zag upwind orientation to locate the female. In addition, male cockroaches move downward when they detect female sex pheromone, assisting them in locating pheromone-secreting females that are below them.

12-039

SOUND COMMUNICATIONS OF TWO SPECIES OF PLEASING FUNGUS BEETLES *DACNE JAPONICA* AND *D. PICTA* (COLEOPTERA: EROTYLIDAE) USING TWO TYPES OF SOUND PRODUCING APPARATUS

E. Ohya

Tohoku Research Center, Forestry and Forest Products Research Institute, Morioka, Japan

Dacne japonica and *D. picta* are pests of the Shiitake (*Lentinus edodes*), the most popular edible mushroom in Japan. Both species are often found aggregated on single mushroom. Males stridulated to chirp using vertex-pronotal apparatus in context of aggression and courtship. The numbers of syllables in chirp and the numbers of chirps in sequence differed significantly between these behaviors in both species. It seemed that there were also differences between species in these chirp characteristics.

Both sexes of both species had elytral binding-patches and at least *D. picta* females used these patches as elytra-abdominal apparatus to produce click sound that kept alerted individuals alert. This is the first record for sub-social beetles to produce a social-functional sound.

12-040

THE INFLUENCE OF A PARASITOID FLY ON SOUTHERN EUROPEAN BUSHCRICKETS

G. Lehmann

Institut of Zoology II, Staudtstraße 5, D-91058 Erlangen, Germany

One function of the bushcricket's song is to attract females of the same species for mating. Predators however, who detect their prey by means of acoustic orientation are also attracted. Among these the tachinid *Therobia leonidei* (Mesnil, 1964) (Diptera: Tachinidae) has a great influence on the males of several bushcricket species in Greece. Within one season the percent of parasitized animals in a population can rise to more than 50%. In the genus *Poecilimon* closely related species produce songs with different syllable numbers within each verse. In this study I want to measure the impact of the fly on the acoustic behaviour of the males. A field experiment shows that a species with a high syllable number were parasitized to a greater amount than species with one-syllable-songs at the same place. The singing and mating behaviour of parasitized compared to unparasitized males was analysed.

12-041

SEX APPEAL IN APHIDS

Jim Hardie, J. Robert Storer, Richard Lilley, Colin A.M. Campbell¹, Fraser J. Cook¹ and Lester J. Wadham²

Aphid Biology Group, Imperial College at Silwood Park, Ascot, UK - 1 Horticulture Research International, East Malling, UK - 2 IACR -Rothamsted, Harpenden, UK

Aphids usually have sex in autumn. In host-alternating species, winged males locate the wingless females using a complex of cues including a sex pheromone released from the hind legs of the females, as well as odour and visual cues associated with the plant on which the females reside. Our experiments with a field-based wind tunnel indicate that males can detect synthetic sex pheromone at a distance of 3-4 m and that they will fly upwind against wind speeds of 0.7 m/s. Recent field studies have also shown that males are attracted to sex pheromone released from water-traps, and that catches are increased when plant volatiles are co-released with the pheromone. In addition, the colour of pheromone-releasing traps affects efficiency; yellow, light green and orange catch more males than transparent, black, white, blue, dark green and red traps. The relative importance of the different cues appears to vary between aphids and will be illustrated with reference to three species.

12-042

CHEMICAL COMMUNICATION IN SCARAB BEETLES WITH RECIPROCAL BEHAVIORAL AGONIST-ANTAGONIST ACTIVITIES OF CHIRAL PHEROMONES

Walter Soares Leal

Laboratory of Chemical Prospecting, National Institute of Sericultural and Entomological Science, MAFF, Tsukuba, Japan.

Female *Anomala osakana* produce (S,Z)-5-(+)-(1-dec-enyl)oxacyclopentan-2-one, which is highly attractive to males; the response is completely inhibited by even 5% of its antipode. These two enantiomers have reverse roles in the *Popillia japonica* sex pheromone system. Chiral GC with an electroantennographic detector suggested that *A. osakana* and *P. japonica* each have R and S receptors. This novel mechanism of reciprocal behavioral agonist-antagonist activities of chiral pheromones appears to play a pivotal role in overcoming the species isolation problem inherent in the use of a single-constituent pheromone system in scarab beetles.

12-043

FEMALE PREFERENCES FOR MALE DRUMMING IN THE WOLF SPIDER *Hygrolycosa rubrofasciata* (Araneae, Lycosidae)

A. Rivero, S. Parri, R.V. Alatalo, J.Kotiaho, J. Mappes

Department of Biological and Environmental Science, University of Jyväskylä, Finland

In many arthropods, females choose their mating partners on the basis of the acoustic signals produced by the male. These signals are generally believed to provide the female with an indication of the quality of the signaller and thus they might serve as honest handicaps for females. *H. rubrofasciata* provides the perfect model system to study the costs and benefits associated to female choice in arthropods. Males produce a characteristic sound (audible to the human ear) by drumming their abdomen against dry leaves laying on the forest ground. The females respond by shaking their abdomens immediately after the male's drum, thus providing the observer with a very clear indication of which male's signal was chosen. We recorded male drumming under different laboratory conditions. Female preferences for different components of the male drumming as well as the variability in drumming components between different males were analysed. Preliminary experiments suggest that females prefer male signals of relatively higher energy content (higher drumming rate and volume) which are more costly to the male. Drumming quality has also been found to be positively correlated to male survival in the laboratory. It is therefore likely that male drumming provides the female with a reliable indicator of the male's quality.

12-045

SEX PHEROMONES AND REPRODUCTIVE ISOLATION IN LEPTOTHORACINE ANTS (HYMENOPTERA: FORMICIDAE)

R. Güsten, A. Buschinger

Institut für Zoologie, Technische Hochschule, Darmstadt, Germany

Sexual behaviour in palearctic ant species of the *Leptothorax acervorum* group involves female calling with emission of a secretion from the poison gland acting on males as an attractant and aphrodisiac. The present study included three independent species of the genus *Leptothorax* and four others which live in socially parasitic association with them. Reaction of males towards female pheromones was investigated using static and dynamic olfactometer designs. Specifically, interspecific efficacy of pheromones was studied to determine their role in reproductive isolation among syntopic species, in particular between social parasites and their hosts. Males of three inquiline parasites of the genus *Doronomyrmex* show no reaction to the poison gland secretion of their host *L. acervorum*. This is also true for *Leptothorax* males exposed to pheromones of *Doronomyrmex* species. In contrast, between *L. acervorum* and another parasite, the slave-maker *Harpagoxenus sublaevis*, some response of males to the other species' secretion is encountered. *H. sublaevis*, however, differs strongly from the other species treated here in the diurnal cycle of sexual activity. Pheromones are cross effective within *Doronomyrmex*, and also between the investigated *Leptothorax* species. Within *Leptothorax*, though, females do not recognize heterospecific males as potential mates upon contact. Thus, in the investigated species group, reproductive isolation between social parasites and their hosts is brought about by different pheromone blends and schedule of daily sexual activity, while pheromones do not play a role in separating sympatric species among *Doronomyrmex* inquilines or independent *Leptothorax*. The significance of these results is discussed as supporting the hypothesis of a sympatric divergence of social parasites from their hosts.

12-044

DRUMMING ACTIVITY AS AN HONEST SIGNAL OF MALE VIABILITY IN A WOLF SPIDER

Johanna Mappes, Rauno V. Alatalo, Janne Kotiaho & Silja Parri

Department of Biological and Environmental Science, University of Jyväskylä, Konnevesi Research Station, P.O. Box 35, FIN-40351 Jyväskylä, Finland.

Conditional handicap models allow females to use male sexual traits as honest signals of male viability. The assumptions for honest signalling are that the traits are costly and that they reflect male phenotypic condition, which causes the optimal trait sizes being largest for the most viable males. However, the experimental evidence of the costs are scarce and phenotypic condition has not been manipulated at the same time. Male wolf spiders *Hygrolycosa rubrofasciata* court females audibly by drumming dry leaves with their abdomen. Females prefer to mate with males of high drumming rate. Males with high food level maintained their drumming rate at a high level, while males with intermediate and low food levels exhibited a reduction in drumming rates. Thus, phenotypic condition of the males affects their sexual signalling. We manipulated part of the males to increase their drumming activity by presenting females in proximity. These males suffered higher mortality and lost significantly more weight than other males confirming that drumming is costly to males. Additionally, males that drummed most actively within the increased treatment group survived better than less active males. Thus males of *H. rubrofasciata* vary in their ability to bear the costs of drumming, which gives an honest signal of male quality for females.

THE ENERGETIC COSTS OF CALLING IN *POECILIMON HOELZELI*, *POECILIMON VELUCHIANUS* AND *CONOCEPHALUS DISCOLOR* (ORTHOPTERA; TETTIGONIOIDEA) MEASURED WITH A HIGH-RESOLUTION RESPIROMETRY

F. Neuhäusser-Wespy, K.-G. Heller

Department of Zoology, Universität Erlangen-Nürnberg, Erlangen, Germany

Acoustic signalling by males to attract conspecific females is widespread throughout the animal kingdom. Several studies have been made to measure the energy required for sound production. These energetic costs are of particular interest in male bushcrickets which produce large spermatophores, which add also to the male mating-costs. None of the methods used in the former studies are suitable for a direct measurement of the energy used for calling in a bushcricket with short calling songs. In our study we used a flow-trough respirometry system, with a fast responding CO₂-Sensor. By omitting water-absorbent we could increase the time-resolution of the system, so that every single action of the animal generated a single CO₂-Pulse. The costs of calling in *Poecilimon hoelzeli* which produces only single-syllable-chirps can now be calculated by integrating the CO₂ pulses caused by the song. In *Conocephalus discolor* a species with varying song length, we can compare costs of long and short songs. The measurements registered also interesting phenomena like discontinuous ventilation.

12-047

THE PHEROMONAL MECHANISM OF COMMUNICATION IN NEST SEEKING SWARMS OF HONEY BEES, *APIS MELLIFERA*
J.O. Schmidt

Carl Hayden Bee Research Center, ARS-USDA, Tucson, AZ USA

Honey bees face dual problems of locating suitable nest cavities for swarms and then coordinating the flight of thousands of individuals to the nest site. Nasonov pheromone produced by worker bees is the key communication system in this process: it communicates the presence of a suitable nest cavity to other scouts searching for nest cavities; it leads the airborne swarm toward the cavity; and it marks the cavity entrance for arriving swarm bees. Although the pheromone is a blend of seven components, two components appear incidental to activity and the ratios of the remaining five components can fall within broad ranges without apparent loss of activity. Choice tests revealed that activity is proportional to pheromone concentration over a large range of concentrations. In tests using crossover designs, queen pheromone was shown to play no role in the nest seeking communication. Other odors, including nest cavity odors, play minor roles in the communication, except that insecticide and other repellent odors can block the pheromone effect. Experiments in progress to determine if Nasonov is truly a pheromone, or if it simply serves as an odor will be presented.

The hypothesized mechanism of pheromonal communication by Nasonov pheromone to nest seeking bees is: scouts that successfully locate a suitable nest cavity scent with pheromone to communicate the presence of the cavity to other scouts; the pheromonal signal acts by generating a large pheromone-containing airspace downwind of the nest cavity which attracts and orients searching scouts which enter the airspace; once the many pheromone alerted scouts of a swarm 'reach a consensus' concerning the best nest cavity, Nasonov pheromone released by flying scouts aids in communicating the flight path to the cavity; and, finally, at the nest entrance Nasonov pheromone alerts and attracts the landing bees to the cavity entrance.

12-049

RHYTHM OF SEX PHEROMONE OF THE ORIENTAL ARMYWORM *MYTHIMNA SEPARATA* WALKER
(LEPIDOPTERA: NOCTUIDAE), AND
NEUROHORMONE REGULATIONMengying Liu, Hong Dong, Xinwen Wang

Department of Biological Semiochemistry, Institute of Zoology, Chinese Academy of Sciences, Beijing, China

The calling periodicity and producing rhythm of sex pheromone of *Mythimna separata* were investigated at 25 °C, under LD 14:10 photoperiod. It was found that the calling activity of *M. separata* is very low during the first six hours of scotophase, and then increases sharply, particularly in the 4-5 day old females. The maximal sex pheromone titre of female *M. separata* was detected in the extracts of the pheromone glands in 4-5 day old females after 6 to 8 hours from the point of the initiation of scotophase.

Tests of discapitation and injection of the brain-SOG homogenate of the adult moths in their 5th scotophase showed that the pheromone titre remains a very low level (average 1ng) by discapitation, and is restored to the control value (average 16ng) after injection of brain-SOG homogenates. During photophase, the brain-SOG homogenate still has a pheromonotropic activity, which exists in the brain-SOG complex of both female and male *Mythimna separata* during both scotophase and photophase.

12-048

A STUDY ON THE PRECISE BLENDING OF PHEROMONE COMPONENTS OF *ANCYLIS SATIVA* LIU. (LEP.: TORTRICIDAE)Lian-chang Li, Gui-biao Han¹, Jie Li²

Shanxi Academy of Agricultural Sciences, Taiyuan, Shanxi, China.

-1 Shanxi Agricultural University, Taigu, Shanxi, China. -2 Shanxi Academy of Agricultural Sciences, Taiyuan, Shanxi, China.

Recently many reports demonstrated the importance of precise blending of sex pheromone components. The present study reports the results of determining the precise blending of the sex pheromone components of *Ancylis sativa* Liu and individual variation within the population of sex pheromone chemical communication system using analytical technique of single pheromone glands. The analytical results of 47 single pheromone glands showed the precise blending of 2 components, 60:40 (E₉₋₁₂:OAC:Z₉₋₁₂:OAC), C.V.=9.8%. The result showed that individual variation within the population is controlled within narrow limits.

12-050

THE FUNCTION OF FEMALE SEX PHEROMONES IN MATE SELECTION OF *OSMIA RUFA* (MEGACHILIDAE) MALESG. Dutzler, M. Ayasse

Institute of Zoology, Dept. of Evolutionary Biology, Vienna, Austria

The function of pheromonal recognition signals in the mating biology of halictine bees is well investigated. Females release species-specific pheromones which give males further information about kin and mating status. Although the biology of the solitary megachilide *Osmia rufa* has been intensively studied, almost no data exist about the chemical communication involved in the mating behaviour. The males search for receptive females at feeding areas and at the often aggregated nests. The females of this monoandric species usually mate immediately after emerging. In behavioural learning experiments, we studied the role of individual female odour signals in male mate selection.

Bioassays showed that newly emerged females were more attractive to the males in comparison to one or two day older already-mated females. Gas chromatographic analyses of cuticular washings of the body showed significant differences in the odour bouquet of unmated and mated females, possibly responsible for the different attractiveness of these female groups to the males. Further behavioural experiments of mate recognition showed that males were able to learn individual female odours during mating attempts and to use this information in further encounters: When a female was offered a second time to the same male, significantly less copulatory activity was observed than in the first test. In a second series of tests, a first female of a pair was replaced by either a sister or a nonsister of the same or of a foreign population. In this case the attractiveness of the second female was not diminished. The results of our behavioural experiments indicate that in *O. rufa* males do not discriminate among receptive females; however, they recognise mated females and avoid spending time in mating attempts with unreceptive females.

12-051

SELECTION GRADIENTS IMPOSED BY PHONOTACTIC PARASITOIDS ON COMPONENTS OF SONG IN THE FIELD CRICKET TELEOGRYLLUS OCEANICUS

J.T. Rotenberry, M. Zuk, L.W. Simmons¹
Department of Biology, University of California, Riverside
CA 92521 USA - ¹ Department of Zoology, University of
Western Australia, Nedlands 6009 Australia

Acoustically-orienting parasitoid flies (Tachinidae: *Ormia ochracea*) impose a selection gradient on calling male field crickets (Gryllidae: *Teleogryllus oceanicus*) by using cricket mating advertisement calls to locate hosts. However, male crickets that remain silent risk losing potential mates. This creates conflicting selection pressures on song structure, which must continue to attract females while simultaneously reducing the attractiveness to parasitoids.

We recorded males in the field on three islands within the Hawaiian Archipelago, which differ in proportion of males parasitized. After recording, each male was collected and scored for the presence of parasitoids. Thirteen temporal variables were measured from a sonogram of each song. Non-linear discriminant function analysis identified several independent combinations of song variables that differed significantly between parasitized and unparasitized males. We discuss these selection gradients in the context of natural and sexual selection.

12-053

A SPERMATOPHORE STRUCTURED IN THE BURSA COPULATRIX OF SOME BUTTERFLY SPECIES AND ITS DEPLETION IN RELATION TO SUGAR CONTENT

M. Watanabe
Department of Biology, Faculty of Education, Mie University,
Tsu, Mie, Japan

During copulation, the male of pierid butterflies fills first a white gel and then structures a spermatophore in the bursa copulatrix of the female. The sperm was ejaculated last, while sugars were observed throughout the copulation. The older male ejaculated a smaller spermatophore than the younger one. Variation in size and sugar content of spermatophores observed in field-captured monogamous females indicated that sugars were consumed immediately after copulation, and that the spermatophore was gradually eroded. Uninterrupted copula durations between virgin male and virgin female in the sulfur butterfly were successful copulations, lasting about 45 min in the laboratory. Most copulations were prolong in the field from those in the laboratory due to lone males harassing, though no male ejaculated a larger spermatophore. The lone males significantly increased the duration of a harassment of the pair that copulated with old males. No severe harassment elicited any particular behavior of the pairs. The female of the pair also ignored the lone males harassing. A few take-over of female by lone males harassing and a few females accepting re-mating with a lone male just after the first copulation were observed. Most of the females were copulated with old males. About 15% of experienced females in the field accepted further mating, requiring longer duration of courtship behavior by lone males than virgin ones. Females that accepted re-mating retained smaller ejaculates in the bursa copulatrix than those that refused re-mating. Severe harassments of pair with old males may be advantageous to lone males due to a small spermatophore ejaculated by the old males.

12-052

SEXUAL BEHAVIOUR AND MATING IN *BLATTELLA GERMANICA* LINN. (BLATTOIDEA ; BLATTELLIDAE)

S. C. Pathak¹, Rita Bhandari²

- 1. - Department of Biological Sciences, Rani Durgavati University, Jabalpur 482001 India.
- 2. - Department of Zoology, Govt. Autonomous Science College, Jabalpur 482001 India.

Exact sequencing of various steps in the courtship, sexual behaviour and mating, starting from the recognition of the potential mate, has been carried out in *Blattella germanica*, with the help of video recording. The males show some specific movements which can be described as courting the female. Some movements, representing sexual foreplay, are however, common to both the sexes. The female does not actually feed from the metanotum of the male, as is believed thus far. All movements of the female, during the process of mounting the male, are in the nature of tactile stimulation only. These movements commence from the last abdominal tergum and shift anteriorwards till they reach the metanotum, and involve tapping of the terga of the male by her maxillary palps. Attempt for interlocking of the genitalia is made immediately as the metanotum of the male comes under the maxillary palps of the female.

12-054

EVOLUTIONARY CHANGES IN NUPTIAL GIFT SIZE CORRELATE WITH EVOLUTIONARY CHANGES IN SPERM NUMBER IN BUSHCRICKETS (ORTHOPTERA: TETTIGONIIDAE).

K.Vahed
University of Derby, Derby, U.K.

The spermatophores of bushcrickets consist of two parts: an ampulla which contains the sperm and a spermatophylax which the female eats following mating. Interestingly, there is a large degree of interspecific variation in the relative size of the spermatophylax. There are two different, though not mutually exclusive, hypotheses concerning the selective pressures important in the evolutionary enlargement of the spermatophylax in bushcrickets. The paternal investment hypothesis proposes that elaboration of spermatophylax size has proceeded through selection for male nutritional investment in their own offspring. The ejaculate-protection hypothesis, on the other hand, proposes that the evolutionary enlargement of the spermatophylax has proceeded through selection to ensure complete ejaculate transfer. The latter hypothesis predicts that evolutionary changes in spermatophylax size should be positively correlated with evolutionary changes in ampulla size (ie. ejaculate volume) and sperm number. Here I present the results of a comparative study designed to test this prediction. Measurements of spermatophylax mass, ampulla mass, sperm number and male body mass were taken for 43 species of European bushcrickets. The data were analysed using the independent comparisons method. This method corrects for similarity between taxa resulting from common ancestry and involves converting the data set into a series of statistically independent contrasts. As predicted by the ejaculate-protection hypothesis, a positive relationship was found, across taxa, between changes in spermatophylax mass and changes in both ampulla mass and sperm number, with male body mass controlled for.

12-055

OVIPOSITING STRATEGY OF *EUPEODES CONFRATER* (DIPTERA: SYRPHIDAE) FEEDING ON *PSEUDOREGMA BAMBUCICOLA* (HOMOPTERA: PEMPHIGIDAE) WITH STERILE SOLDIER CASTE

H. Shibao

Graduate School of Environmental Earth Science Hokkaido University, Sapporo 060, Japan

Recent studies on aphidophagous syrphid flies demonstrated that females, in searching oviposition sites, assess qualitative and quantitative value of aphid colonies as suitable and sufficient food resource for their offspring. However, oviposition behavior of syrphid flies feeding especially on soldier-producing aphids is never intensively studied. My study on ovipositing strategy of *Eupeodes confrater*, which feeds on eusocial aphid *Pseudoregma bambucicola* with a special soldier caste, demonstrated that female flies selected large colonies for their food and laid eggs on various sites such as fine threads of spider webs and hairy objects in or close to aphid colonies. Since the aphid soldiers were able to attack syrphid eggs using their frontal horns, only the eggs laid on spider threads could escape. Female flies could change their oviposition sites in relation to soldier density. For instance, when the soldier ratio of aphid colonies was high, most of females did not lay eggs in or close to the aphid colonies, but on spider threads near the colonies. In contrast, when the soldier ratio declined (nearly 0%), females laid eggs directly on the colonies. These results possibly suggest that females of *E. confrater* select optimal sites for oviposition in response to the density of aphid soldiers.

12-056

THE INTERACTION BETWEEN THE EFFECTS OF TERRITORY AND SEX RATIO ON COPULATION DURATION IN THE WALNUT FLY *RHAGOLETIS JUGLANDIS*

H. Alonso-Pimentel and D. R. Papaj

Department of Ecology and Evolutionary Biology and Center for Insect Science, University of Arizona, Tucson, Arizona USA

Ecological factors such as operational sex ratio (OSR) and territoriality are known to play important roles in mating dynamics. While most studies address the effect of each factor independently, the interaction between them is seldom considered. Using a combination of field and laboratory assays, we examined the role of both factors in the mating dynamics of the tephritid fly *Rhagoletis juglandis*. This species is characterized by a resource defense mating system in which males defend walnuts and mate with females that arrive on the fruit to lay eggs.

In the field, copulation duration in *R. juglandis* was distributed bimodally, most copulations being either short (≤ 200 sec) or long (> 600 sec). In both field and laboratory, OSR had a strong effect on copulation duration: at male biased sex ratios, copulations tended to be long; at even or female-biased ratios, copulations tended to be short. Individual flies were able to shift copulation duration in response to changes in sex ratio occurring over a scale of a single day.

In a final laboratory assay, the effect of OSR on copulation duration was found to depend on the presence of fruit. In the presence of surrogate fruit, the usual effect of sex ratio on copulation duration was expressed; in the absence of such fruit, however, the effect disappeared. In the same assay, the effect of fruit presence on copulation duration depended on OSR. At a female-biased ratio, the presence of a surrogate fruit tended to result in relatively more short copulations. At a male-biased sex ratio, however, the presence of fruit had no effect on copulation duration.

12-057

The Effect of the Oviposition Behaviour on the Fitness of *Callosobruchus maculatus* (Fab.) (Coleoptera: Bruchidae)

Y. S. Shiao, S. B. Horng, R. Schopf¹

Department of Plant Pathology and Entomology, National Taiwan University, Taipei, Taiwan, R.O.C., -1 Lehrstuhl für Angewandte Zoologie, Universität München, München, Germany

For the observation of the effect of the oviposition behaviour of bean weevil (*Callosobruchus maculatus*) on its fitness on azuki beans and mung beans, three strains from Taiwan, 4C6-4, 13M23 and 10CG-8, were used. These geographically different strains showed significant differences in the longevity, the fecundity, the adaptation ability to hosts and the degree of larval competition. Because of the non-feeding culture in adult stage and the lack of the ability of self-dispersal in larval stage, these differences will directly influence the fitness, which was defined as the number of offsprings. All the above reproductive characters were described quantitatively and used to compare the fitness of the three strains among two hosts. A random egg distribution simulated by computer according to the observed fecundity was also compared with the observed egg distributions to enumerate the benefit of the oviposition behaviour. It was found that the female bean weevils of all three strains tended to lay their eggs in a nearly uniform distribution and their fitness was increased by this oviposition behaviour, but the connection between larval competition and egg dispersion was lost. It suggests that although the behaviour of uniform egg dispersion should be a result of selection, the cost of barring this behaviour could be relative low when compared with its benefit.

12-058

NO HOST-QUALITY PREFERENCE BY THE HYPERPARASITOID, *EURYTOMA* SP. (HYMENOPTERA: EURYTOMIDAE), FOR THE COCOONS OF THE PARASITOID, *COTESIA GLOMERATA* (HYMENOPTERA: BRACONIDAE)

J. Tagawa

Department of Applied Science, Okayama University of Science, Okayama, Japan

Eurytoma sp. is a solitary hyperparasitoid which attacks *Cotesia glomerata* cocoons of various ages. Under laboratory conditions of 20°C and 16L8D photoperiod, the number of eggs laid per day in old cocoons was nearly the same as that laid in young ones. However, females laid more male-eggs in old cocoons than in young ones. The developmental period of *Eurytoma* sp. was longer and the mortality was higher when laid in old cocoons than those laid in young ones. Apparently, the old cocoons were less suitable for *Eurytoma* sp. than young ones.

However, *Eurytoma* sp. females did not show any preference for good cocoons when offered young and old host cocoons simultaneously.

Investigations of *C. glomerata* cocoons in the field showed that the hosts of many clusters developed relatively equally. Further, the longevity of the female *Eurytoma* was as long as 2.5 months or more at 20°C. The number of eggs laid in a day by young females was nearly 10. Even old females could lay several eggs in a day. The ability of egg production was considered high for both young and old females. Therefore, under natural conditions, it might be advantageous for females to lay eggs immediately after encountering the host cocoons.

12-059

REPRODUCTIVE BEHAVIOR OF THE PAPAYA FRUIT FLY *TOXOTRYPANA CURVICAUDA* (DIPTERA: TEPHRITIDAE) IN THE CENTRAL MEXICO.
M. CAMINO-LAVÍN*, R. ARZUFFI*¹, F. CASTREJÓN-AYALA*, A. JIMENEZ-PEREZ* AND M. J. GARCIA-RAMIREZ.

Centro de Desarrollo de Productos Bióticos-IPN. ¹ Escuela Nacional de Ciencias Biológicas-IPN. México.

Full understanding of insect behavior and its relevance to the Integrated Pest Management process will lead eventually to application of more effective and safe pest management practices.

The papaya fruit fly, *Toxotrypana curvicauda* is the main pest of papaya crop in central part of Mexico.

Studies were conducted at field conditions in order to know dispersal behavior and in laboratory to know reproductive behavior.

Ethograms were made considering the relative frequency of 21 patterns. Results showed a low dispersion of adult in the crop. The flies were found mainly at the border of the papaya crop. Dispersion did occur at 17:00 hrs. and flies arrived to the papaya grove at 11:00 hrs next day. At laboratory, patterns of behavior differs significantly between males and females. Patterns were found in higher numbers as the flies became older. In males, patterns with high frequency were setting, grooming and calling while in females, they were setting, flying, mouthparts moving.

12-061

WHY A MALE CRICKET COURTS ANOTHER MALE ?

K. Khazraie, M. Campan

U.P.S. Laboratoire d'Ethologie et Psychologie Anomale, CNRS - URA 1837, 118 Route de Narbonne, 31062, Toulouse cedex, France

Adult males of *Gryllus bimaculatus* court their partner independently of their sex. The courtship being only if the partner is immobile, whether female, subordinate male or a dummy (male or female anaesthetized by carbon monoxide). The main stimulus which provokes courtship therefore seems to be the behaviour (immobility) of the partner.

The frequency of courtship between two males ("homosexuality") decreases as the available surface increases. We conclude that the greater the possibility subordinates have to escape, the less likely they are to become immobile when confronted by a dominant partner.

In the context of Evolutionary Game Theory, immobility can be considered as a tactic, adopted by subordinates, to inhibit aggressivity of dominant individuals when escape is not possible or too costly.

12-060

THE ROLE OF NUTRITION AND JUVENILE HORMONE IN REGULATING MATING BEHAVIOR IN BOTH SEXES OF *PHORMIA REGINA* (MEIGEN)(DIPTERA: CALLIPHORIDAE)
J.G. Stoffolano, Jr., W.-H. Qin, C.-M. Yin
Department of Entomology, University of Massachusetts, Amherst, MA 01003-2410 USA

Mating behavior of both sexes of *Phormia regina* is dependent on nutrition, which in turn influences the corpora allata to produce juvenile hormone (JH). Sugar-fed flies do not exhibit mating behavior while protein-fed flies mate. Approximately 10 mg of liver was required for 80% of the males to inseminate females whereas 20 mg of liver was required for 78% of the females to become inseminated. For females, less protein is required to activate sexual receptivity (i.e., 10 mg) than to develop mature eggs (i.e., >15 mg). Allatectomy greatly suppressed mating behavior of both sexes. Topical application of 10 ug of methoprene (a JH hormone analogue) at 12 h after the onset of liver feeding significantly increased sexual activity of both allatectomized males and females.

12-062

REPRODUCTIVE STRATEGY AND VARIABLE MATE GUARDING BEHAVIOUR OF GYPSY MOTH, *LYMANTRIA DISPAR JAPONICA* L. (LEPIDOPTERA, LYMANTRIIDAE).

C. Koshio
Naruto University of Education,
Takushima, Naruto-cho, Naruto-city, Tokushima,
772, Japan

Male and female reproductive strategies were investigated in a Japanese population of the gypsy moth, *Lymantria dispar japonica* L. in the laboratory and field.

During the days, mated females stayed motionless at the copulation sites. At dusk, the females began to walk and/or fly actively in search of oviposition sites. Oviposition began at night and continued for several days at the same site. Females ceased oviposition every morning after covering the eggs with a thin layer of scales from their abdomens. In the field, females showed multiple mating before oviposition.

Gypsy moth in Japan, show two patterns of copulation; short duration and long duration. Short duration copulation was sufficient to fertilize almost all the eggs of a female. Long duration copulation continued until a female began pre-ovipositional behavior and occurred when other males were attracted to the copulating pair. Extended copulation, therefore, appears to be a mate guarding strategy by males. Males change their strategies from mate searching to mate guarding according to the disturbances by other males. I also compared the reproductive strategies of the gypsy moth with those of other temperate and tropic diurnal moths.

12-063

MALE MATING BEHAVIOR AND A CONTACT SEX PHEROMONE OF THE YELLOW-SPOTTED LONGICORN BEETLE, *PSACOTHEA HILARIS* (PASCOE) (COLEOPTERA: CERAMBYCIDAE).

M. Fukaya, S. Wakamura, T. Yasuda

Department of Insect Physiology and Behavior, National Institute of Sericultural and Entomological Science, Ohwashi, Tsukuba 305, Japan.

A male of the yellow-spotted longicorn beetle, *P. hilaris* recognized a female when he directly contacted her with his antennae, tarsi and/or palpi. A contact pheromone revealed to be essential in releasing male mating behavior of this beetle. The female sex pheromone consisted of at least two factors with different functions, the one caused dash behavior toward female, and other did holding, mounting and abdominal bending behavior. A major component of the pheromone was isolated from cuticular hydrocarbon fraction of female elytra extract. It was identified as (Z)-21-methyl-8-pentatriacontene, which accounted for ca.60% of the hydrocarbon components. The synthetic compound released the typical mating behavior including holding, mounting, and abdominal bending in males when treated on a gelatin capsule as an artificial female dummy. The activity was the component, however, considerably lower than the extract of female elytra.

12-065

MALE REPRODUCTIVE BEHAVIOUR IN TWO SPECIES OF *SYSTROPHA* BEES (HALICTIDAE)

R.J. Frabberger, M. Ayasse

Institute of Zoology, Dept. of Evolutionary Biology, Vienna, Austria

Populations of the two solitary bees *Systropha planidens* and *S. curvicornis* are very rare in Central Europe. Females of both species can often be found in mixed nest aggregations. Females of the oligolectic species tend to forage mainly in the morning on flowers of *Convolvulus arvensis*. No information exists about the mating biology. We investigated the mating biology of both species by behavioural observations and field experiments.

Flowers are very often encounter sites in oligolectic bees. In fact, we found patrolling males of both species moving constantly along fixed routes between flowers of *Convolvulus arvensis*. The flight routes of single males overlap within and between species. Territory owners strike intruding conspecific males as well as *S. curvicornis* males with their last sturdy tergites. In behavioural experiments, dead males and females of both species, previously killed by freezing, were offered to territory owners by placing them in *Convolvulus* flowers. The observed male behaviour indicates that the odour bouquets on the cuticular surface are species-specific and encode information about sex: *S. planidens* males tried to mate with conspecific unmated and already mated females, and showed more aggressive behaviour towards conspecific males in comparison to *S. curvicornis* males. The hypothesis that the odour bouquets on the cuticular surface encode sex- and species-specific information is presently being investigated by chemical analyses.

12-064

MATING STRATEGIES AND MATE SELECTION BEHAVIOUR OF *DYSDERCUS KOENIGII* F.

K.K. Gupta, S.S. Sehgal¹

Department of Zoology, Deshbandhu College (University of Delhi), Kalkaji New Delhi-19, India - ¹ Department of Zoology, University of Delhi, Delhi-7, India

The female of *Dysdercus koenigii* exhibits multiple mating behaviour. After attaining sexual maturity the bugs were observed to mate 5-7 times. The first mating was of the longest duration. The copula lasted up to 72 hr. The females although were mating - receptive throughout their life, tended to be refractory for mating after copulation. Mating refractory behaviour of a female was shown to depend on the duration it remain in copula. A female, for example was allowed to mate for 24 hr after which it still remained receptive to mating. However, 48 hr mating evoked a mating refusal behaviour which was more pronounced in the female that mated for 72 hr. Renewal of mating receptivity occurred in the female after oviposition. Regarding the mate-selection behaviour of the female, it was observed that it mated with any male encountered first. In a choice test a male which had earlier mated for shortest duration would prefer to mate again. The male on the other hand preferred to mate with either a virgin female or 24 hr mated female. Significance of male substance in suppression of mating receptivity in the female and possible evolutionary advantage of mate-selection behaviour of male *Dysdercus koenigii* is discussed.

12-066

STUDIES INVOLVING THE MECHANISMS OF "SPERM PRECEDENCE" IN *TRIALEURODES VAPORARIORUM* (HOMOPTERA: ALEYRODIDAE)

M. Calvitti, C. Govoni

ENEA Cre Casaccia- Dip. Innovazione- Settore Agrobiotecnologie, Roma, Italy

T.vaporariorum males have been radiosterilized by means of "gamma rays" to a dose of 50 Gy.

At this dose males preserve a partial spermatozoid competitiveness and sperm transfer capacity. However spermatozoa are unable to fertilise eggs and produce viable embryos.

We have analysed the egg mortality and the sex-ratio in progeny born in the following mating types:

A: virgin females x normal males

B: virgin females x sterile males

C: virgin females mated firstly with normale males and then with sterile males.

We found a significant higher mortality in B and C (about 35%) compared to A (0.2%). We considered the major egg mortality found in B and C to be a measure of the fertilization capacity of spermatozoa produced by sterile males.

Moreover, we found both the sexes in progeny produced in mating A, while an exclusively male off-spring was born in mating B.

The sexual analysis of progeny produced in mating type C, has showed, in the first days of adult emergence, a completely male off-spring. Subsequently rare females have appeared. According to these results we may suppose that the spermatozoa of the most recent matings were favored in the fertilization process.

12-067

THE NESTING BEHAVIOUR OF CENTRIS (HETEROCENTRIS) ANALIS (FABRICIUS, 1804) (HYMENOPTERA, ANTHOPHORIDAE).

B.M.V. Jesus, C.A. Garófalo
Departamento de Biologia - Faculdade de Filosofia, Ciências e Letras de Ribeirão Preto - USP - Ribeirão Preto, SP, Brasil

The nesting behaviour of Centris analis was studied on the University Campus of Ribeirão Preto, SP, Brazil. The bees nested in trap-nests made with black cardboard having 5.8 cm in length and 0.6 cm of internal diameter introduced into holes made in wood plates which were placed on the shelves of two shelters built at the study site. After a suitable trap has been found, the female collects oil to line internally the trap. Subsequently she begins to collect plant material to construct the bottom wall of the nest and the beginning of the first cell partition in the form of a small ring that encircle all the circumference of the nesting tube. The plant material consists essentially of pollen, anther fragments, filament, shaving of pollinic sacs and fibres. Four to 11 pollen-collecting trips are made to provision one cell. Cells that produced females were provided with more trips of pollen than those that produced males. After all the pollen has been deposited, the female collects additional plant material and adds it to the cell ring. After that the female performs from 2 to 8 nectar-collecting trips to complete the provision of the cell. No difference was observed between the number of nectar-collecting trips for female and male cells. After depositing nectar on the provisions, the female oviposits and immediately seals the cell by constructing the cell partition from material previously deposited on the cell ring. The number of brood cells in each nest ranged from 1 to 4, usually followed by an empty vestibular cell. The nest plug is constructed of the same material as partitions and it is lined externally with oil. The time needed to complete a cell ranged from 1 to 5 days, but mostly within one day. The maximum number of nests and cells built by a female were 3 and 9, respectively. The largest period in which a female remained nesting in the area was 30 days.

12-069

ASSESSMENT OF APHID COLONIES BY THE HOVERFLY
(EPISYRPHUS BALTEATUS (DE GEER))(DIPTERA: SYRPHIDAE)

E. Kan, T. Hidaka¹
Behavioural Biology Department, The International Centre of Insect Physiology and Ecology, Nairobi, Kenya - ¹ Shiga Prefectural University, Hikone, Shiga, Japan

In the syrphid hoverfly Episyrphus balteatus (de Geer), females in search of oviposition sites are assessing the qualitative and quantitative value of aphid colonies for securing the successful development of their offspring. They select small, young and "promising" aphid colonies consisting of nymphs and/or fundatrices as their oviposition sites, and neglect large, older ones including winged adults. Such "buy-futures" tactics will benefit the offspring in finding suitable and sufficient food.

THE NESTING ACTIVITIES OF CENTRIS (HEMISIELLA) VITTATA LEPELETIER (HYMENOPTERA, ANTHOPHORIDAE).

M. Pereira, C.A. Garófalo
Departamento de Biologia - Faculdade de Filosofia, Ciências e Letras de Ribeirão Preto - USP - Ribeirão Preto, SP, Brasil

Observations on the nesting activities of Centris vittata were conducted at Santa Carlota Farm, Município of Cajuru, SP, Brazil. The bees nested in bamboo canes which were placed along shelves in a shelter built at the study site. The diameters of canes utilized (n=67) varied from 1.0 to 1.9cm and their lengths from 8.9 to 22.2cm. Once a cane is selected, the female begins to forage for nest construction material that consists of a mixture of soil+oil. Thirty-seven to 53 material-collecting trips are required to construct one cell and the beginning of the cell cap that encircle part of the cell opening. Material collecting trips lasted 35-1754 sec. (n=200). After the cell is built, the female performs a variable number (9-14) of oil-collecting trips to line internally the cell. Oil-collecting trips lasted 76-3096 sec. (n=88) Twelve to 22 pollen-nectar collecting trips, which lasted 75-3427 sec. (n=144), are made to provision one cell. Total time spent in cells to deposit nectar and pollen loads ranged from 33 to 902 sec. (n=140). After cell provisioning is completed, the female collects additional oil (1 to 5 oil-collecting trips) and deposits it on the cell cap partially constructed. After that female lays the egg and immediately seals the cell from material previously there deposited. Following the same sequence, a serie of cell (from 1 to 6 cells) are constructed in a cane. Female progeny are normally produced in the inner cells and the males in the outer cells of each nest. C. vittata nested during most of the hot and wet season (September-April).

GLUING EGGS ON ANOTHER'S BACK IN
PHYLLOMORPHA LACINIATA (HETEROPTERA, COREIDAE): - EGG DUMPING OR PATERNAL CARE?
A. Kaitala

Department of Zoology, University of Stockholm, Stockholm, Sweden

Females of Phyllomorpha laciniata Vill. lay eggs on the backs of conspecifics, females and males. In nature males carry twice as many eggs as females. Eggs do not survive in nature undefended but survive rather well on an individual's back. Experimentally, I tested if females lay eggs on the backs of their mating partner after mating as expected if egg carrying is paternal care. If sex ratio was even, females laid eggs randomly with respect to paternity. However, when sex ratio was male biased most eggs were laid on mating partner's back. Some individuals rubbed off eggs from their backs by brushing their backs against different objects. Individuals that had five or more eggs rubbed off eggs more often than individuals carrying only a few eggs. A male's voluntary egg carrying (when several males competed over access to a female) is more likely to be explained as post zygotic mate guarding or mating investment rather than paternal care because some males rubbed off their own eggs. The field data and laboratory experiments convince that P. laciniata is not a species with exclusive paternal care in contrast to what is assumed in the literature. I conclude that females have adopted a "cuckoo" reproductive strategy by gluing eggs on another individual's back and "forcing" others to carry them. I will discuss on the possible evolutionary explanation on why females accept other female's eggs and why males accept eggs they have not fertilized.

NESTING AND NESTS' PROVISIONING IN *OXYBELUS ARGENTATUS* (HYMENOPTERA: SPHECIDAE) IN ALTA VALTELLINA (NORTHERN ITALY)

A. Martinoli, M. Casiraghi, E. Passerini, T. Bosco, F. Andrietti
Dipartimento di Biologia, Sezione di Zoologia e Citologia,
Università degli Studi di Milano, via Celoria, 26 Cap 20133,
Milano, Italy

During three summers from 1993 to 1995 about 50 nests of the solitary wasp *Oxybelus argentatus* have been observed at Le Prese (Alta Valtellina, Sondrio province, Lombardia).

All the females and their nests have been marked. Each nest has been observed since the beginning of the digging to the final sealing. Daily wasp behaviour was recorded since early morning, before the first wasp left, to late afternoon when all the activities stopped.

The study has been focused on the duration of the following actions: nest digging, nest provisioning, and nest closure. Inferences about prey number in each cell and cell number in each nest have been drawn.

Collected preys have been listed.

12-072

BUILDING ACTIVITY IN *POLISTES* WASP : LOCAL STIMULUS, SHAPE OF THE NEST AND CONTEXTUAL EFFECTS

M. Soleilhac, J. Gervet

Laboratoire d'Ethologie et de Psychologie Animale,
Université Paul Sabatier, Toulouse, France

The building activities, owing to the long-lasting marks they leave, are especially suited to the study of how an animal makes itself acquainted with its environment in order to determine its behaviour. The studies available clearly show the influence of stimuli received locally, but, frequently do not allow to distinguish their direct releasing influence from the effect of the context in which the reception occurs.

Our experimentation aims at testing the effect of such contextual influences. In a succession of experiments, we offered to digynous *Polistes* colonies several devices with structures that differ from natural nests concerning either local stimulus or general outline : inverted nests, nests associated back to back... In these situations were studied the effects of several parameters : flatness of the comb, presence of a colonial chemical mark, orientation to gravity...

These effects were evaluated by the subsequent building behaviour and the shape of the newly built structures. These results are interpreted in terms of local stimulations and contextual influences.

12-073

NEST RECOGNITION AND ASSOCIATED BEHAVIOUR OF TWO SPECIES OF GRYLLACRID CRICKETS (ORTHOPTERA : GRYLLACRIDIDAE).

Roderick J. Hale.

Department of Zoology, University of Western Australia, Nedlands,
6907, Australia.

Gryllacridids are a group of primitive, nocturnal crickets that are unusual in their ability to form 'nests'. These nests, constructed from silk secreted from an individual's mouthparts, represent a costly investment by the animal. Individuals of both sexes would therefore be expected to be able to recognise their own nests, and defend these nests from conspecifics.

Observations on *Ametrus* and *Hadrogryllacris* species reared in the laboratory show that nest construction and associated behaviour commonly occurs within 4 days of hatching. Thus, nests appear to be an important resource for juvenile crickets of these species.

At the onset of daylight, juveniles return to their own nests more than 55% of the time. Those that fail to return spend the day outside of any nest; occupation of a conspecific's nest is extremely uncommon. Research has shown that pheromones play an important part in recognition of nests. However, spatial cues (indicative of memory) and/or behavioural interactions may also be important factors in nest recognition.

12-074

NEW INSIGHTS TO FOOD AND OVIPOSITION PREFERENCE OF THE BUSHCRICKET *PHANEROPTERA FALCATA* (PODA) (ENSIFERA: PHANEROPTERIDAE)

J. Samietz, G. Köhler

Institute of Ecology, University of Jena, Germany

So far, in Central Europe *Ph. falcata* is generally characterized as connected with bushes on semiarid grassland. All over the literature this connection is explained as a result of oviposition inside of leaves of several shrub species. In the present study, the actual relation of *Ph. falcata* to habitat was investigated with regard to oviposition and food preference. Some laboratory experiments and field studies were conducted between 1992 and 1995.

In first laboratory experiments, some species of shrubs were offered to the bushcrickets in several combinations. A distinct oviposition preference to some plant species could be proved. Also the insects fed the leaves of offered shrubs in regular patterns and preferred some plants.

In contrast, the field study showed a clear food preference to blooms of herbaceous plants. Surprisingly, in the natural habitat the females chose almost only leaves of grasses (Gramineae) for the oviposition. Laboratory experiments clearly confirmed this behaviour. The bushcrickets laid their eggs not only inside of grass species of the semiarid sites (*Bromus erectus*, *Brachypodium pinnatum*), but in grasses of fresh meadows too (*Dactylis glomerata*).

In Further laboratory experiments the food preference observed in the field study could be proved as well. Firstly, *Ph. falcata* preferred blooms of mostly herbaceous plants. Secondly, the species chose faded blooms, fruits and seeds. Not until these food sources had been removed or got very dry, the bushcrickets fed leaves of shrubs and herbaceous plants in larger quantities.

Therefore, with regard to oviposition and food, a relation of *Ph. falcata* to scrubby vegetation could not be proved. The obvious occurrence of the species on such habitats may be discussed as a covered influence of the habitat management. The eggs of the bushcrickets laid inside the leaves of grasses would be removed by any mowing in autumn or by intensive grazing. Thus, a less management allows the survival of *Ph. falcata*, but is combined with an increase of bushes.

SPIDER MITE INFLUENCE BEHAVIOR OF ONION THRIPS ON CUCUMBER CROP UNDER GNEENHOUSE CONDITONES.

V.A.Razdobyrdin

Dep.of Entomology and Plant Immunity to Pests, All-Russian Inst. for Plant Protection

Spider mite, *Tetranychus urticae* K. and onion thrips, *Thrips tabaci* L. often invade cucumber plant in association with each ther providing that both species are present in a greenhouse. This phenomenon might be observed in some cases even in the situations approaching to ecological vacuum. The behavior of *Th.tabaci* has been studied in free choice experiments during the investigation; spider mite invaded cucumber plants were compared to intact ones.

It has been shown that thrips response to the presense of spider mites on cucumber leaves depends on stage of insect development: mainly negative response was notified for adults while thrips larvae responded positively. It has been known that food specializations of adults and larvae of onion thrips differ to some extent. In particular, the ability of thrips to play the role of mite predator is characteristic of larvae only. The preferences of thrips larvae in relation to the host plant are rather similar to that of spider mite. Larvae of the insect prefer to feed within mite locus if the latter is available on the cucumber leaf. In the case if locus square is over than 3-5 cm² thrips larvae prefer to feed in its border areas. As a rule the share of larvae feeding within mite locusus is higher on cucumber genotype being resistant to the both pest species as compared to that on sisceptible plants. It is probable that the same immunological barriers might be involved in interactions of cucumber plants with the both pest species.

VISUAL CONTROL IN THE GIANT HONEYBEE *APIS DORSATA*: THE OCELLAR SYSTEM CONTRIBUTES TO FORAGING RECRUITMENT
G. Kastberger, O. Winder ¹, M.Habibulla ²

¹ Institute of Zoology, University of Graz, Austria; ² Jawarharlal Nehru University, School of Life Sciences, New Delhi, India

Honeybees start to forage nectar or pollen under conditions that are given mainly by colony factors, weather and season. However, the decision to dare a foraging flight is not made by the colony but by the individual itself. The individual factors releasing foraging activity deal in particular with the interplay of exploiting a food source in accordance with its profitability. A source of food may become unprofitable if e.g. the flow of nectar is diminished or otherwise, if visual orientation becomes intricate for the forager bee to find the path to the food source or back to the hive. It is an open question whether besides the compound eyes also the ocellar system is engaged in managing such tasks of visual orientation. We studied the possible roles of the ocellar system in *Apis dorsata* in visual orientation by stepwise modifying the stage of difficulty for securing food. We investigated the behavior of two differently treated groups of trained fully sighted bees, of one group of trained ocelli-occluded bees and one group of newcomers, when flying through apertures - variable in size - to come to a feeder or back to the hive. The results of two experiments (1994,1995) comprise more than 30.000 observations and show that the bees will stop revisiting the feeder if visual orientation gets difficult for them to a certain extent. Hereby, the ocelli-occluded bees stay away from the feeder at lower stages of difficulty (at wider openings) than fully sighted bees do. This is plausible as occlusion of the ocelli makes the bees clumsy regarding visual orientation, which can be observed e.g. in their lower capability for adjustment of the flight course during foraging. On the other hand, ocelli-occluded bees hold the memory of a food source, as they revisit the feeder on consecutive days obviously to check its profitability. This is the first evidence for a role of the ocelli in controlling the recruitment of forager bees. Moreover, the data disclose that the behavioral differences of ocelli-occluded bees are caused specifically by the lack of ocellar functions and not just by their discomfort through the dye on their heads.

ASSOCIATIVE LEARNING BY ANTHOCORID PREDATORS PLAYS A ROLE IN PREY ODOUR RECOGNITION.

Bas Drukker

University of Amsterdam, Department of Pure and Applied Ecology, Kruislaan 320, 1098 SM Amsterdam, The Netherlands
E-mail: Drukker@bio.uva.nl

Anthocorid predators (*Anthocoris nemoralis* Fabricius, *A. nemorum* (L.) and three species of *Orius*) respond to odours emitted by pear trees attacked by pear psyllids (*Cacopsylla pyricola* (L.)). Predators seem to be rather variable with respect to their response to the compounds present in the odour blend emitted by trees. If adult anthocorids are collected in pear trees, the majority (75-96%) is attracted to methyl-salicylate -one of the compounds present in the odour blend- over clean air in a Y-tube olfactometer. If they are collected in the hedgcrows surrounding the orchard, fewer individuals (60-75%) seem to respond positively to the compound. However, the response of captive *A. nemoralis* adults reared on a diet of lepidopteran eggs hardly exceeds 50%. These findings suggest that expericnce with odour cues may play a key role in prey recognition and prey finding by the bugs. In a series of experimnts it is demonstrated that associative learning is not limited to hymenopteran insects such as honey bees and parasitoids, but can also be found in anthocorid predators.

12-078

ORIENTATION RESPONSES OF THE PREDARORY BUG *PERILLUS BIOCULATUS* TO VOLATILE BLENDS FROM THE POTATO-COLORADO POTATO BEETLE COMPLEX

J.J.A. van Loon, E.W. de Vos

Department of Entomology, Wageningen Agricultural University, The Netherlands

The predatory bug *Perillus bioculatus* Fabricius (Pentatomidae: Heteroptera) is a specialized natural enemy of chrysomelid beetles, such as the Colorado potato beetle (CPB), *Leptinotarsa decemlineata* Say (Chrysomelidae: Coleoptera). We studied the locomotory behaviour of *P. bioculatus* in response to different stimuli using an automated locomotion compensator. Males or females were exposed to a stream of clean air (speed 0.25 m/s), to air carrying the odours of intact or mechanically damaged potato plants and to air passed over plants infested with feeding or non-feeding CPB larvae. Air passed over intact potato plants evoked locomotory responses similar to clean air. Air passed over the potato-CPB complex elicited distinct orientation responses from *P. bioculatus*, characterized by significantly higher values of upwind fixation (a measure for upwind orientation i.e. upwind length divided by track length) than those displayed in response to volatile blends from intact potato plants or clean air. *P. bioculatus* responded to odours emitted by mechanically damaged plants in a way similar to the CPB-potato complex, but this response disappeared within 1 hour after damage was inflicted. In contrast, feeding damage produced oriented locomotion for several hours after removal of CPB. Gas chromatographic analyses of headspace volatiles emitted by intact potato plants and plants damaged either mechanically or by feeding CPB, showed that several volatiles are emitted only after feeding by CPB and that the release of these compounds is sustained for several hours after removal of CPB larvae. No consistent differences in locomotory behaviour were found between the sexes.

12-079

HOW VISUAL SHAPE SURROUNDING THE NEST HELP FOR NEST LOCALIZATION BY THE SOLITARY BEE, *MEGACHILE ROTUNDATA* (F.) (HYMENOPTERA: MEGACHILIDAE)

K. Fauria, R. Campan, N. Youssef¹, A. Grimal

Laboratoire d'Ethologie et de Psychologie Animale, Université Paul Sabatier, Toulouse, France - 1 Department of Biology, Utah State University, Logan, UT USA

Female of leaf-cutter bee, *Megachile rotundata*, has to localize its nest after each foraging trip, carrying a piece of alfalfa leave, nectar or pollen. Guiding is about exclusively visual. We have experimentally measured, in natural conditions, in which respect visual cues closely surrounding the nest participated in guiding the final approach before landing on the familiar nest hole.

The experimental device consisted of styrofoam nesting blocks (10X10cm side area) with 49 spaced holes filled with a soda straw. Each block was evenly flushed at the centre of a 40x40cm metal platform hanging vertically. Nine of these devices were spaced in an horizontal row. Each nest block was surrounded by 4 geometrical shapes, fixed with magnets, then movable and removable. The experiments were conducted by disturbing or removing the 1-4 shapes.

The results showed that nesting females used a limited extent the shapes pattern surrounding their nests, and each individual shape as well. Nest localization was delayed but never prevented. Removing from 1 to 4 shapes increased the delay, but the effects of the positions of the removed shapes appeared unclear. Pivoting the whole pattern does not make any difference. The results will be discussed within the frame of the snapshot theory.

12-081

ORIENTATION BEHAVIOUR IN *CATAGLYPHIS CURSOR* (HYMENOPTERA, FORMICIDAE) AT THE INDIVIDUAL LEVEL

S. Chameron, G. Beugnon, V. Fourcassie

Laboratoire d'Ethologie et Psychologie Animale, URA - CNRS 1837, Université P. Sabatier, 118 route de Narbonne, 31062 Toulouse cedex, France

Many studies of orientation in insects have emphasized their powerful abilities for finding their way home. In the ant *Cataglyphis cursor* for example, Pastergue-Ruiz et al. (1995) have shown that foragers are able to home in a strictly controlled laboratory environment using only visual cues. Whereas in most of these latter studies orientation has been measured as the average performance of a group of individuals, the aim of our experiments was to study specifically the individual performance of the workers.

Our main purpose was to test the well-known "snapshot model", which postulates that insects use a snapshot-like representation as a template to locate particular places of their environment (Collett, 1993). Homing trips of individually marked ants were recorded and studied using computerized methods allowing a fine statistical track analysis. A particular algorithm was used to detect the "breaking points" of the tracks, i.e. the points where a switch in the path characteristics occurred from a search to a more direct trajectory. We hypothesized that from these points on ants had identified and were able to use the cues they had memorized to reach their goal. By mapping the location of these points for several successive trips of the same ant we were able to delimit the "catchment area" characteristic of each individual, i.e. the area where adjustment between the memorized template and the retinal image becomes possible. This method allowed us to measure the flexibility of the localization system, and therefore to infer the cognitive processes underlying orientation tasks in ants.

This study shows in addition that within the same species of ants several different navigational strategies can be used, some of them based on kinesthetic, others on visual cues.

EFFICIENCY OF SOME INDUSTRIAL DEVICES FOR NEST LOCALIZATION BY THE LEAF-CUTTER BEE, *MEGACHILE ROTUNDATA* (F.) (HYMENOPTERA: MEGACHILIDAE).

K. Fauria, R. Campan, R. Bitner¹, P.F. Torchio²

Laboratoire d'Ethologie et de Psychologie Animale, Université Paul Sabatier, Toulouse, France - 1 R. Bitner, Pioneer, Caldwell, ID USA - 2 USDA, ARS, Utah State University, Logan, UT USA

Megachile rotundata is broadly used for alfalfa pollination by the seeds producers in North America. Large quantities of bees are released in alfalfa crops and the females are offered to nest in various devices differently efficient in allowing a female to find its own nest. The more efficient is the localization the shortest the rate of the cycle and the pollination process.

Three types of devices were evaluated in this respect. First, a shelter (2mx1.5mx1.5m), one of its long side opened and a trailer (5mx4mx3m) opened to its back wall. Both devices were settled in the crops and provided with several styrofoam boards for nesting. A third device consisted of 5 roll-a-boards (40cm diameter), clustered on a pillar in a garden, and made of rolled undulated cardboard.

These devices appeared very poor for nest localization. Because of the high density of nests holes and the large number of insects in the same area, the bees were wasting time and energy searching for their own nest and fighting with conspecifics. The homing efficiency could be drastically improved by additional visual cues and by reducing board size and density of nest holes. Improving the device should allow a decreased of the number of bees required for pollinating an alfalfa crop.

12-082

DO INSECTS HAVE EXPECTANCIES ?

I. Pastergue-Ruiz, G. Beugnon, S. Chameron

Laboratoire d'Ethologie et Psychologie Animale, URA-CNRS 1837, Université P. Sabatier, 118 route de Narbonne, 31062 Toulouse cedex, France

Workers ants of the species *Cataglyphis cursor* forage individually using terrestrial visual cues. Former laboratory experiments indicated that *C. cursor* can encode and store different visual landmarks, as geometrical forms, to locate the direction of their nest (Pastergue-Ruiz et al, 1995). In the present work we constrained the ants to follow a route to find their way back home. Four sequentially separated rooms (A, B, C, D), connected with plastic tubes, linked a food site to the nest. In each room, ants were confronted with a spatial binary choice corresponding to the entry of one of two plastic tubes, one leading to a dead-end ("wrong" choice) and the other one to the following room ("correct" choice), and this up to the nest entry. Each of the two issues in each room was identified by a specific visual landmark, i.e. a cross (indicating the correct entry) versus a circle (indicating the wrong entry) or a triangle versus a square, and so on. The ants rapidly learned the correct sequence of visual cues and homed quickly. When the four rooms were permuted (C, D, B, A), workers homed correctly but were disturbed with many back and forths between the box D and the box B (one of the two landmarks in the box D indicating the nest in the learning condition). Thus ants bear more care on the last cue of the sequence which is spatially and temporally linked with the nest entry. In other words, ants behavior seems to indicate a kind of expectancy of an event: i.e. the entry in their nest at a given time and place.

HOST PREFERENCE IS A PHYSIOLOGICAL AND NOT A BEHAVIORAL TRAIT.
 S. Gilboa and D. Rosen
 Dept. of Entomology, Faculty of Agriculture, Rehovot. The Hebrew University of Jerusalem, Israel.

Host preference, which is often measured as the number of eggs females lay on different hosts, is considered a behavioral trait. Until now the only physiological factor tested on host preference was egg load. We studied the physiological effect of the host on the rate of oocyte maturation in the potato tuberworm (PTW), *Phthorimaea operculella*. When its host is unavailable, PTW readily lays eggs on low quality hosts or even on non-hosts. Among its hosts, potato is the most preferred and tomatoes the least. Starved and 10% sucrose solution fed females were allowed to oviposit on potato tubers or tomato foliage. Females were dissected the following morning and the number of mature oocytes counted. Across all hosts, 54% of the starved females compared to 5% of the fed females had no mature oocytes in the ovaries. The number of mature oocytes in fed females on potatoes was higher than on tomatoes. Fed females laid significantly more eggs on potatoes than on tomatoes. Starved females laid similar numbers of eggs and had similar numbers of oocytes on both hosts. So both female feeding condition and the type of host affected the number of available eggs. We therefore conclude that the PTW lays all its available eggs during the night, regardless of which host it is on. Thus host preference in the PTW reflects physiological condition and is not a behavioral trait. We hypothesize that host preference measured as the number of eggs laid might be physiological in other synovigenic insects that readily lay their eggs on any oviposition substrate.

12-085

GENERALIZATION, DISCRIMINATION AND PREFERENCE AMONG FIGURES IN *BOMBUS TERRESTRIS* L. AND *APIS MELLIFERA* L. (HYMENOPTERA: APIDAE).
 G. Celli, B. Maccagnani
 Istituto di Entomologia "Guido Grandi", Università di Bologna, Italy.

The capacity of honeybees and bumblebees to generalize some features of shapes was investigated. The bees were trained to suck up the reward (50% sugar solution) through a capillary hole (Ø 1.5 mm). All the figures presented in the following experiments were fotocopied on a white paper and had a small hole in the centre which allowed the bees to reach the capillary. After a two-figure (test 1) and a group (test 2) training to discriminate between rewarded stars and unrewarded circles, the star was substituted with a five segment figure (test 3), then reduced to three (test 4), two (test 5), one (test 6), then five irregularly grouped ones (test 7), all rewarding figures. Two unrewarded figures were contemporarily presented in each test, both with a continuous perimeter. In the behaviour of bumblebees a generalization process occurred in the choice and explains the high percentages of landings on the segment-made figures in the beginning of tests 3-7, whose trends do not resemble a learning process. Honeybees showed much more difficulty in extracting the segment as the common element of the generalization sequence and they could not follow the complete breaking down of the segment-made figure. Showing the honeybees the one-segment figure caused them to stop their visits to the experimental plate. In order to explain the different behaviour of the two bees, discrimination and preference tests were performed. The 6 pairs of filled-up or empty figures the insects were offered in the generalization experiment were directly compared in the discrimination experiment. Both species showed a good discrimination ability: bumblebees could discriminate between all 6 pairs of figures, while honeybees did not distinguish an empty circle from an empty triangle. In the preference tests, the three different figures of each generalization test were compared. The segment-made figures were never the preferred ones, either in bumblebees or in honeybees. While bumblebees showed high variability in the preferred figures, honeybees expressed strong preference for figures other than the segment-made ones, with high homogeneity. This is likely to be the reason for the honeybees difficulty in choosing them in the generalization experiment.

12-084

OLFACTORY MEMORY IN THE HONEYBEE : PERSISTENCE AND RESISTANCE TO EXTINCTION
 J.C. Sandoz, B. Roger, M.H. Pham-Delègue
 Laboratoire Neurobiologie Comparée des Invertébrés, INRA/CNRS, 91440 Bures-sur-Yvette, France.

In the honeybee, olfactory learning has been widely studied using the proboscis extension bioassay in restrained individuals, where an odour (conditioned stimulus - CS) is associated with a sugar reward (unconditioned stimulus - US). Based on this bioassay, we investigated the persistence of the memory trace along time, and its resistance to the interference of contradictory information. After a single CS (pure linalool)-US (30 % sucrose solution) pairing, 55 % of the bees showed lifetime conditioned response to the CS, when presented once. The unrewarded presentation of a previously rewarded CS induces an extinction of the conditioned responses. Five successive trials are sufficient to bring the bees' responses back to a spontaneous response level, independently of the inter-trial duration. This decrease was found to be possibly transient since a recovery of the level of response could be observed at a later stage, as shown by varying the durations between the conditioning and extinction trials (1 or 10 min), between the extinction trials (1 or 10 min), and between the extinction trials and a later trial (1, 15 min, 1 or 24 h). Thus, up to 70 % recovery could be obtained at the last trial. In addition, we carried out successive extinction phases alternating with recovery periods (1h) and/or with recall trials (rewarded presentations of the CS). The best conditions to maintain a high and stable level of conditioned responses were to apply both 1 h recovery period and 1 recall trial between the extinction phases. These experiments led us to tentatively define the temporal limits between a transient loss and a permanent impairment of the olfactory memory. These data are discussed with regard to the adaptative ability of honeybees to forage on floral sources with variable nectar reward.

THE INTENSITY AND SITE OF INFECTION OF *Aedes Aegypti* (DIPTERA: CULICIDAE) LARVAE WITH METACERCARIAE OF THE ENTOMOPATHOGENIC DIGENEAN *PLAGIORCHIS ELEGANS* (TREMATODA: PLAGIORCHIDAE) AFFECT THE ATTRACTIVENESS OF THEIR WATERS TO OVIPOSITING, CONSPECIFIC FEMALES
 N. Zahiri, M.E. Rau and D.J. Lewis
 Department of Natural Resource Sciences, Macdonald Campus, McGill University, Ste-Anne-de-Bellevue, QC, Canada H9X 3V9

A series of biological assays was conducted in the laboratory to assess the oviposition responses of gravid *Aedes aegypti* females to waters that had harboured conspecific larvae parasitized with the digenean *Plagiorchis elegans*. Infections were of various intensities and locations within the bodies of second, third and fourth instar larvae. Regardless of instar and location of infection, repellency of the waters to ovipositing females increased with the intensity of infection of the larvae. Similarly, waters derived from larvae with infection of the thorax and head tended to be more repellent than waters from larvae with abdominal infection only, regardless of instar and intensity of infection. Oviposition repellency was greatest in response to waters from second instar larvae infected with as few as three metacercariae. The number of eggs laid on these waters was only 61% of the distilled water controls. Similarly, second instars with infection of the thorax yielded waters which attracted only 50% as many eggs as controls. These data suggest that, under field conditions, sublethal infections of *Aedes aegypti* larvae with *Plagiorchis elegans* may reduce recruitment into the larval population.

12-087

SWARM FLIGHT BEHAVIOUR OF *RHAMMATOCERUS SCHISTOCERCOIDES* (REHN, 1906) IN MATO GROSSO, BRAZIL (ORTHOPTERA, ACRIDIDAE, GOMPHOCERINAE).

M. Lecoq, I. Pierozzi Jr.¹

CIRAD-GERDAT-PRIFAS, BP 5035, 34032 Montpellier Cedex 1, France - ¹EMBRAPA-NMA, CP 491, 13001-970 Campinas SP, Brazil

A study of swarm flight behaviour in *Rhammatocerus schistocercoides* (Rehn, 1906), pest grasshopper of Mato Grosso State (Brazil), revealed a limited dispersal potential, in contrast to prior theories on their migration habits. The grasshoppers were monitored throughout the imaginal stage. In September, when their flight behaviour is maximal, several swarms were studied from morning to evening, with their behaviour noted at 1-min intervals. On average, their daily movements did not exceed a few hundred metres, even under optimal thermal conditions. The longest distance covered in one day was 2.8 km. Swarms showed standard rolling-type flight behaviour, and many grasshoppers remained at roost as others took flight. The swarms flew at quite low altitudes, not higher than 5-10 m. Flight directions were mainly determined by the direction of prevailing winds. These corresponded to local migrations that enabled the swarms to fully explore their environment (savanna regions with shrubs and trees) during the dry season when conditions are generally unfavourable. A predominant theory over the last 10 years holds that these grasshoppers regularly migrate eastwards; this now seems quite unlikely.

Since the species is much less mobile than previously supposed, a preventive control strategy aimed at detecting and destroying hopper bands during the rainy season could be possible. Control operations conducted jointly with producers' groups should significantly reduce the grasshoppers populations.

TERRITORIALITY AND CLEPTOPARASITISM IN A POPULATION OF *AMMOPHILA SABULOSA* (HYMENOPTERA: SPHECIDAE) IN ALTA VALTELLINA (NORTHERN ITALY)

A. Martinoli, M. Casiraghi, E. Passerini, T. Bosco, F. Andrietti
Dipartimento di Biologia, Sezione di Zoologia e Citologia,
Università degli Studi di Milano, via Celoria, 26 Cap 20133,
Milano, Italy

This study has been carried out at Le Prese (Alta Valtellina, Sondrio province; Lombardia), in the period June-August from 1993 to 1995. The behaviour of about 400 marked *Ammophila* has been recorded. They were followed every day from 08.30 a.m. to 07.00 p.m.. All nests digged by the females have been labeled and numbered, aiming at acquiring more informations about species territoriality.

Some cases of cleptoparasitism have been observed between females nesting in neighbouring areas. This behaviour has been performed by a "thief" female soon after provisioning, nest closing and leaving of the "owner" female.

12-088

THE BEHAVIOR OF GERMAN COCKROACH, *Blattella germanica*, TO LOCATE A NEW HIDING PLACE

A. KANAYAMA, K. KOSONE, M. TOBA

Yokohama City Institute of Health, Isogo, Yokohama, Japan

The behavior of finding out a new hiding place by German cockroach, *Blattella germanica*, was investigated experimentally under laboratory condition.

As an experimental setting, a large container (64x38x15 cm) set with feed and drinking water at the center was connected with a small box (15x11x8 cm) as a hiding site. A group composed of 25 cockroaches were released into a small box and acclimated to the experimental environment for a period of seven days. After adaptation, a new small box was set up as a new hiding place at the opposite side of the container, and the number of individuals were counted every day.

In experiments using separate groups (populations composed of only males, gravid females, or ungravid females), it was observed that the adult male groups disseminated evenly to the whole area of the container and also immigrated into the new hiding site more rapidly than gravid female or ungravid female groups.

In case of mixed groups of adult males and gravid or ungravid females, the former migrated into the new hiding place more quickly than the latter. However, spreading behavior of males seemed to be influenced by the presence of gravid or ungravid females, because they were not so active as observed in the test employing separate male groups.

12-090

THE IMPORTANCE OF BODY SIZE IN THE COCKROACH WASP *AMPULEX COMPRESSA* (F.) (HYMENOPTERA; SPHECIDAE; AMPULICINAE)

Wijnand R.B. Heitmans

Institute of Evolutionary and Ecological Sciences, Leiden University, P.O. Box 9516, 2300 RA Leiden, The Netherlands

An important relation in parasitoid behavioural ecology is that between size and fitness. Differences in body sizes are often assumed to affect the reproductive success of females more than that of males. Size related components of fitness take place in a variety of direct and indirect forms. Some of them were studied in *A. compressa*, an idiobiont, solitary parasitoid of several species of blattid cockroaches. The wasp's body size is determined by host size and may differ up to a factor 5.

No correlation was found between size and fitness, when fecundity and longevity were used as fitness parameters. Beyond fecundity and longevity the reproductive success of *A. compressa* females was also measured by investigating the influences of size and ownership-status on the outcome of owner-intruder contests for oviposition sites. Both body and status influence outcomes of contests: larger females nearly always win, but after oviposition, outcome is modified in favour of owners also when intruders are much larger.

It is unlikely that males have direct contests for virgin female resources. The benefits of being larger could not be established in males and they also do apparently not suffer from being small.

12-091

SWARMING IN BLOOD-SUCKING MOSQUITOES (DIPTERA,CULICIDAE)- RITUAL OR COMPETITION?

S.Serbenioug, M.Fedorova
Department of Entomology, Faculty of Biology,
Moscow State University, Moscow. 119899, Russia

The emergence, sexual maturation, swarming and mating behavior were studied in natural population of *Aedes communis* DeGeer. The duration of male sexual maturation period was estimated by the content of proteins in the accessory gland secret. During this period the quantity of proteins increased 2.5 times and reached maximum on the 5th day after male emergence when the swarming behavior started. Simultaneously the appearance of inseminated females was observed. This shows the correlation between swarming and mating in *A.communis*. Two types of males were revealed in the population: large males with longer wings and higher protein content in accessory gland secret and small ones with shorter wings and lower protein content. Only large males were observed to swarm and mate. The mating however rarely occurred in swarms. Moreover, only a few swarming mosquitoes were attracted to virgin females flying across the swarm. Thus during swarming the majority of males was not ready to couple. Usually the males left the swarm after 6-10 min of swarming and started a free flight which could result in 1) joining another swarm or 2) landing or 3) mating. The data suggest that swarming behavior seems to be necessary for selection of more viable males and serves for their sexual excitement.

12-093

TEMPORAL PATTERNS OF PRESENCE AT MICROHABITATS AND LOCOMOTION FOR THE GERMAN COCKROACH, *BLATTELLA GERMANICA*, IN SEMI-NATURAL CONDITIONS

T.-S. Chon, Y. S. Park and M. H. Ross¹
Department of Biology, Pusan National University, Pusan, Republic of Korea - ¹ Department of Entomology, Virginia Polytechnique Institute, Blacksburg, Virginia, USA

A genetic mutant, orange body (ob), of the German cockroach, *Blattella germanica*, was observed continuously in semi-natural conditions through video taping and data processing by computers. In a rearing cage, four microhabitats were provided to represent important behavior of the test insect, resting, feeding, drinking, and communicating with other individuals. Adult males from the same maternal origin were randomly selected, and presence at the microhabitats was individually observed for 4 - 6 days continuously under the light condition of L12:D12. Relatively large variations were observed among individuals in the daily temporal patterns of presence and visiting at the microhabitats. In average they stayed at the place for resting for the longest duration, about 50 percent of the total observation time, while they were present at the other microhabitats for feeding, drinking, etc. for a short period, less than 3 percent of the observation time. Daily peaking time in presence and visiting was observed at some microhabitats. Although there were variations among all the individuals observed for the study, similar temporal patterns of presence and visiting at microhabitats were observed in some individuals from the same maternal origin when the continuously observed data for each individual were expressed in daily averages. The variations in presence at microhabitats were interpreted with principal component analysis, and the closeness in temporal patterns among different individuals was quantitatively demonstrated in this study.

12-092

ASYMMETRY AND HANDEDNESS IN CRADLE FORMATION OF SOME ATTELABID WEEVILS - AN ETHOLOGICAL APPROACH TO A BEHAVIOUR CONTROLLING SYSTEM (ATTELABIDAE).

K. Sakurai
Junior College, Seijo University
Seijo, Setagaya, Tokyo, JAPAN

The formation of cradles, which are made of a young plant organ (e.g. a leaf cut and/or rolled), is a characteristic maternal habit among attelabid weevils. Concerning the rolling direction of the leaf, there are two types of cradles (i.e., dextral and sinistral ones). The two types form mirror images of each other and occur in the field commonly. The cradle formation process of several attelabid weevils (including *Phymatopoderus pavens* Voss and *Apodrus balteatus* Roelofs) was observed in the field and the laboratory. When a cradle was made, the rolled direction of the leaf was recorded for each weevil. Female weevils made both types of cradles, though the ratio of one rolling direction to the other was not always even. The side of the legs used at a certain stage of cradle formation of a cradle type was concretely fixed at left or right. These phenomena show that each female weevil can manipulate the legs of both sides, and also that in the process of a given cradle formation she behaves asymmetrically, right handed or left handed. A series of experiments were conducted for *P. pavens* to clarify the controlling mechanisms of this behavioural sequence and that of the laterality of the legs. The results suggest that the direction of asymmetrical manipulation of the legs is decided at an early stage after which it can not be reversed (e.g. form right handed to left handed).

12-094

DOMINANCE STATUS AND RECOGNITION OF THE OPPONENT IN MALE *GRYLLUS BIMACULATUS* (ORTHOPTERA : GRYLLIDAE) DYADIC CONFLICTS

K. Khazraie, M. Campan

U.P.S. Laboratoire d'Ethologie et de Psychologie Animale, CNRS - URA 1837, 118 Route de Narbonne, 31062, Toulouse cedex, France

Both males of the dyad behave similarly at the beginning of their first encounter. In *Gryllus bimaculatus* dyads conflicts stable dominance was rapidly established. Along with successive encounters of the same males, aggressive behaviour was decreasing as the dominance status of each one was gradually settled. That process appeared weaker when one of the male is changed at each successive encounter. It has been concluded that the status of the tested male seemed established at the first session and was not modified by further encounters whether the opponent was familiar or not. One data did not demonstrate any time individual recognition but some kind of familiarity.

12-095

THE MYSTERY OF METHYL EUGENOL: II. LICKING BEHAVIOR OF THE CARAMBOLA FRUIT FLY, *BACTROCERA CARAMBOLAE*, ON A SPADIX OF *SPATHIHYLLUM CANNAEFOLIUM* (DIPTERA: TEPHRITIDAE - ARLES:ARACEAE)

O. Iwahashi and T. Syamsudin Subahar¹

Department of Entomology, University of the Ryukyus, Senbara Okinawa 903-01, Japan - ¹ Department of Biology, Institut Teknologi Bandung, Jl. Ganeqa 10 - Bandung, Indonesia

To test the hypothesis that naturally occurring methyl eugenol (ME) decreases the efficiency of the male annihilation technique using ME (Shelly, 1994), we observed the licking behavior of the carambola fruit fly, *Bactrocera carambolae*, on a spadix of *Spathiphyllum cannaefolium* which contains ME on the island of Java, Indonesia. Although distribution of ME-traps containing 1 g of poisoned ME placed 50 m from the *S. cannaefolium* community resulted in a decrease in number of males visiting the flowers, many flies were still attracted to the flowers. A series of outdoor screen cage observation showed that the degree of response to the flowers by the males which had licked ME on the flower on the previous day varied greatly among individuals, i.e. some did not respond at all while others licked at almost the same frequency or even more. Although the results seemed to support the hypothesis in part, additional observations are required to derive any conclusions.

12-096

UNUSUAL CALLING BEHAVIOUR IN *THERESIMIMA AMPELOPHAGA* BAYLE-BARELLE (LEPIDOPTERA: ZYGAEINIDAE) FEMALES

M. Subchev

Department of Experimental Zoology, Institute of Zoology, Bulgarian Academy of Sciences, Sofia, Bulgaria

Theresimima ampelophaga Bayle-Barelle females were found to perform unusual calling behaviour. At the time of active attraction males in field they never extruded the tip of the abdomen like almost all other lepidopterans. Instead of this females of this species curved dorsally their abdomen and remained in this posture for hours. Biotests with extracts of different parts of the female abdomen on conspecific males, further confirmed the presence of a pheromone source at the dorsal part of the abdomen. The presence of pheromone gland cells on this part of the female abdomen was also confirmed histologically.

Some data about other details of *T. ampelophaga* females calling behaviour are also presented.

The presentation of this work was supported financially by a grant (No 446/1994) from the Bulgarian National Foundation "Scientific investigations".

SEX PHEROMONAL STUDY OF THE TEA CLUSTER CATERPILLAR *ANDRACA BIPUNCTATA* WALKER. (LEPIDOPTERA: BOMBYCIDAE)

Y. S. Chow

Institute of Zoology, Academia Sinica, Nankang, Taipei 11529, Taiwan, ROC.

Sex interactions between male and female of the tea cluster caterpillar *Andraca bipunctata* Walker (Lepidoptera: Bombycidae) are mediated primarily through pheromonal signals. Females produce a four-component pheromone blend in the pheromone gland, but only one major compound attracts males in the field. The major compound is identified as E11,E14-18:Ald by GC, GC-Mass and EAG method. The function of other three-component pheromones in the courtship of adult moths is also discussed.

12-098

APOSEMATIC SIGNALS IN MUTILLID WASPS (MUTILLIDAE, HYMENOPTERA)

G. Tschuch

Entwicklungsbiologie, Institut für Zoologie der Martin-Luther-Universität, Halle, Germany

Mutillid wasps are solitary. Their larvae are parasitoids of the immatures of other insects, mainly of Aculeata (Specidae, Apidae). The female Mutillid wasps have a powerful sting, the integument is extremely thick and hard, and they are wingless. On account of searching host animals the females are exposed to manifold predators. The production of poison is not up to such kind of condition, and the poison production costs are high. Therefore, female Mutillid wasps produce multimodal aposematic signals before and during sting. In contrast to the optical signals, previous knowledge of the acoustical and the chemical signals is limited.

Mutillid wasps possess abdominal stridulatory organs between their 3rd and 4th tergites. The mechanical system is extreme damped. So the signal contains many harmonics. Because of the large wavelength of the fundamental frequency (relative to the tergite dimensions) the radiation of higher harmonics is proportional to the square of their frequency. Therefore, the spectrum is broad. The signals sound something like aposematic or startle signals of vertebrates. They are broadband noises similar to that sort of signals produced by hissing or rattling.

Additional to this it was found a third, possibly aposematic, signal: the chemical secretion in the mandibular gland. This gland contains a cocktail of 4-methyl-3-heptanone, and some pyrazines.

THE EVOLUTION OF SOLDIER CASTE IN APHIDS

S. Akimoto

Systematic Entomology, Faculty of Agriculture, Hokkaido University, Sapporo, Japan

Soldiers in aphids are nymphs that defend their colonies against insect predators. Soldiers are characterized by sclerotized skin and enlarged legs or horns. These characters are used as weapons to counterattack predators. Aphid soldiers in some species do not molt after birth and constitute a caste distinct from normal nymphs. This dimorphism is determined before birth. Other species produce "monomorphic defensive nymphs", which are composed of all individuals at a specific nymphal stadium and can develop into adulthood. Monomorphic defenders have been considered as an evolutionary precursor of a sterile soldier caste.

To understand factors leading to a sterile soldier caste, this study focused on the function of monomorphic defenders of some pemphigid aphids. Aphid colonies producing monomorphic defenders were characterized by a high proportion of defenders, which usually accounted for more than 50% of all the members. This high proportion was due to the prolongation of the defensive nymphal stadium. Prolonging the defensive nymphal stadium is advantageous in increasing the proportion of defenders, but decreases the rate of population increase. A simple simulation model predicted that the evolution of dimorphism is more favored when the colony lasts longer and when predation pressure is higher. In addition to the consideration of these ecological factors, this study advances a hypothesis to explain how the soldier morph originated in the aphid populations.

HORMONAL ASPECTS OF PHASE POLYMORPHISM IN LOCUSTS; ARE THERE SIMILARITIES TO CASTE POLYMORPHISM IN SOCIAL INSECTS?

M.P. Pener

Department of Cell and Animal Biology, The Hebrew University of Jerusalem, Jerusalem, Israel.

Locust show density-dependent continuous phase polymorphism. They appear in two forms, termed phases, "gregarious" and "solitary" which differ in many characteristics. There are intermediates between the two phases and phase transformation, induced by changes of density, is not instar or stage specific.

It was generally accepted that high activity of the corpora allata and high juvenile hormone (JH) titres induce the solitary phase. JH indeed induces certain solitary phase characteristics, the green solitary colour being the best demonstrated example. However, some phase characteristics are not affected by the JH and JH even shifts some other phase characteristics toward gregarious direction. The possible roles of neurohormones in phase change have been neglected, probably because of the overestimated importance of the JH. Recent research started to close this gap; phase-dependent differential responses to adipokinetic hormones were demonstrated and a dark colour-inducing neurohormone affecting phase colour polymorphism was discovered. Although pheromonal effects on phase change are intensively reinvestigated, the endocrine relations of aggregating pheromonal effects have not yet been studied. Nowadays the endocrine aspects of locust phase polymorphism seems to be more complex than it was previously assumed and this conclusion may be instructive also for research on the endocrine basis of caste polymorphism in social insects.

13-003

ORIGIN AND EVOLUTION OF IRREVERSIBLE DECISION POINTS IN TERMITE DEVELOPMENT

Y. Roisin

Laboratoire de Biologie animale et cellulaire, Université Libre de Bruxelles, Belgium

In termite societies, every individual sooner or later reaches decision points where it faces alternative developmental pathways: e.g., for a termitid larva, following the sexual (wing-budded nymph, alate) or neuter (worker, soldier) developmental pathway; for a worker, moulting to the next worker stage or to a presoldier, etc. The most remarkable decision points are those leading to well-defined morphological castes: soldiers and workers. The omnipresence of the fully sterile soldier caste in extant termites makes investigations into its origin difficult. By contrast, the diversity of caste patterns regarding the individuals performing worker tasks allows a comparative approach to the origin of the true workers, which evolved independently of soldiers to constitute a second eusocial caste in the higher termites. The physiological bases of worker differentiation can be traced back to roaches and are widely expressed, reversibly, during regressive moults from nymphs to pseudergates in lower termites such as *Neotermes* or *Proterhinotermes*. Sterile soldiers and true workers are both characterized by the irreversibility of the developmental decisions leading to these castes. Their remarkable diversification suggests that the irreversibility of developmental choices is a threshold of major evolutionary significance. An overview of termite caste systems suggests that true workers evolved in populous colonies inhabiting large logs (like some present-day Rhinotermitidae) and diversified later on to develop complex foraging strategies.

STORED PROTEINS IN CASTE AND COLONY DEVELOPMENT IN ANTS

D.E. Wheeler

Department of Entomology, University of Arizona, Tucson, Arizona, USA

Storage proteins are important during development in ants, as they are in most insects, allowing temporally distinct periods of eating and metamorphosis. In addition, adult ants in some taxa are able to store the same kinds of proteins normally accumulated during development. These proteins stores can then serve as an amino source for intensive protein synthesis by the storer herself. Or, it can be transferred to nestmates, profoundly affecting their nutritional state.

Claustrally-founding queens accumulate large quantities of protein between eclosion and the mating flight. These reserves, along with fats, are depleted while the first brood of minor workers is reared. In ants today, stored protein is associated with the claustral mode of colony founding. The ability to express the predominantly larval genes for storage protein synthesis in the adult stage could have been a key to the evolution of claustral founding.

Workers in some species of *Camponotus* are capable of storing protein over winter. I hypothesize that reserves are mobilized in the spring and transferred to larvae to support growth, and to the queen to support higher rates of egg production. Workers of other Formicidae species, such as *Formica* and perhaps *Prenolepis*, appear to store large quantities of fat but little storage protein in their abdominal fat bodies. The role of proteins stored elsewhere in the body in supporting seasonal egg laying and brood production should be evaluated. Stored protein, along with other reserves, could provide the basis for seasonal production of exceptionally rich larval food. In ants, distribution of this rich food would be regulated temporally, with larvae present at a restricted time of year receiving the mixture. As in honeybees, exposure to a rich diet could play a role in caste determination. Distribution of royal jelly in honey bees, in contrast, is regulated spatially, with workers giving the substance only to larvae in specially constructed cells.

13-006

HORMONAL CONTROL OF HONEY BEE CASTE DEVELOPMENT

A. Rachinsky, K. Hartfelder

Zoologisches Institut, LS Entwicklungsphysiologie, Universität Tübingen, Tübingen, Germany

Juvenile hormone (JH) has long been known as a key factor in caste morphogenesis of social insects. In the honey bee, caste-specific JH titers in the fifth larval instar are produced by differential activity of the corpora allata (CA), and it is particularly during the first half of this instar that JH production in CA is much higher in queen than in worker larvae.

Using a radiochemical in vitro assay to monitor CA activity we attempted to identify factors that modulate JH synthesis in honey bee larvae. Extracts prepared from larval brains were found to exhibit both stimulatory and inhibitory effects. Among these factors we could single out two biogenic amines, octopamine and serotonin that stimulated CA activity in worker larvae. The action of these biogenic amines appears to be mediated by cAMP as second messenger. In the feeding phase, however, JH synthesis in worker larvae could only be stimulated to a limited extent and never be brought to the levels measured for queen larvae. This appears to be due to a rate-limited conversion of methyl farnesoate in a terminal step of JH biosynthesis.

The mode of action of JH in honey bee caste differentiation can best be described as pleiotropic. Probably one of the most important steps is an interendocrine activation of the prothoracic glands to install a queen-specific program of ecdysteroid synthesis. Partially this involves a direct pathway, as shown by in vitro stimulation of prothoracic glands by methoprene. In the gonads, the organ exhibiting the most divergent caste-specific morphology, juvenile hormone application to fourth instar worker larvae induces full differentiation of germ cells and follicle epithelial cells, and thus prevents initiation of a cell death program normally occurring in the fifth instar in most of the ovarioles. Later in the fifth instar, ecdysteroids then come to play important roles in caste development. In vitro experiments demonstrated that caste-specific expression patterns of two major proteins in the larval ovary are regulated by methyl farnesoate. As one of these is a heat shock protein, generalized secondary effects of ecdysteroids on ovary morphogenesis are to be expected.

13-005

FOOD, FEEDING AND CASTE DIFFERENTIATION IN BUMBLEBEES

J.J.M. Pereboom

Dept. of Comparative Physiology, Ethology and Socio-ecology Group, Utrecht University, the Netherlands

Caste polymorphism in bumblebees is like in all social Hymenoptera related to differences in larval nutrition. In *Bombus terrestris* caste specific development is in the first instance determined by queen pheromones¹. This paper deals with whether or not, differences in feeding behaviour or in larval food composition play a role in caste determination and differentiation in *B. terrestris*.

Comparisons of food samples collected from prospective worker, queen and male larvae revealed no differences in pollen, protein and carbohydrate concentration. Therefore caste differentiation in *B. terrestris* is not influenced by qualitative differences in larval food. The glandular secretions added by feeding workers, are salivary in function rather than food additives playing a major part in caste differentiation.

The distinct difference in the feeding frequency for prospective queen and worker larvae could account for caste specific development. In *B. rufocinctus* adult size is the outcome of differential growth rates and silk production, as a result of differences in feeding frequency². In-vitro feeding experiments show that *B. terrestris* larvae stop feeding and prepare for pupation, even when growth is not restricted by the silk production or if the feeding frequency is increased dramatically.

In experimental set-ups starved larvae were provisioned by workers significantly earlier and more often than control larvae. This suggests that larvae themselves influence the feeding frequency as a result of their nutritional status, and that feeding rate is not imposed on them by the workers. The fact that feeding frequencies differ for worker and queen larvae suggests that they have different nutritional needs.

Our results show that worker and queen larvae have alternative developmental programs, switched on or off at an early age by queen pheromones, and that caste development is regulated by this program and the amount of nutrition.

13-007

THE EFFECT OF SOCIAL ENVIRONMENT IN THE COLONY ON CASTE DETERMINATION AND JH SYNTHESIS IN *BOMBUS TERRESTRIS* LARVAE

J. Cnaan, A. Hefetz

Department of Zoology, Tel-Aviv University, Tel-Aviv, Israel

Queen production in *B. terrestris* occurs late in colony development and is correlated with the onset of the competition phase between workers and their mother queen. To understand the impact of the existing queen on caste determination, we compared the development and JH production by the corpora allata (CA) in queen and worker prospective larvae. This is the first time that JH production has been measured in bumble bee larvae.

In queen larvae the duration of all 4 instars was longer, and their head width at the third and fourth instars was significantly larger than worker larvae. In addition worker larvae were characterized by a constant low JH biosynthesis that did not surpass 5 pmolJH/h/pair. In queen larvae JH production was higher (peaking at 45 pmolJH/h/pair) starting from the end of the second instar and throughout most of the third instar.

The effect of the social environment on caste determination was examined by transplanting egg cups from young "donor" colonies into "host" colonies either before or during the competition phase. When the resulting larvae were 5 days old, they were weighed, their larval instar was determined according to head width, and their CA activity was measured. Larvae that developed before the competition phase had accelerated development as compared to those reared after this phase. They were heavier (57.3±27.8mg and 34±13.8mg respectively) and greater proportions were at an advanced developmental stage: 40% at the 2nd instar, 40% at the 3rd instar and 20% at the 4th instar, as compared to 70% at the 2nd instar, 25% at the 3rd instar and 5% at the 4th instar for larvae that developed in nests during the competition phase.

CA activity in these larvae was characterized by two distinct levels of JH synthesis parallel to the two different castes. Larvae between 2-5 days old when the competition phase began, had a low JH synthesis rate of 5.7±2.8 pmol/h/pair and eventually developed into workers. Larvae younger than 2 days when competition began, had a significantly higher JH synthesis rate of 20.7±5.6 pmol/h/pair and developed into queens.

In conclusion, queen development involves longer developmental time of each larval instar and is associated with high JH production, both of which are apparently affected by the social status of the queen in the colony.

13-008

THE STOMOGASTRIC NERVOUS SYSTEM AND THE NEUROENDOCRINE AXIS IN HONEY BEE DEVELOPMENT

Z.L. Paulino Simões and Isabel Cristina Boleli

Departamento de Biologia, Faculdade de Filosofia, Ciências e Letras de Ribeirão Preto, Universidade de São Paulo-Brazil.

Anatomical and morphological studies in insects show the existence of direct connections between the stomogastric nervous system (SNS) and the digestive and endocrine systems. Compared to the central nervous system (CNS), the SNS of the honey bee has received little attention with the most recent studies dating back to the 40's. We therefore decided to reevaluate the structural organization of the stomogastric NS using modern histological methods, and related it to the function of the neuroendocrine system.

During the fifth larval instar we observed the frontal ganglion, the center of the stomogastric NS, to be more developed than in the pupal phase, the same being true for the connections of the recurrens nerve with the brain and oesophagus. The hypocerebral ganglion presents short branches along its lateral margins in close connection with the digestive system. We detected in the brain of this larvae 22 neurons expressing prothoracicotropic hormone (PTTH, a regulator of postembryonic development in insect), distributed in 5 clusters. These were in the subesophageal ganglion, in the antennal rudiments and also in the corpora allata (CA) and corpora cardiaca (CC). Only a single pair of neurons expressed PTTH in white-eyed pupae. Similar results were obtained when we immunostained serotonin (5-HT)-expressing neurons in larval honey bee CNS. The presence of varicosities and a small number of cells directly adjacent to the CA, oesophagus and in the wall of the aorta, point to a possible neuromodulator and neurohormonal mode of action, respectively, for PTTH and 5-HT of larvae and pupae of honey bees.

A lack of immunoreactive axons suggests a secondary role for the classical neuroendocrine axis, at the same time that immunoreactivity in the CC, within the CA and morphological alterations in the frontal ganglion and recurrent nerve in the 5th instar, appear to indicate that the SNS has a much greater role in developmental control of honey bee than was previously thought.

PHYLOGENY, BIOGEOGRAPHY, AND SYMBIOTIC FLAGELLATE COMPOSITION OF *RETICULITERMES* SPI (ISOPTERA: RHINOTERMITIDAE) AROUND THE JAPAN ARCHIPELAGO

O. Kitade, T. Matsumoto

Department of Biology, College of Arts & Sciences, The University of Tokyo, Komaba, Meguro, Tokyo 153, Japan.

Lower termites possess symbiotic flagellates that take an important part in cellulose digestion of their hosts. Species composition of the symbiotic flagellates is generally known to be specific to their host species or regional populations.

In this study, the flagellate species composition was investigated of *Reticulitermes* spp. colonies around the Japan Archipelago. Phylogeny of these host species and regional populations was also estimated from the partial sequences (591bp) of the mitochondrial gene (cytochrome oxidase subunit II: COII), using neighbour-joining method.

The general trend of the species- or regional population-specificity of the flagellate composition was observed. The patterns of the similarity show well correspondence to the geographical distribution of the hosts. The largest difference of the composition was detected across the Watase Line, biogeographical border between paleoarctic region and oriental region in the area. Host species around the Japan Archipelago were divided into two monophyletic groups from the analysis of COII sequences. The largest genetic break that is supported by high bootstraps was detected across the Watase Line. The phylogeny of the hosts shows good accordance to its patterns of geographical distribution except a few species. Host phylogeny and flagellate species composition also show considerable correspondence and a large effect of host phylogeny on the flagellate composition is suggested. However, the mapping of the states of each flagellate (presence or absence) onto the host phylogeny does not result in good congruence in some flagellate species. It was possible that these flagellates were horizontally transmitted between sympatric host lineage.

SIMILAR TRENDS IN HYMENOPTERA EUSOCIALITY (MELIPONINAE, BOMBINI, EPIPONINI)

R. Zucchi¹, F.B. Noll¹, S.N. Shima² & S.Mateus¹. Financial support by Fapesp and CNPq.

1-Depto. de Biologia, FFCLRP, Universidade de São Paulo, Av. Bandeirantes 3900, 14040-901 Ribeirão Preto SP, Brazil. 2- Departamento de Zoologia e Centro de Estudos de Insetos Sociais, Instituto de Biociências, Universidade Estadual Paulista- UNESP. 13506-900 Rio Claro (SP). Brazil.

Bionomical aspects of *Bombus atratus* and stingless bees (e.g. laying workers) are focused under insights derived from studies on the swarm-founding Polistinae wasps in which the intriguing presence of intermediate females is quite common. They were first evidenced by Richards & Richards (1951) as he recorded uninseminated but ovary-developed wasps in colonies of several Epiponini taxa. Although their role remains largely unknown there are direct observations on their frequent egg-laying and oophagy in *Protopolybia exigua* (Simões, 1977) and *P. acutiscutis* (Naumann, 1970). Presently, ongoing morphological studies on caste differences have been providing interesting results on their distribution, morphological and physiological identities, etc. In this connexion, their presence seem to be negatively correlated to inter-caste differences. They are invariably absent under stronger queen-worker dimorphism (*Agelaia*, *Apoica*), invariably frequent at inconspicuous castes differences (*Pseudopolybia*, *Parachartergus*, *Brachygastra*), and cyclically present (Noll, 1995) when caste differences are slighter (*Protopolybia*, *Polybia occidentalis*). In addition, intermediates can be transitional in *Parachartergus*, that is, after mating they can reach the queen status (S. Mateus, unpub.) while in other taxa their consistent morphological characteristics seemingly warrant them their fixed intermediate characteristics (Shima et al., in press). On these grounds, the intermediate concept is expanded to other inclose groups, namely the laying workers of stingless bees of which the produced trophic eggs constitute important part of queen's nutrition, and the two kinds of laying females that precisely characterize parts of the unusual colony-cyclic of the neotropical *Bombus atratus* by eventually producing males and females.

A NEW GENUS OF DOLICHODERINAE (HYMENOPTERA: FORMICIDAE) IN DOMINICAN AMBER, WITH A REAPPRAISAL OF THE PHYLOGENY OF THE SUBFAMILY AND A RECONSTRUCTION OF IMMATURE TRANSPORT

C. R. F. Brandão, C. Baroni Urbani¹ & J. Wagensberg²

Museu de Zoologia da Universidade de São Paulo, SP, Brasil - 1. Zoologisches Institut der Universität, Basel, Switzerland - 2 - Museo de la Ciencia, Barcelona, Espana.

We describe a new genus of Dolichoderinae ants, based on workers, and larvae, preserved along with eggs and pupae of the same species and four other insects, in one piece of amber ("Jorge Caridad") found in Palo Quemado Mine, near Santiago, Cordillera Septentrional, Republica Dominicana (Oligocene to lower Miocene). We discuss the affinities of this genus with the other extant and fossil Dolichoderinae and offer an interpretation of the fossilization event, in special the immature transport by the ant workers.

Our analysis of 64 characters of workers, gynes, males, and larvae of 23 extant Dolichoderinae genera allow us to propose a new arrangement and to justify the description of the new genus.

To each ant worker we were able to assign a group of eggs (3 groups), a mature larva or a group of young larvae (31 larvae in total), or a pupa (18 individuals). This suggests that a group of "nurses" was trapped in resin, while carrying immatures away from the imminent peril.

The description of an extinct genus of Dolichoderinae strengthens the notion that this subfamily seems to be retracting from its former dominant status. If we consider the very closely related Aneuretinae plus Dolichoderinae against Myrmicinae, this impression becomes even stronger, as only *Aneuretus* lives today, and the other four aneuretine genera are extinct.

13-012

QUEEN MATING FREQUENCY AND WORKER REPRODUCTION IN THE WASP *DOLICHOVESPULA ARENARIA*F. L. W. Ratnieks, J. J. Boomsma¹

Dept. of Animal & Plant Sciences, Sheffield University, Sheffield, U.K.

Dept. of Ecology & Genetics, Aarhus University, Aarhus, Denmark.

Theoretical studies indicate that worker policing, the mutual inhibition of reproduction by workers, will be most strongly favored by natural selection in single-queen hymenopteran societies when the effective mating frequency of queens is greater than two. Comparative studies of mating frequency and worker production of males in bees (Apidae) support this prediction. Species with multiple-mated queens (*Apis*) produce few workers' sons in queenright colonies. Species with single-mated queens (*Bombus*, *Meliponini*) produce many workers' sons in queenright colonies.

The vespine wasps provide an ideal group for studying the effect of variation in queen mating frequency on worker reproduction across a group of species with similar life cycle and general biology. Ross (1986, *Nature* 323:798-800) has demonstrated queen mating frequency greater than two and absence of worker production of males in two N. American *Vespula* species. Here we report that in *Dolichovespula arenaria* queen mating frequency is close to one and workers frequently produce males in queenright colonies. Thus, the data on reproduction in vespines are in good agreement with the predictions of worker policing theory.

Allozyme analysis of two variable loci (HK, PGD) was carried out on males, workers, and the mother queen (where present) in 28 *D. arenaria* colonies collected during the reproductive phase of the life cycle near Berkeley, California. By analysis of workers double mating was confirmed in 7/28 queens. The probability of detecting a second mating was c. 0.7. Worker production of a large proportion of adult males (all from eggs laid prior to queen death) occurred in approximately half the colonies. Detailed analysis of one colony indicated that queen control of male production occurs but is incomplete. In this colony, most males reared in the centre of the nest (combs 3, 4) were the queen's sons and most in the upper and lower parts (combs 1, 2, 5) were workers' sons. Queen control gradually diminished with time until the queen produced no males, presumably because she was killed by the workers.

13-013

SEX ALLOCATION AND PARENTAGE IN COLONIES OF THE FACULTATIVELY POLYGYNOUS ANT *MYRMICA TAHOENSIS* (HYMENOPTERA: FORMICIDAE)

J.D. EVANS

Department of Entomology, University of Georgia, Athens, GA 30602 USA and

Rocky Mountain Biological Laboratory, PO Box 519, Crested Butte, CO 81224 USA

In eusocial Hymenoptera, workers are often related asymmetrically to the male and female sexuals they rear. The magnitude of this relatedness asymmetry is predicted to depend on both queen number and the mating frequency of queens. When the number of related queens, or the number of times these queens mate, vary across nests in a population workers are predicted to specialize on producing the sex to which they are relatively most closely related. This hypothesis is one of several that might explain the widespread occurrence of split sex ratios (colonies specializing on the production of males or females) in ants.

In this study, I used variation at highly polymorphic microsatellite DNA loci to assess genetic relatedness in male- and female-producing colonies of the facultatively polygynous ant *Myrmica tahoensis*. Relatedness levels (and the relatedness asymmetry) were highest in colonies of *M. tahoensis* that produced female sexuals, providing support for the Relative Relatedness Asymmetry hypothesis. An experimental manipulation suggests that workers use cues presented by larvae when making their sex-allocation decisions, and that they can bias sex ratios long after the eggs destined to become reproductive offspring are laid. Both fertile workers and queens produced males in *M. tahoensis* colonies, leading to potential conflicts over male parentage. In some colonies, workers produced all or most males, while queens appeared to dominate male-production in other colonies. The relative degree of worker reproduction did not appear to covary with genetic relatedness or other colony characteristics. Female sexuals were unanimously produced by a single, once-mated queen, even in colonies whose workers were the progeny of two or more queens.

SEX RATIO BIAS, WORKER-QUEEN CONFLICT AND SELECTIVE MALE BROOD DESTRUCTION IN ANTS

L. Sundström^{1,2}, M. Chapuisat^{2,3}, L. Keller^{1,2}

Ethol. St. Hasli, Bern University - 1 IZEA, Lausanne University - 2 Museum of Zoology, Lausanne, Switzerland

New insights of the role of kin selection in the evolution of eusociality come from models centering on worker-queen conflicts and sex allocation in social Hymenoptera. Sterile workers may enhance their inclusive fitness by biasing sex ratios towards the sex they are relatively more related to as compared to the population average. Evidence to date largely supports worker control of sex allocation in several species. However, queens control the proportion of unfertilized (male) and fertilized (female) eggs they lay and are expected to lay a primary (egg) sex ratio of unity. Here we test whether workers manipulate queen-laid sex ratios to match their own colony-specific optimum by selectively eliminating male brood.

As predicted by theory *F. exsecta* colonies headed by a singly mated queen specialize in female production, whereas colonies headed by a multiply mated queen specialize in male production. In our two-year data set, primary sex ratios were close to unity in both classes of colonies. However, in colonies headed by a singly mated queen the proportion of females significantly increased between the egg and the adult stage, whereas no such changes occurred in colonies headed by a multiply mated queen. Thus workers raised their favoured female-biased sex ratios by selectively destroying male brood in colonies headed by a singly mated queen, whereas no male brood destruction occurred in colonies headed by a multiply mated queen opting for male biased or mixed sex ratios. Our results thus demonstrate for the first time that workers manipulate colony sex ratios by selectively destroying male brood in colonies headed by a singly mated queen to match their colony-specific optimum.

13-015

REPRODUCTIVE SKEW AND RELATEDNESS IN *LEPTOTHORAX* COLONIES (HYMENOPTERA: FORMICIDAE)

J. Heinze

Theodor-Boveri-Institut, LS Verhaltensphysiologie und Soziobiologie, Am Hubland, D-97074 Würzburg

The co-existence of several inseminated queens in ant societies causes conflicts about the partitioning of reproductive rights. In colonies of several formicoxenine ants, these conflicts break open and lead to the formation of reproductive dominance hierarchies by overt or ritualized aggression, in which only the top-ranking queen lays eggs (functional monogyny). In other species, all queens reproduce at more or less similar rates (polygyny). In a model proposed by Bourke and Heinze (1994), the extent of reproductive skew has been linked to various ecological parameters. Whereas apparent reproductive skew estimated from egg laying rates and ovarian development in *Leptothorax* and *Formicoxenus* closely fits the predictions made by this model, genetical data suggest that the factors underlying the sociogenetic structure of Formicoxenini societies are somewhat more complicated. Nestmate relatedness as calculated from allozyme frequencies is significantly lower than expected in apparent high-skew species, probably due to a frequent exchange of the highest-ranking queen. In contrast, in some, but not all populations of polygynous *Leptothorax*, in which queens seem to contribute equally to the egg-pile, nestmate relatedness is much higher than assumed from the number of queens present. A detailed analysis of field data and relatedness estimates in the Reichswald population of *L. acervorum* indicates that this might result from cyclical changes in queen number, caused by the adoption of new queens and colony budding, queen death or emigration, and a negative correlation between the number of adult queens and the production of female sexuals.

13-016

TESTING REPRODUCTIVE SKEW THEORY IN MULTIPLE-QUEEN ANTS USING MICROSATELLITES

A.F.G. Bourke, H.A.A. Green, M.W. Bruford

Institute of Zoology, Zoological Society of London, Regent's Park, London, U.K.

Vehrencamp (1983) and Reeve and Ratnieks (1993) developed a kin selection theory for the evolution of a stable reproductive skew in societies of multiple breeders. The theory predicts low skew (equitable sharing of sexual production) in facultatively polygynous ants (having multiple, egg-laying queens in some colonies). We are attempting to test this prediction in the ant *Leptothorax acervorum*. The method involves a parentage analysis using variation at seven polymorphic microsatellite DNA loci. Three of the loci were identified using information on the sequences of the flanking regions of microsatellites in two other ant species (a *Leptothorax* and a *Myrmica*); four of the loci were identified for the first time in *L. acervorum*. On average, each locus has 16 alleles (range, 2-44). Eight polygynous *L. acervorum* colonies were collected from a single field population. Almost all the dealate (colony) queens, along with a sample of the sexual progeny, were then typed at each of the seven loci. In total, 434 individuals were typed (on average, 5 colony queens, 17 young queens and 32 males per colony). Preliminary analysis of the data suggests that in some colonies a large proportion of progeny derive from mother queens that were not present on collection. This suggests high turnover of colony queens. In other colonies, preliminary analysis indicates mixed maternity of the progeny as expected if skew is low. Precise quantification of skew levels in order to test the theory awaits further analyses of these data.

13-018

MULTIFACETED PARENTAL INVESTMENT AND SEX RATIOS IN SOCIAL HYMENOPTERA.

P. Nonacs and J. A. Rosenheim¹

Dept. of Biology, Univ. of California, Los Angeles, USA - ¹. Dept. of Entomology, Univ. of California, Davis, USA

Theories of parental investment and sex ratio generally assume that a single resource (food) limits reproduction, but many organisms invest two or more qualitatively different types of resources in the production of offspring. Thus, these models fail to address observed variations in offspring size or correlations between environment and investment patterns. We examine the consequences of "multifaceted parental investment" (MFPI) for offspring provisioning and sex allocation when parental behavior is limited by more than one ecological variable. Under MFPI, the factor limiting parental fitness determines the currency of the optimization problem and colonies should adjust reproductive behavior to maximize fitness returns per unit of the limiting resource. In social Hymenoptera with long developmental times as sexual larvae and a short reproductive season as adults, resource abundance late in larval development cannot be used to increase the number of sexual offspring. In such colonies, the key limiting resource will be offspring number rather than food per offspring. Therefore, food surpluses should lead to larger offspring and an increase in the proportional investment in females. These predictions from MFPI are consistent with widely observed patterns of variation in offspring provisioning and sex allocation in the social Hymenoptera.

13-017

THE IMPORTANCE OF KIN-CONFLICT IN RESOURCE ALLOCATION DECISIONS IN ANTS

G.L. Chan

Institute of Zoology, Zoological Society of London, Regent's Park, London, U.K.

All organisms must consider the life history trade-off between present and future reproduction. For social insects, this means investing a given amount of resources into both colony maintenance and production of sexual offspring. Because queens and workers have different relative relatedness values to male and female offspring in a colony, these parties are expected to attempt to maximize different fitness curves with respect to colony maintenance and sexual output. Furthermore, monogynous (singly-queened) and polygynous (multiply-queened) colonies have different relative relatedness asymmetries, and are expected to differ in sex allocation and resource allocation decisions (Pamilo, 1991). In a single population of the facultatively polygynous ant species, *Leptothorax acervorum*, monogynous colonies were found to invest more heavily in the production of sexuals than polygynous colonies, which favoured investment in new workers. As colony size (and therefore probability of survival) increased, monogynous colonies, but not polygynous colonies invested increasingly in sexuals. All polygynous colonies invested heavily in new males, and the larger colonies invested decreasingly in new queens. These results suggest that polygynous colonies reproduce partly by budding, and their daughter colonies may experience local resource competition. Environmental stress and/or habitat saturation may cause polygynous colonies to favour reproduction through budding (Keller, 1995) and both queens and workers from small monogynous colonies to invest in colony maintenance.

13-019

REPRODUCTIVE STRUCTURE IN PRE-EMERGENCE COLONIES OF THE SOCIAL WASP, *POLISTES CAROLINUS*

P. Seppä, D.C. Queller, J.E. Strassmann

Dept. Ecol. & Evol. Biol., Rice University, Houston, TX, USA

We studied reproductive conflicts in pre-emergence colonies of *Polistes carolinus* in Texas, USA. We combined census data on natural wild colonies from initiation to the end of the study with periodic videotaping and assessment of relatedness and parentage from DNA microsatellites. With these data we test hypothesis about relative roles of order of arrival, size, and relatedness in reproductive conflict among foundresses. We further evaluate predictions of the skew hypothesis in an experiment, where we removed eggs from nests, recorded behavior before and after the egg-removal, and genotyped the eggs removed.

Of the 28 colonies observed, 23 had more than 1 foundress at some point during the study period. None of the 5 single-queen nests survived till the end of the period. At the time of collection, 2 nests had a single queen, and 15 had multiple queens (2-8, mean 3.1). There was a certain amount of movement of foundresses between nests, especially when the foundresses came from the same natal nest.

The behavioral data consist of several hours (> 10 h/nest) of videotaped behavior. This allowed us to identify the behaviorally dominant female among the foundresses, as well as record many other types of behavior including work ratio and aggression levels. From the egg-removal experiment we determined whether aggression between foundresses increased, and if so, if it had anything to do with whose eggs were removed. We also determined if foundresses preferred their own progeny in feeding.

The genetic analysis was based on 8 highly variable microsatellite loci. All foundresses collected, the sperm in their spermatheca, and a sample of eggs and larvae from each nest were analyzed. With these data, each offspring was assigned to its mother. Preliminary results show that multiple foundresses were typically full sisters, which was somewhat unexpected based on previous allozyme results. Foundresses were also singly mated, and several females had reproduced in all multiple foundress nests.

EXPLANATIONS FOR HELPING BEHAVIOUR IN HOVER WASPS.

J.P. Field¹ & W.A. Foster²¹Department of Biology, University College London, UK²Department of Zoology, University of Cambridge, UK

Explanations for the evolution of worker behaviour in Hymenoptera have been dominated by the concepts of indirect fitness and genetic relatedness. In contrast, models of helping behaviour in cooperatively-breeding vertebrates emphasize the costs (ecological constraints on independent breeding), rather than the benefits of group living. Published work suggests that several features of the biology of stenogastrine wasps (Hymenoptera, Vespidae) more closely resemble cooperatively-breeding vertebrates than other social insects. For example, after foraging for a while on their natal nests, female offspring often appear to leave and reproduce elsewhere ('delayed dispersal'). Genetic relatedness between female nest-mates is lower than in any other primitively eusocial Hymenoptera. We use a mixture of observations and manipulative field experiments to approach three questions:

(1) Do non-dominant helpers monitor reproductive opportunities elsewhere, and will they abandon their roles as helpers when a high-quality opportunity arises?

(2) Do some females become helpers because they have low reproductive potential and cannot initiate nests and lay eggs on their own?

(3) What is the likely relative importance of benefits versus costs in the maintenance of helping behaviour in stenogastrines?

13-021

DEFENCE ALLOCATION IN CLONAL ANIMALS: SOLDIER INVESTMENT IN APHIDS OF THE GENUS *PEMPHIGUS*

William A. Foster and Philip K. Rhoden

Department of Zoology, University of Cambridge, U.K.

Aphids include the only highly social insects that are parthenogenetic. Kin-selected altruism ought to be rife in aphids, since all the members of an aphid colony, provided they are descended from a single individual and there have been no mutations, will be genetically identical. Yet reproductive altruism is rare: only about 1% (50/4,400) of aphid species have been reported to have soldiers. We will discuss this intriguing paradox in the context of a recent model of soldier investment in aphids.

This model (Stern & Foster, 1996) considers how selection might act on aphid clones to produce optimal investment in soldiers. It predicts that investment in soldiers will be favoured as birth rate decreases, instar duration increases, gall duration increases, predation rate increases, and clonal mixing decreases. We present here the results of recent experiments on soldier behaviour in five species of *Pemphigus* in the U.K., which provide the first tests of some of these predictions.

Stern, D.S. & Foster, W.A. (1996). The evolution of soldiers in aphids. *Biological Reviews* 71: 27-79.

13-022

FACTORS AFFECTING COMMUNAL GALL OCCUPATION IN THE APHID *TAMALIA COWENI* (HOMOPTERA: APHIDIDAE)

D. G. Miller

Department of Environmental Science, Policy and Management, Division of Insect Biology, University of California, Berkeley USA

Establishing plausible paths for the evolution of higher social behavior in the gall-making aphids requires the identification of stages intermediate to those of the free-living aphids and the gall-makers with a sterile soldier caste. One such stage is represented by the primitively social gall-maker *Tamalia coweni*: as it is facultatively communal, with a range of from one to ten foundresses occupying a gall, *T. coweni* offers the opportunity to test hypotheses concerning the origins and maintenance of group behavior.

I tested the effects of density on both the frequencies of gall-making and, more specifically, communal gall occupation. Both of these were significantly positively related to the number of foundresses per available gall-making site, although in no case were the available sites entirely occupied. Foundress survival to adulthood was significantly negatively related to the number of foundresses per gall, suggesting that communal gall occupation bears a fitness cost. Communal foundresses bore a further cost in reproductive fitness: the average biomass produced per foundress was negatively related to the mean number of foundresses per trial. However, the total number of foundresses surviving per gall was higher in two-foundress galls than in galls occupied by one or by three foundresses. If two foundresses occupying a gall are clone-mates, sharing a gall might thereby prove beneficial to the clone. Genetic markers are being developed to further elucidate the nature of the social relationships in *T. coweni*.

LIFE EXPECTANCY AND RISK-TAKING IN FORAGING HONEY BEE WORKERS

M. Woyciechowski¹, J. Kozłowski², G. Grzanka¹¹Bee Research Department, Agricultural University, Al. 29 Listopada 52, 31-425 Kraków, Poland²Institute of Environmental Biology, Jagiellonian University, ul. Ingardena 6, 30-060 Kraków, Poland

The hypothesis that life expectancy is the main factor influencing risky foraging by worker honey bees was tested. We investigated whether diseased workers or workers with worn wings, and therefore with a shorter expected remaining life span, undertake foraging in poorer weather conditions than healthy workers or workers with unworn wings. Using a dynamic programming model we show that foraging honey bee workers should vary their foraging behaviour with age or disease status, foraging mainly under safe conditions when young or healthy with increased risky foraging with age or disease. Field observations of water collecting foragers confirm the model's predictions. Workers collecting water were captured in the middle of one cold and one warm day in April, May and July. Comparing each pair of days the ratio of individuals infected with *Nosema apis* spores was always higher on the cold day than on the warm day. We also found that there were more workers with worn wings collecting water on the cold days than on the warm days.

13-024

LIFE-HISTORY STRATEGIES IN ARBOREAL TERMITES FROM NEW GUINEA

M. Leponce¹, Y. Roisin, J.M. Pasteels

Laboratoire de Biologie animale et cellulaire, Université Libre de Bruxelles, Belgium - ¹Institut Royal des Sciences Naturelles, Bruxelles, Belgium

In coconut plantations on the north coast of New Guinea, three species of arboreal-nesting termites compete for food and space: *Nasutitermes princeps*, *N. novarumhebridarum* and *Microcerotermes biroi*. The three species build their nest on coconut tree trunks and forage for dead plant material on trees and on the ground. We investigated whether the three species display different life-history strategies. The number and morphology of the functional reproductives found in unmanipulated nests or obtained after orphaning experiments differ among species and suggest that *M. biroi* and *N. novarumhebridarum* are best adapted for colonizing trees by independent founders, whereas *N. princeps* would more easily spread by budding. Long-term field studies indeed showed that *Microcerotermes biroi* is very efficient at establishing new colonies in a virgin habitat, by means of nuptial flights. *Nasutitermes novarumhebridarum* also relies on nuptial flights to colonize new sites, but is more commonly associated with dead trees. By contrast, *N. princeps* seems to be a poorer colonizer, but established colonies are able to expand their territories by budding and form large unicolonial systems. Their fighting capacities allow *N. princeps* workers and soldiers to kill colonies of *M. biroi* and invade their territory. We suggest that differences in life-history strategies may account for the frequent co-occurrence of the three species in coconut plantations, in spite of the obvious competition between them.

13-026

PLASTICITY OF SOCIAL ORGANIZATION IN A FOREST ANT SPECIES

J. M. Herbers and V.S. Banschbach²

Department of Biology, Colorado State University, Fort Collins CO USA - ² Department of Biology, Davidson College, Davidson NC USA

The ant species *Myrmica punctiventris* displays remarkable variation in a number of life history characteristics. In a Vermont population, this ant has polydomous colonies, headed by a single-once-mated queen. There, coefficients of relatedness are very high, and sex ratios conform to predictions based on kin selection theory. By contrast, a population in New York has monodomous colonies headed by several queens, with lower relatedness coefficients and highly male-biased sex ratios. Furthermore, the New York population shows evidence of inbreeding and population subdivision. To understand the ecological factors that might produce such different patterns of social organization, we conducted an experiment on the Vermont population that added food and/or nest sites in a full factorial design. We found that the food supplementation had dramatic and consistent effects on the patterns of polydomy, polygyny, relatedness coefficients, sex ratios, and levels of selection. The nest site supplementation treatment also affected some aspects of social organization, and an interaction between the treatments was important for others. Thus our data show that social organization is ecologically labile. Studies of colony organization must take into account the environment in which those colonies occur.

13-025

SOCIAL STRUCTURE OF *LEPTOTHORAX* SP. A: INFLUENCE OF GENETIC COMPOSITION, AGGRESSION AND FERTILITY OF INDIVIDUAL QUEENS

D. Ortius, J. Heinze

Theodor-Boveri-Institut für Biowissenschaften, Zoologie II, Am Hubland, D-97074 Würzburg, Germany

The North American formicoxenine ant species *Leptothorax* sp. A was thought to be strictly functionally monogynous (i.e. although several queens are present only one reproduces) and the observed fighting among intermorph (wingless) queens after hibernation leads to budding of the colonies and secures functional monogyny. We report a second fighting period during the annual colony cycle after the adoption of young mated queens into their mother colony, which does not lead to budding. Instead young queens are integrated into the existing hierarchy. Aggression can continue very weakly throughout the year, indicating that it is necessary for the inhibition of subordinates, as experiments suggest a lack of pheromonal inhibition. Furthermore, sampling data reveal a high number of monogynous colonies and dissecting data of queens from 35 polygynous colonies suggest, that colony organization in this species is far more diverse. Colonies can either be mono-, fet. mono- or polygynous. As models on ESS predict covariance of relatedness and asymmetry of reproduction and relatedness data show that multi-queen colonies in this species can be mother/daughter, daughter/daughter and/or mother/daughter/-aunt/nieces associations, these would be ultimate factors for *Leptothorax* sp. A in the process of deciding to fight and become fet. monogynous or not to fight and become polygynous. Among the proximate factors, size, weight, morphology and insemination have no influence on dominance ranking in queens. Individual fertility of a queen is shown to have a substantial influence. Experiments indicate that developing ovaries of a queen can be sensed by workers since they exhibit a preference for the most fertile queen and not the one having been dominant following aggression. This also indicates that aggression is energetically costly for the individual queen. Giving a queen a head start in ovary development before the others leads to budding of the colonies without aggressive behavior and the fertile queen is surrounded by the most worker and brood force. The conclusive prediction is that depending on the relatedness composition of a colony (influenced by the adoption of related queens and/or frequent superseding of high ranking queens) aggressive behavior can occur and if so, influence individual fertility of a queen by its energetic impact and thus, leading to differential reproduction and functional monogyny.

13-027

WEAKLY SPECIALIZED QUEENS AND THE ABILITY OF WORKERS TO MATE AND REPRODUCE: LIFE HISTORY OF THE PONERINE ANT *HARPEGNATHOS SALTATOR*

C. Peeters

CNRS, Laboratoire d'Ethologie Expérimentale et Comparée, Université Paris Nord, 93430 Villetaneuse, France

In the indian ant *H. saltator*, new colonies are established by single queens. Young workers are able to mate with males from their own nest, but they remain sterile in presence of the foundress. However, when the latter dies, several mated workers become the reproductives (= gamergates). Since new workers mate annually, an orphaned colony can thus survive for some years. Alate queens continue to be produced in gamergate colonies, and they disperse and outbreed. Unlike other ponerine ants, the nests of *H. saltator* become extremely complex as they grow larger, and represent a valuable resource (Peeters & Hölldobler 1995). Colony emigration and eventual fission are thus unlikely to occur, and flying queens remain essential to start new colonies. *H. saltator* has small colonies (average 51 workers), but its life history resembles that of many termites - valuable nests are inherited by neotenic (wingless) reproductives, and outbreeding alternates with inbreeding. *H. saltator* is an interesting contrast to the several ponerine ants where queens have disappeared permanently. In these, colonies with gamergates can multiply through fission (the nests are often simple or short-lived), and the workers are thus totipotent. It appears that the weakly specialized queens (no claustral foundation; low fecundity; short lifespan) characteristic of morphologically "primitive" ants are selected against in various ecological contexts, but in *H. saltator* their production remains adaptive because colonies do not fission.

Peeters C. & B. Hölldobler (1995) *PNAS* 92: 10977-10979.

13-028

EVOLUTION OF EUSOCIALITY IN TERMITES: ROLE OF ALTRICIAL OFFSPRING

C.A. Nalepa

Entomology Dept., North Carolina State Univ Raleigh, NC USA

There are obvious gradients in the maturity and relative size of cockroaches at hatch, ranging from immature and helpless (altricial) to complete independence from adults (precocial). The subsocial, wood feeding Cryptocercus punctulatus represents the extreme of altricial development among cockroaches. 1st instar nymphs lack compound eyes; eye pigment does not develop until the 2nd instar. The cuticle is pale and thin, with internal organs clearly visible through the surface of the abdomen. Gut symbionts are not established until the 3rd instar, making young nymphs dependent on adults for food. 1st instars are small, averaging just .06% of their final adult dry weight. The small size of neonates is associated with the production of small eggs by the female; length of the terminal oocyte is 5% of adult length, contrasting with the 9-16% exhibited by 6 other species of oviparous cockroaches. It is proposed that the subsocial ancestor of termites exhibited a suite of life history characteristics that included altricial development of offspring. By producing small eggs from which hatch dependent offspring, the female avoids incurring a large metabolic expense prior to hatch. A portion of reproductive investment is postponed until the post-embryonic stage, allowing some of the cost to be shared with other family members: the male and older offspring.

13-030

LIFE HISTORY STRATEGIES IN SWARM-FOUNDING WASPS

R.L. Jeanne

Departments of Entomology and Zoology, University of Wisconsin, Madison, WI, USA

Swarm-founding Polistinae are the dominant social wasps in the tropics. To understand the reasons for their success we need to analyze life history variation within the group. To date there have been virtually no studies directly addressing life histories in these wasps. For a handful of species, however, data do exist that can be used to estimate colony age and size at maturity, frequency of reproduction, seasonal timing of reproduction, and swarm size and number. I draw on these data to outline some of the variables and constraints involved and to begin to discern patterns in the life history strategies and trade-offs adopted by these wasps. Among the issues addressed are the following. (1) Because its 'offspring' are swarms of workers and queens, the swarm-founding colony has a potentially unlimited flexibility to adjust the trade-off between offspring size and number. A colony of swarm-founders can opt to produce a few large swarms or a larger number of smaller ones. These options are examined in light of the recent finding for *Polybia* that the per capita rate of production of offspring rises with swarm size. (2) In addition to the usual components of a species' life history, social wasps make decisions about the size of the nest. Because brood are reared singly in cells, the size of the brood population the colony can rear is tightly constrained by the number of cells in the nest. How large a nest to build is an especially important decision for swarm-founding wasps because the swarm completes the nest in the first 5-7 days of the colony's existence and then lives within its limits for the next several weeks. The fact that the size of the nest is tightly correlated with the number of wasps in the swarm suggests strong selection to optimize nest size. I examine nest size in species for which data exist in an attempt to identify what some of these selective pressures may be.

13-029

GEOGRAPHIC VARIATION IN SOCIAL ORGANIZATION OF HALICTINE BEES AND THE ECOLOGICAL SIGNIFICANCE OF SOCIAL FLEXIBILITY

William T. Wcislo

Smithsonian Tropical Research Institute
Balboa, Republic of Panama

On-going studies show that social organization and life history attributes vary between populations of the neotropical sweat bee, Lasioglossum (Dialictus) umbripenne (Hymenoptera, Halictidae).

These populations are located along a north-south transect in eastern Panama, near the continental divide, and are separated by a distance of approximately 5 kilometers.

Colony size, social structure, and seasonal activity differ between these sites, but resource availability does not. Differences in seasonal activity may relate to local rainfall patterns.

Data from the Panamanian populations are compared with data from two conspecific populations in Costa Rica, which also differ in life history characteristics. Comparative data from temperate and tropical species show the great ecological success of halictid bees has been due, in part, to the flexible nature of their social behavior, which permits different phenotypic expression under different climatic conditions.

13-031

SIZE IN SOCIAL INSECTS--MULTIPLE COMPONENTS, MULTIPLE CAUSES

M. Kaspari

Body size is a key covariate to life history in unitary organisms. Social insect colonies, in contrast, are modular, making "body size" an intriguing concept. The mass of a social insect colony is (minimally) the product of *Size*--the mass of adults and larvae--and *Number*--the respective allotment to each. Size and Number are only weakly correlated across the ant species sampled, suggesting that they are largely under separate control.

I discuss the functional relevance of size and number in ant colonies, focusing mainly on allocation to the worker caste. I do this through a combination of literature review, field observations, and comparisons of the size makeup of ant assemblages from the Arctic Circle to Central America. I test the following hypotheses: 1) Size/Number is constrained by the architecture of the environment; 2) Size/Number is an optimal response to geographic variation in environmental productivity; and 3) Size/Number is an optimal response to survival during periods of resource shortage.

13-032

PATTERN AND PROCESS IN THE DEMOGRAPHY OF PAPERWASPS
(HYMENOPTERA: VESPIDAE, POLISTINAE)

J. H. Hunt

Department of Biology, University of Missouri-St. Louis,
St. Louis, Missouri 63121 U.S.A.

Demographic studies of social wasps have traditionally focused on the growth of single colonies. Stages of colony development have been named and described, and the population increase and decrease of individual colonies have been quantified within this descriptive framework. Studies of population demography (many nests) of social wasps are much less common, but that literature reveals that large numbers of foundress colonies never pass through the sequence of stages described in the colony-level studies. Natural history studies have additionally revealed that even for colonies that pass through the described stages, the potential reproductive activities of offspring are more numerous and varied than is typically reported. The population demography of paperwasps is thus more realistically modeled by a life cycle graph with multiple pathways than by the traditional model of sequential stages.

A life cycle graph has been developed and used as the conceptual framework for several seasons of preliminary experimental studies on the population demography of *Polistes metricus* in Missouri, U.S.A. Early season supplementation of honey led to larger colonies with more offspring but with a lower frequency of apparent worker behavior. Diminishment of larval saliva led to small colonies with low productivities and survivorship. Quantification of transitions in the life cycle graph remains to be undertaken, but the preliminary studies strongly suggest that typical colony ontogeny, and therefore also typical population demography, are shaped in part by the nutritional environment.

13-034

LATITUDINAL VARIATION OF SEASONAL DEVELOPMENT
STRATEGIES IN *MYRMICA* ANTS

E.B. Lopatina, V.E. Kipyatkov

Department of Entomology, Faculty of Biology,
St. Petersburg University, St. Petersburg, Russia

In *Myrmica* ants the duration of colony's annual cycle of development is controlled by an endogenous timer along with temperature and photoperiod. The seasonal development strategies of *Myrmica rubra* L. and *Myrmica ruginodis* Nyl. appeared to be quite different in Belgorod (50°NL) and St. Petersburg (60°NL) regions. The pupation of larvae originated from the eggs laid during the same summer (so-called rapid brood) starts early in July in Belgorod and only at the beginning of August in St. Petersburg when the weather is already rather cool there. That is why in Belgorod rapid brood is abundant whereas in St. Petersburg only a few rapid brood pupae appear. One could suggest that numerous rapid brood pupae in St. Petersburg do not develop because of direct influence of the inferior temperature in August. Natural spring colonies of both species were maintained in a laboratory at long (20 h) or short (12 h) days and 17, 20 or 25°C. Pupation of the rapid brood larvae ceased inevitably in all regimes but short days and low temperature significantly reduced the length of pupation period and the number of larvae pupated. St. Petersburg colonies appeared to differ from Belgorod ones by far shorter pupation period and much weaker rapid brood production at the same temperature and photoperiod. Thus, the dramatic difference between Belgorod and St. Petersburg populations in seasonal development strategies, which is a result of adaptation to really distinct climates, is not due to direct influence of temperature but is primarily determined by the innate endogenous mechanisms that regulate colony's development.

13-033

Social insect life history in different environments

Paul Schmid-Hempel & Regula Schmid-Hempel, ETH Zürich,
Experimental Ecology, ETH-Zentrum NW, CH-8092 Zürich

Bumble bees (*Bombus* spp.) often live in unpredictable environments. In addition, parasites are important selective factors for survival and reproductive success of colonies. We experimentally tested how unpredictable or low food availability affects productivity of colonies, the timing of reproductive events, offspring size and defence against parasites in lab colonies of *B. terrestris* exposed to simulated environments. When compared controls, low food availability, as expected, led to reduced colony growth with smaller workers, and fewer and smaller males. With unpredictable food supply, however, colony growth was increased with larger workers and heavier males. Furthermore, in all environments, the same level of parasite defence, as measured by the encapsulation response, was maintained. These results compare with conflicting field data and further experimental tests on the cost of parasite defence. Taken together, our conclusion is that colonies respond to unpredictability with increased production at a higher food acquisition level, and that other, usually more subtle critical needs, such as immune defence, may eventually become compromised.

13-035

ANNUAL DEVELOPMENTAL CYCLE STRATEGIES
IN TEMPERATE CLIMATE ANTS

V.E. Kipyatkov, E.B. Lopatina

Department of Entomology, Faculty of Biology,
St. Petersburg University, St. Petersburg, Russia

Temperate climate ants have heterodynamic seasonal development characterized by the presence of winter diapause. We distinguish two main annual cycle strategies in these social insects. The most widespread is the strategy of prolonged (extensive) development distinguished by a significant delaying of development of a large share of larvae (so-called slow brood) which continue to grow in autumn, hibernate in diapause and pupate during next summer. The appearance of larval diapause in evolution provided ants with several advantages: (1) workers can rear larvae from early spring to late autumn thus using the whole warm period of a year; (2) the development of larvae can be extended to two or even three summer seasons; (3) it is possible to adapt to the duration of the warm season by changing the quantity of so-called rapid brood (larvae that develop from egg to pupa without hibernation). The strategy of concentrated (intensive) development is characteristic to genera *Cataglyphis*, *Formica*, *Proformica*. The development of all brood stages is restricted to the warm season in these ants. Only queens have winter diapause; larvae finish their development during the summer, all new workers emerge from pupae and ants hibernate, therefore, without brood. This strategy can only be appropriate for northern ants in a combination with the very fast brood development allowing them to rear sexuals and new workers from the eggs during a short warm season. Among temperate ants *Formica* species have the shortest developmental times that are about twice lesser than, for example, in *Myrmica* and *Leptothorax*.

13-036

QUEEN ACOUSTIC BEHAVIOUR IN THE SICILIAN HONEY-BEE (*APIS MELLIFERA SICULA*)

D. Brückner, H. Schmidt-Uhlenkamp

Forschungsstelle für Bienenkunde, FB 2,
Universität Bremen, 28334 Bremen, Germany

The acoustic behaviour of queens of *Apis m. sicula* was investigated during the swarming season of 1995 in Sicily and compared to the acoustic behaviour of queens of *Apis m. carnica*. Queen tooting has been shown to delay emergence from queen cells up to several days in *Apis m. carnica*. Since we could show that queens of *Apis m. sicula* do emerge from queen cells in the presence of free running queens, it was tested in this study, if tooting signals do occur at all in this honey-bee race, and if so, if they are different in any parameter from those of *Apis m. carnica* queens.

We found that tooting signals were produced by free running queens of the Sicilian honeybee and quaking signals by queens still in their queen cells. A comparison showed that these signals did not differ from the tooting and quaking signals of *Apis m. carnica* queens.

13-038

KING'S ROLE IN TERMITE SOCIETY: THE CASE OF *KALOTERMES FLAVICOLLIS* (ISOPTERA: KALOTERMITIDAE)

L. Maistrello and G. Sbrenna

Department of Biology, University of Ferrara, Ferrara, Italy

Activities and social interactions of male and female replacement reproductives of *Kaloterмес flavicollis* were compared in an ethogram type investigation.

The study was conducted on colonies whose members, suitably representing all castes and developmental stages, were individually labelled. Data were collected using THE OBSERVER (Ver. 3.0, Noldus Information Technology, Wageningen), by scan-sampling all subjects of each colony from videorecorded images performed at preprogrammed intervals evenly arranged along the 24 hours, during a 16 days period.

Behavioural patterns of the king and the queen were similar in size, consisting in 13 elements, representing the behavioural categories of individual maintenance, feeding, communication and social interactions, but were extremely different in the frequency of some behaviours. The male reproductive appeared as the most active member of the colony. Its continuous shiftings within the nest and the abundance of vibratory movements, together with the high frequency of social contacts and peculiarity of grooming patterns, seem to confer to the king a very important function in termite society. These data suggest a sex-based behavioural specialization of the two reproductives in colony organization and equilibrium.

PHEROMONAL DOMINANCE SIGNALS IN PRIMITIVELY EUSOCIAL BEES

M. Ayasse, T. Marlovits, J. Tengö¹, T. Taghizadeh², W. Francke²

Institute of Zoology, Dept. of Evolutionary Biology, Vienna, Austria

- 1 Ecological Research Station of Uppsala University, Färjestaden, Sweden

- 2 Institute of Organic Chemistry, University of Hamburg, Germany

In highly eusocial bees, queen pheromones regulate the dominance hierarchy and inhibit ovarian development in workers. Based on the results of behavioural experiments in primitively eusocial bumble bees and sweat bees, pheromonal dominance or recognition signals have been postulated, but have never been identified by chemical methods. In the primitively eusocial sweat bee *Lasioglossum malachurum* (Halictidae) and in the bumble bee *Bombus hypnorum* (Apidae) the behaviour of workers was observed in order to characterise them as foragers or guards in the sweat bee, and as dominant, subordinate or foragers in the bumble bee. Volatiles from queens and functional worker groups were chemically analysed and compared by statistical methods.

In *L. malachurum* queens, foragers and guards were different in their odour bouquets and in physiological traits. In *B. hypnorum*, dominant or subordinate workers and foragers could be characterised by physiological traits and by odour bouquets. In Dufour's gland-, head extracts, cuticular washings and headspace samples, queens, the worker groups classified by behavioural observations and age showed significant differences in both the total amounts and the relative proportions of volatiles. From all the worker groups, dominant workers showed the most similar volatile patterns in comparison to the queens. Behavioural tests with gland extracts and body surface washings indicated a communicative function as either recognition or dominance signals.

A FEEDING STIMULATING SIGNAL IN THE LABIAL GLAND SECRETION OF THE TERMITE *RETICULITERMES SANTONENSIS* SJÖSTEDT (ISOPTERA: RHINOTERMITIDAE)J. Reinhard¹, M. Kaib²¹ Bundesanstalt für Materialforschung und -prüfung, Berlin, Germany² Lehrstuhl Tierphysiologie, Universität Bayreuth, Bayreuth, Germany

Chemical signals from secretions of different exocrine glands modulate a variety of behavioural patterns in termite societies. During food exploitation workers of the African termite *Schedorhinotermes lamanianus* Sjöstedt (Isoptera: Rhinotermitidae) release the secretion of their labial gland directly onto the food. The secretion carries a signal, which stimulates feeding and leads to aggregations of gnawing workers at feeding sites (Kaib & Ziesmann, 1992, Ins. Soc. 39, 373-384; Reinhard & Kaib, 1995, Physiol. Entomol. 20, 266-272).

The paired labial gland of the French termite *Reticulitermes santonensis* Sjöstedt (Isoptera: Rhinotermitidae) is located in the meso- and metathorax. In the head, the gland ducts join with the ducts of the nearby located water sacs. In a feeding bioassay, workers of *R. santonensis* had to choose between two semicircles of moist filterpaper as food. The termites significantly preferred one of the semicircles, if labial gland secretion was applied on it. That is, the labial gland secretion of *R. santonensis* carries a feeding stimulating signal as well. The content of the water sacs is not active in this context. The feeding stimulating signal proved to be extremely polar (soluble in water only), heat-resistant up to 100°C for at least 24h and thus to be very persistent. These chemical properties point to e.g. salts or saccharides as signal substances.

Apart from its own secretion, the labial gland secretions of 8 further termite species from 5 different families, including *S. lamanianus*, all proved to have this feeding stimulating effect on *R. santonensis*. This points towards a chemically similar or even identical principle in the labial gland secretion of termites.

13-040

SLAVE RAIDING BEHAVIOUR IN SOCIALLY PARASITIC *STRONGYLOGNATHUS* ANTS (HYMENOPTERA: FORMICIDAE)

M. Sanetra, A. Buschinger

Institut für Zoologie, Technische Hochschule, Darmstadt, Germany

Slave raids were observed in five species of the Palearctic genus *Strongylognathus*, obligatory social parasites of *Tetramorium* host species, with a poorly known life history. In arena experiments we demonstrated that *S. caeciliae* FOREL 1897, *S. destefanii* EMERY 1915, *S. emeryi* MENOZZI 1921, *S. ceconii* EMERY 1916 and *S. silvestrii* MENOZZI 1936 are capable of conducting raids upon foreign *Tetramorium* nests, including host brood retrieval. Single raids differed considerably in various details, however, the following characteristic traits can be outlined. Scouting activity increases in the evening, and experiments were thus mainly performed during the night. Most impressive in *Strongylognathus* raids is group recruitment on pheromone trails. Fighting appears relatively obscure and inconspicuous, though the saber-shaped mandibles are used to penetrate into the central nervous system of defending *Tetramorium* via the mouthparts. During some fights even the strongly chitinized head capsule was eventually pierced. *Tetramorium* slaves join raiding parties and fighting, whereas brood transportation to the slave-makers' nest is carried out exclusively by *Strongylognathus* workers. Larvae, pupae and even adults are pillaged from a raided nest, and often all the conquered host colony was incorporated into the parasite society. Acceptance of foreign host colony queens after two raids may represent an artefact. Notwithstanding some minor deviations from typical slave-maker behaviour we thus found evidence for dulotic life habits in the *Strongylognathus* species studied.

TESTING KINSHIP THEORY WITH *ROPALIDIA MARGINATA*

H.S. Arathi¹, Mallikarjun Shakarad¹ and Raghavendra Gadagkar^{1,2}

¹Centre for Ecological Sciences, Indian Institute of Science, Bangalore, India
²Jawaharlal Nehru Centre for Advanced Scientific Research, Bangalore, India

Ropalidia marginata is a primitively eusocial wasp in which new nests are initiated by one or a group of individuals. In the latter case, all but one individual take on the role of sterile workers. Per capita productivity does not increase significantly with number of foundresses and hence is not a potential explanation for the apparent altruism of the workers. Polyandry and serial polygyny significantly reduce intra-colony genetic relatedness so that kinship theory based on genetic asymmetries created by haplodiploidy is not a satisfactory explanation either. It is therefore of interest to examine the possible existence of intra-colony kin recognition that can potentially lead to nepotism. Young wasps, 0-8 days old, were readily accepted into alien conspecific nests. This may have partly to do with their lack of ovarian development but age *per se* was more important in influencing the probability of acceptance than ovarian development. In any case this provided a method for us to create genetically mixed colonies. In 12 such colonies studied, we could detect no evidence of kin-specific interactions, task specialization or nepotism. The alien wasps went on to become foragers or replacement queens with probabilities that were indistinguishable from those with which natal wasps did so. These results suggest that genetically unrelated wasps are as amenable to cooperative nest building and brood rearing as related wasps are. To test if there is any cost at all of living in genetically mixed colonies, we measured the productivities of pairs of wasps that were either nestmates or non nestmates and found no significant differences. Our results suggest that factors other than haplodiploidy based kin selection must be sought as explanations for the evolution of worker behaviour.

13-041

CHARACTERIZATION OF THE MANDIBULAR GLAND ORIFICE AND ITS CONTROL MECHANISM IN ANTS (HYMENOPTERA: FORMICIDAE)

E. Schoeters and J. Billen

K.U.Leuven, Laboratory of Entomology, Leuven, Belgium

The mandibular gland in ants is generally known as the source of alarm pheromones. About the morphology and topographical organization of the control mechanism and the position of the glandular duct and its orifice, some inaccurate data were reported until now. This is due to the difficulties in making it accessible for morphological research because of the position of the mandible and the orifice underneath the heavily sclerotized fore margin of the head capsule. Dissected and critical point dried mandibles showed a narrow slit, starting near the mesal edge where the mandible articulates with the head capsule, then extending more anteriorly on the upper surface of the mandible and curving towards its inner margin. The part of the mandible where the mandibular orifice occurs, is known as the mandalus in literature. The aim of our investigation is to come to a comparative study of the control mechanism in species belonging to the different ant subfamilies. We observed a lot of variability of mandibular gland openings in different ant species. There is no direct relation between the size of the mandibular gland and that of the glandular orifice. When looking at the functioning of the control apparatus of the mandibular gland duct in ants, we see that the chitinous structure of the mandalus functions as a flexible plug, with a position that can be changed slightly by action of the musculus abductor mandibularis. Usually, when ants are alarmed, they open their mandibles towards the aggressor. This opening of the mandibles is assumed to be sufficient for the widening of the slit-like mandibular gland orifice. This assumption gains in importance when we look at semi-thin sections : no sphincter or other muscles could be detected in association with the mandibular gland duct

13-043

DYNAMIC OPTIMIZATION MODELING AS APPLIED TO PREDICTING LIFE HISTORIES IN THE SOCIAL INSECTS.

P. Nonacs

Dept. of Biology, Univ. of California, Los Angeles, USA

Social insect colonies live in complex, always changing, environments. Clearly, one of the great advantages of sociality is the ability to exploit positive changes and to withstand negative changes. Previous models of colony behavior or ontogeny are static in considering the environment only in its expected, average state (if the environment is included at all!). However, with the advent of powerful personal computers, the effects of environmental variability can be studied and not ignored. The numerical techniques of dynamic optimization generate models that predict colony behavior in response to the simultaneous and changing factors of their own, internal needs and the external environment. Using such models we can ask questions such as:

1. What is a colony's optimal growth strategy in the face of changing levels of predation risk or competition?
2. What is the optimal allocation ratio between workers, soldiers and sexuals? And how sensitive should these ratios be to short term changes in the environmental conditions?
3. Do larvae serve as a cannibalizable caste under "normal" levels of food availability, or should they be eaten only under extreme stress? An example of such a model will be presented.

13-044

COLONY DEVELOPMENT IN THE BUMBLEBEE *BOMBUS TERRESTRIS* - A MINIMAL MODEL

M. Beekman, F.M. Kleijne, R. Lingeman, M.W. Sabelis
Pure and Applied Ecology, section Population Biology,
University of Amsterdam, the Netherlands

Bumblebees are annual eusocial insects. In early spring the overwintered queen starts a colony with the production of workers: the ergonomic phase. This phase ends when reproductives are raised: the reproductive phase. In the reproductive phase no more workers are produced. This is what is called a bang-bang strategy.

The more workers are present, the more reproductives can be raised (Pomeroy & Plowright 1982). But colonies that have a long ergonomic phase will start to reproduce late in the season. The risk of failure due to environmental hazards will be higher for late reproducing colonies (Müller & Schmid-Hempel 1992). Thus the colony faces a dilemma. Early reproduction decreases the number of reproductives, yet late reproduction increases the chance the colony will fail to reproduce at all.

Colonies of the bumblebee *Bombus terrestris* show a large variation in the number and sex ratio of reproductives they produce. Despite of several efforts to identify factors that influence the development of bumblebee colonies and thus the reproductive output, we still lack knowledge on the underlying functional mechanisms that direct reproduction in this bumblebee. Our model, which is an extension of the model of Macevicz and Oster (1976), is an attempt to fill this gap. Timing of the onset of the reproductive phase is optimal when the number of workers is sufficient to collect resources needed to raise the maximum number of reproductives at the end of colony lifetime.

NUMBER OF MATINGS IN THE GENUS *APIS* (HYMENOPTERA: APIDAE) REVEALED BY HYPER-VARIABLE MICROSATELLITES

B. P. Oldroyd, R.H. Crozier¹

School of Biological Sciences, University of Sydney,
Sydney, Australia - ¹ School of Genetics and Human
Variation, LaTrobe University, Melbourne, Australia

It has been postulated that multiple mating by social insect queens is adaptive because: 1) Genetically diverse colonies may be able to tolerate a wider range of environmental conditions, perhaps by increased polyethism or the potential for caste differentiation, or by increased tolerance to pathogens. 2) Multiple mating eliminates the possibility of a queen mating with a single drone carrying the same sex allele as herself. 3) Multiple mating can reduce conflict between workers and queens over the preferred sex ratio.

Understanding the evolution of multiple mating requires good estimates of the number of matings in a broad range of species. We have been using microsatellite markers to detect paternity and maternity of workers so that the number of males that mated with queens can be determined. Our results show that in the species so far examined, queens mated with > 6 to > 30 drones depending on the species. These results substantially increase previous estimates of the number of matings in the genus obtained from sperm counts.

13-045

Patterns of Genetic Diversity in the Polyandrous Leafcutter Ant *Atta colombica*

Else J. Fjerdingstad & J.J. Boomsma, Dept. Ecology & Genetics,
Aarhus University, Aarhus, DENMARK

Polyandry (ie. multiple mating by queens) in eusocial insects is considered an evolutionary puzzle. Polyandry is likely to be costly in terms of predation risk, time and energy expenditure for young queens and it reduces intracolony relatedness and hence inclusive fitness for reproductively altruistic workers. Two main hypotheses have been put forward to explain how polyandry might be favoured by natural selection. One hypothesis (Cole, 1983) suggests that multiple mating might be a queen strategy to obtain more sperm and thus be able to build up larger colonies and eventually produce more reproductive offspring. The other hypothesis focuses on potential benefits arising from the increase in genetic diversity brought about by polyandry (Hamilton, 1987).

We have carried out an analysis of queen sperm stores in the monogynous Panamanian leafcutter ant *Atta colombica*. The average ratio of queen to male sperm content was close to one. However, a DNA microsatellite genetic analysis of mother-offspring groups revealed *A. colombica* to be the most highly polyandrous ant yet reported (Fjerdingstad, Boomsma & Thorén, in prep.). We found no relationship at the individual queen level between genetic mating frequency and queen sperm content. Thus Cole's fecundity hypothesis for multiple mating can be rejected for *A. colombica*.

Hence, it seems that the evolutionary explanation for polyandry in *A. colombica* may be related to genetic diversity benefits. If more genetically diverse colonies have a higher survival fitness, eg. are more resistant towards parasites and pathogens attacking either the ants or their symbiotic fungus, then we might expect to find that the effective genetic diversity of mature colonies (which have succeeded in surviving for many years) would be higher than that of young, incipient colonies. We examine this using microsatellite markers.

13-047

DNA SEQUENCES REVEAL THAT SOCIALITY EVOLVED TWICE IN SOCIAL WASPS (HYMENOPTERA, VESPIDAE)

J. Schmitz

Institut für Biologie, TU Berlin, Germany

For the evolution of sociality in wasps, the oriental Stenogastrinae are a group of considerable interest. They show broad diversity in social behavior. On the basis of morphological and behavioral data the Stenogastrinae are placed phylogenetically in the family Vespidae intermediate between the solitary Eumeninae and the social Polistinae and Vespinae. This placement of Stenogastrinae is not undisputed because of several morphological and behavioral characters that are very different from the other social Vespidae. However these autapomorphies are not suited to overthrow the existing phylogenetic placement.

Nucleotide sequences were obtained from the mitochondrial 16S ribosomal DNA, and the nuclear 28S ribosomal DNA region for two *Apis* species, and 12 social and three solitary wasp species of the family Vespidae. Solitary wasps of the family Ichneumonidae and Pteromalidae were used as outgroups. Parsimony and distance methods give strong evidence that the conventional phylogenetic position of Stenogastrinae is inappropriate. The solitary Eumeninae have to be placed as the sistergroup to Polistinae and Vespinae. This implies that sociality has independently evolved once in Stenogastrinae and a second time in a common ancestor of Polistinae and Vespinae. This is one time more than previously assumed.

13-048

NESTMATE RECOGNITION IN THE PRIMITIVE SOCIAL WASPS STENOGASTRINAE (HYMENOPTERA: VESPIDAE).

S. Turillazzi, R. Cervo, F.R. Dani¹.Dipartimento di Biologia Animale e Genetica, Università di Firenze, Firenze, Italy - ¹ Department of Chemistry, Keele University, Staffordshire, England.

The stenogastrine are generally considered the least socially evolved subfamily of wasps. Information collected during studies on the social biology of some species indicates that these wasps reject conspecific intruders from the nest. However, their nestmate recognition capacity has not yet been investigated.

We performed field experiments on nestmate recognition in *Parischonogaster jacobsoni* and two species of *Liostenogaster*, *L. flavolineata* and *L. vechti*. Conspecific hetero- and homocolonial females were presented to colonies of all the above mentioned species, observing the behaviour of the resident females. Experiments show that wasps are able to discriminate between nestmates and alien wasps. In particular *L. flavolineata* and *L. vechti*, which form large clusters of nests, reject also wasps coming from other colonies of the same nest cluster. These results suggest that the nestmate recognition of these wasps is very efficient, notwithstanding their poorly evolved sociality.

Behavioural tests on *L. flavolineata* show that, like other social insects, epicuticular lipids are the cues used for recognition.

Further experiments on *P. jacobsoni*, in which the wasps of a colony were faced with an alien nest containing immature brood, indicate a capacity for nest recognition. However the alien nests were always accepted and, in contrast with the massive destruction of alien immature brood observed in similar experiments in some polistine, brood was rarely destroyed in this species. In our opinion, the acceptance of alien nests and brood is not due to a lack of recognition capacity but is probably related to the great investment necessary for egg deposition and nest building in this subfamily.

13-049

NESTMATE RECOGNITION AND THE GENETICAL "GESTALT" OF *FORMICA POLYCTENA* COLONIES

M. Beye, P. Neumann, R. F. A. Moritz

Inst. für Biologie, TU Berlin, Franklinstr. 28/29, 10587 Berlin, Germany

Social insects live in colonies and it seems to be common that they resist mixing with other colonies even of the same species. Individuals recognize those of other colonies through differences in odoural cues. Crozier and Dix (1979) developed a Gestalt model suggesting that workers respond to a colony odour which is produced by all colony members. Here we determine the genetic Gestalt of nests and look for its impact on nestmate recognition in the polygynous ant *Formica polyctena*.

Nestmate recognition was tested by measuring the aggression level between several individuals of different nests. The aggression was scored in arena tests on 3 level scale from 0 to 2. We found that one population (9 nests sampled in Berlin) had different levels of aggression (0.04 to 1.88) while the second one (7 nests sampled in Schwedt) showed low levels of aggression (0.07 to 0.52). 40 individuals of each nest were genetically typed as a DNA pool by multilocus fingerprinting, yielding the genetic composition of the whole nest (genetic Gestalt).

We found a strong negative correlation between the level of aggression and the similarity of DNA banding patterns between the genetic Gestalts ($p < 0.02$). Pairs with high aggression levels had fewer bands in common than pairs with low aggression. We suggest that nestmate recognition of ants in the species *Formica polyctena* is strongly influenced by the genetic composition of the whole nest as predicted by the Gestalt model.

Crozier and Dix (1979) Behav Ecol Sociobiol 4: 217-224

We thank K. Joyeux for recognition analysis. This work was supported by the DFG.

13-050

THE FORMATION OF A "GESTALT" ODOR IN *CATAGLYPHIS NIGER*. DO QUEENS MATTER?

V. Soroker, S. Lahav and A. Hefetz

Department of Zoology, Tel Aviv University, Tel Aviv 69978, Israel

The postpharyngeal gland (PPG) is an ant specific organ, present in all castes. Its secretion consists mostly of long chain methyl branched hydrocarbons which are congruent with those found on the cuticle. In workers the gland sequesters the hydrocarbons from both internal and external sources. By receiving and mixing hydrocarbons from multiple nestmates, the gland can be considered as a colonial reservoir of recognition cues that is shared by all the members of the society and thus responsible for creating the unified colony odor. We further evaluated the impact of the queen in this process in the colonies of *C. niger*. Chemical analyses of PPG secretions of queens and workers using GC/MS have shown that although the hydrocarbon content of the two castes is similar and queens are not much larger, they possess a significantly greater amount of hydrocarbons in their PPG. Interestingly, comparative studies on *de novo* hydrocarbon biosynthesis and their distribution using radiolabeled [¹⁴C] precursors have shown that although in both castes radiolabeled hydrocarbons were detected in the gland and on the cuticle, the total amount of hydrocarbons produced and their relative proportions in the gland were significantly higher in workers. Moreover, dyadic encounters between prelabeled queens and non labeled workers and vice versa revealed that although transfer occurs in all the cases, hydrocarbons were transferred significantly less from queens to workers than between workers.

Although, the discrepancy between the high hydrocarbon content of the gland and the low biosynthetic rate in the queen remains to be resolved, our results imply that in mature colonies of *C. niger*, the queen can not be considered as a main source of colony odor.

13-051

DO ANTS REARED IN A MIXED SPECIES GROUP RECOGNIZE ONLY THEIR NESTMATES' ODORS OR THE CORRESPONDING ALLOSPECIFIC ODORS IN GENERAL.

A. Hefetz and C. Errard, Department of Zoology, Tel Aviv University, Israel and Lab. Ethol. Exp. Comp., Université Paris Nord, France.

Ants reared in a mixed species group (*Manica rubida* co-nesting with *Formica selysi*) constantly exchange recognition cues, resulting in a uniform group odor composed of substances produced by both species. To unravel whether the postpharyngeal gland is a source of recognition cues we tested the reaction of *M. rubida* to nestmates treated with glandular secretion from various sources.

Behavioral tests comprised two consecutive encounters between five ants and their color marked nestmate. The first (control) encounter was performed with an untreated ant, while in the second encounter the marked ant was treated with postpharyngeal gland exudate. Scoring was done using an aggression index obtained by direct observation, and an agitation index deduced from a frame by frame analysis of videotapes of the various tests. Tests were conducted with *M. rubida* originating from homospecific colonies or from a mixed species group. The postpharyngeal gland source was either from *M. rubida* or from *F. selysi*, as appropriate.

In tests using ants from homospecific colonies, applied with glandular secretions originating from an alien *M. rubida* ant or from a *F. selysi* belonging to a homospecific nest, the ants became very agitated and were aggressive towards their nestmate. In contrast, the application of exudates originating from a nestmate *M. rubida*, left the ants generally calm, although their rates of selfgrooming increased. Having established that the glandular secretion is a source of recognition cues, we repeated these experiments using *M. rubida* reared in a mixed species group. In general, the reaction of these ants was much milder and was graded depending on the source of the secretion. The highest aggression appeared towards ants applied with exudates of *F. selysi* from homospecific colonies. At the other extreme, the reaction towards ants applied with secretion belonging to *F. selysi* nestmates was not significantly different from the control.

The fact that worker *M. rubida* reared in mixed species group and exposed to a heterospecific colony odor are rendered more tolerant to ants bearing a similar bouquet, indicates their ability to generalize learned cues. Nevertheless the odor of nestmates or alien ants reared in similar mixed species groups seems to be the most familiar.

COLONIAL FUNGUS RECOGNITION OF THE ANT *ACROMYRMEX SUBTERRANEUS* (HYMENOPTERA FORMICIDAE)A.M.M. Viana¹, A. Lenoir^{1,2}

1 Laboratoire d'Éthologie Expérimentale et Comparée, Université Paris Nord, France - 2 New address: Laboratoire d'Éthologie et Pharmacologie du Comportement, Université de Tours, France.

We investigated the capacity of the fungus-growing ant *Acromyrmex subterraneus subterraneus*, Forel 1893, to recognize nestmate and non-nestmate brood. As brood is reared in the fungus which is a full part of the nest, we investigated also the specificity of the fungus. The different behavioural steps leading from discovery to transport into the nest, or reject in the dump of items encountered outside the nest were used to characterize the colonial recognition by workers. Tests were performed with larvae, pupae and fungus pellets. Nestmates (from the same colony: homocolonial), and non-nestmates, either heterocolonial (different colony) or heterospecific (other *Acromyrmex* species) items were used. Workers can easily discriminate between nestmates and non-nestmates. Homocolonial items were readily picked up and carried into the nest and placed in the fungus garden. Non-nestmate items (alien brood or fungus) were always rejected. The fungus is treated exactly like the brood, accepted or rejected according its origin. The colonial identity, a characteristic of eusocial insects, extends to the fungus. We discuss evolutionary mechanisms for this remarkable coevolution between an ant and a fungus.

STRUCTURE OF TERMITE MOUNDS - AN ADAPTATION TO AMBIENT TEMPERATURE?

J. Korb and K. E. Linsenmair

Theodor-Boveri-Institut für Biowissenschaften, Zoologie III, Würzburg, Germany

Since 1992, we are studying the influence of ambient temperature on the structure of *Macrotermes bellicosus* mounds in a West African Guinea Savannah. In the Comoé-National Park (Ivory Coast) the mound architecture differed greatly between the two adjacent habitats, shrub savannah and riparian forest, with highly structured mounds ('nids en cathédrale') in the former and less structured mounds in the latter ('nids en dôme'). By measuring the surfaces of the mounds directly with a new technique we found a quantitative correlation between ambient temperature and mound complexity. Experimental manipulations of the ambient temperature confirmed the causal relationship between these two variables. The dome shaped structure of mounds of *M. bellicosus* in the riparian forest is viewed as an adaption to this cooler habitat by reducing loss of internally generated heat to the environment. Evidence as to the adequacy of this hypothesis is given by data on the respective amount of energy required to heat mounds in both habitats.

13-053

STRATEGIES OF COLONY FOUNDING IN THE FACULTATIVE SLAVE-MAKING ANT *FORMICA SANGUINEA* LATR. (HYMENOPTERA, FORMICIDAE)

A. Mori, F. Le Moli

Dipartimento di Biologia Evolutiva e Funzionale, Università degli Studi, Via delle Scienze, Parma, Italy

Little is known about the mode of formation of new colonies in the facultative European slave-making ant *Formica sanguinea*. Nevertheless, the observation on colony founding by queens of this species is considered to be crucial for the understanding of the evolutionary origin of slavery (or dulosis) in ants.

To investigate this phenomenon, a series of laboratory experiments was conducted utilizing newly-mated females of *F. sanguinea* collected from polygynous pure and dulotic colonies. In particular, the following modes of colony foundation were studied: *i*) independent (one or more homocolonial females together); *ii*) in alliance with a female of host species; *iii*) for usurpation in an incipient or a mature host colony; *iv*) for pillage of host pupae; *v*) for adoption into an incipient or a mature queenright host colony; *vi*) for adoption into a incipient or a mature orphaned host colony.

Independent foundation was possible only when several females were kept together. Alliances followed by egg-depositions were obtained with females of two *Serviformica* species (*F. cunicularia*, *F. rufibarbis*). Usurpations and adoptions were more frequent in the incipient than in the mature host colonies. Mixed colonies were always obtained after the sack of the host pupae.

It seems likely that, besides homospecific adoption of queens followed by budding, *F. sanguinea* relies on temporary parasitism to start new colonies.

INVESTIGATION OF HONEYBEE BODY TEMPERATURE IN A WINTER CLUSTER BY INFRARED THERMOGRAPHY

H. Pressl, A. Stabentheiner, N. Hrasnigg, K. Crailsheim

Institut für Zoologie, Universität Graz, Universitätsplatz 2, A-8010 Graz, Austria

In temperate and cold climates overwintering honeybees regulate the core temperature of winter clusters in the range of 12-33.5°C (Fahrenheit et al. 1989, J Comp Physiol B 159: 551-560). In the present study we measured the *body* surface temperatures of bees (*Apis mellifera carnica*) at the periphery and along a cross-section through the cluster with minimum disturbance by means of thermography (Stabentheiner & Schmaranzer 1987, Thermology 2, 563-572). The colony was placed on 4 combs in a plexi glass hive which could be opened at the periphery and in the middle.

At ambient temperatures of 1-5.5°C, nearly all bees on the periphery (with only one exception) had thoracic temperatures (T_{th}) higher than 9°C: 9.5-12.5°C at the top, 10.5-19°C at the center and 8-15°C at the low end of the clusters. Head (T_{ca}) and abdominal (T_{ab}) temperatures ranged from 10-18°C and 6.5-15°C, respectively.

Along a vertical cross-section through a winter cluster with brood cells T_{th} ranged from 17-19°C at the top to 33-38°C at the core and 18-22°C at the low end. T_{ca} ranged from 18-19.5°C at the top to 31-36°C at the core and 15.5-20°C at the low end, and T_{ab} was 13-18°C at the top, 28-30.5°C at the core and 12-16.5°C at the low end.

Since in most individuals of the cluster surface the temperature of different body parts followed the rule $T_{ca} \geq T_{th} > T_{ab}$, these bees seem primarily to be heated passively by heat from the cluster's interior. Only in a few of the surface bees slight active heat production was indicated ($T_{ca} < T_{th} > T_{ab}$). By way of contrast, active heat production was clearly more frequent in bees inside the cluster, maximum heat production occurring in the center and lower half of the cluster.

Supported by the Austrian Fonds zur Förderung der Wissenschaftlichen Forschung (FWF) and the Austrian BM für Umwelt, Jugend und Familie.

FEEDING FREQUENCY IN BUMBLE BEE LARVAE

M. F. Ribeiro

Department of Comparative Physiology, Ethology and Socio-Ecology Group, University of Utrecht, Utrecht
The Netherlands

Caste in bumble bees may be, among others factors, influenced by food. Therefore, the feeding frequency of *Bombus terrestris* larvae (workers, males and queens) was studied by using video-recordings (4 hours a day), during the entire larval development.

The analysis of the tapes showed that in the beginning all larvae receive food at a very low frequency (less than 1 feeding in 4h). In the following days the frequency increases, reaching a peak one or 2 days before the end of the development (in average, 9 times for workers, 11 to males and 15 times to queens, approximately). Finally, all groups of larvae are fed less often just before pupation.

Worker larvae of the first brood have lower feeding frequency than the ones from the second and third broods. Male larvae receive food more often than workers, mainly in the last phase of their development. And queens have a much higher feeding frequency than workers and males, but only after the 10 th day of development.

Feedings do not occur regularly, i.e., the interval between two feedings may vary from a few seconds up to 3 hours or more. Obviously, the maximum intervals become smaller with the approximation of the peak of feedings.

Moreover, there is a large variation in the number of times different larvae of the same egg cell receive food, suggesting there are individual differences among the larvae and/or the feeders.

THE NASONOV PHEROMONE OF THE JAPANESE HONEYBEE, *Apis cerana japonica* Rad.

S. Matsuyama, T. Suzuki, M. Sasaki¹, Hiromi Sasagawa²
Institute of Applied Biochemistry, University of Tsukuba,
Tsukuba, Ibaraki, Japan -1 Faculty of agriculture, Tamagawa
University, Machida, Tokyo, Japan -2 Department of Physiology
and Behavior, National Institute of Sericultural and Entomological
Science, Tsukuba, Ibaraki, Japan.

Much of the knowledge on honeybee pheromones has been obtained from the European honeybee, *Apis mellifera* L. (Am). In this presentation, we demonstrate that the Japanese honeybee, *Apis cerana japonica* Rad. (Acj) utilizes different components of the Nasonov pheromone from those of Am.

GC and GC/MS analyses of the Nasonov gland extracts, and of the airborne volatiles of workers corroborated the occurrence of previously identified components in Am samples, but none of these compounds were found in Acj. By contrast, linalool and four types of linalool oxide (*cis* and *trans* of both furanoid and pyranoid) were identified in the Acj extracts. Chiral GC analysis revealed that the natural linalool oxide were identical to those prepared from (S)-(+)-linalool. In a laboratory bioassay, Acj workers placed in polyethylene bags were attracted (52-94%) to authentic linalool oxide (5-500ng, furanoid, racemate, 1:1 mixture of *cis* and *trans*). Neither Acj extract nor linalool oxide was attractive to Am workers. These results suggest that linalool oxide comprises the Nasonov pheromone of Acj.

Field bioassay using linalool and linalool oxide with natural absolute configurations and biological activities of other compounds in the extract will be discussed.

A PRELIMINARY WORK ON THE PUTATIVE GROUP SPECIFIC PHEROMONES IN ANTS

Y. Çamlitepe
Trakya Univ. Fen-Ed.Fak. Biyoloji Bölümü 22030, Edirne, Turkey

Horstmann (1976) showed that red wood ant (*Formica polyctena*) foragers lay scent trails emanating from the rectal glands and that in protein or sugar-starved laboratory colonies, these scent trails caused directional recruitment to a protein or sugar source (Horstmann et al., 1982; Rosengren and Fortelius, 1987). Chemical constituents of these trail pheromones have not been identified yet but there is the possibility that they may also be specific for groups of foragers in the same colony, serving as directional cues for route fidelity.

To test the use of group specific pheromones in the red wood ant *Formica rufa*, worker responses to artificial trails prepared from gaster extracts of foragers taken from two branches of a field route were examined in the laboratory. The ability of foragers collected from one branch route to distinguish between scent trails to achieve route fidelity in darkness was tested.

The results showed that the distribution of these foragers between two artificial trails was random and provided no evidence for such group-specific pheromones.

REPRODUCTIVE CONFLICTS IN COOPERATIVE ASSOCIATIONS OF FIRE ANT QUEENS (*SOLENOPSIS INVICTA*)

G. Bernasconi¹, L. Keller^{1,2}

¹ Ethologische Station, Zoologisches Institut, Universität Bern, Hinterkappelen, Switzerland - ² Université de Lausanne, Institut de Zoologie et d'Ecologie Animale, Lausanne, Switzerland

In ants unrelated queens frequently associate to initiate a colony cooperatively. The joint reproductive effort of the cofoundresses increases growth and survival of the incipient colony. Yet, such associations are unstable. Soon after emergence of the first workers, queen-queen and queen-worker fights lead to the death or expulsion of all but one cofoundress. Because no sexual offspring are produced in incipient colonies the surviving queen monopolizes the entire future reproductive success of the colony. Two factors, the queens' relative fighting ability and their relative contribution to worker production (assuming that workers can recognize and selectively favour their mother) have been proposed to influence the survival prospects of individual queens within associations. The effect of these two factors were tested in the fire ant *Solenopsis invicta*. Initial size differences, a potential measure of the queens' fighting ability, affected the outcome of the conflicts, so that the initially heavier queen was more likely to survive. Differential weight loss by initially equal nestmates was also related to survival, with the queen losing more weight being more likely to die. The manipulation of the queens' relative contribution to the worker brood had no significant effect on the queens' survival probability, suggesting that workers are unable to favour their mother.

QUEEN-WORKER CONFLICTS AND SEX RATIO BIAS IN THE ANT *PHEIDOLE PALLIDULA*S. Aron¹, L. Keller², L. Passera¹, E. Campan¹¹Laboratoire d'Ethologie et Psychologie Animale, Université Paul-Sabatier, Toulouse, France - ²Institut de Zoologie et d'Ecologie Animale, University of Lausanne, Switzerland

Queen-worker conflict over the sex ratio of reproductive offspring in eusocial Hymenoptera provides a good model for testing the predictions of inclusive fitness theory and sex-ratio theory. To determine the extent to which workers and queens respectively control sex ratio in the ant *Pheidole pallidula*, we compared the primary sex ratio (at the egg stage) and the secondary sex ratio (reproductive pupae and adults) of colonies. There was a strong bimodal distribution of secondary sex ratios, with half of the colonies producing mostly females and other half mainly males. By contrast, there was no evidence of a bimodal distribution of primary sex ratios; all queens laid a same proportion of males eggs, decreasing from 0.40 in early spring to about 0.1 in summer. Moreover, the population sex-ratio investment was female-biased. These data are consistent with workers controlling the secondary sex ratio by selectively eliminating male brood in about half the colonies. We are currently testing whether the selective elimination of males is influenced by food availability and/or inter-colony variation in relatedness asymmetry, two factors that have been proposed to account for sex specialisation in social Hymenoptera.

13-062

PLASTICITY OF REPRODUCTIVE STRATEGIES OF THE FACULTATIVELY POLYGYNOUS ANT, *MYRMICA SULCINODIS*

J.S. Pedersen, J.J. Boomsma

Department of Ecology and Genetics, University of Aarhus, Aarhus, Denmark

In polygynous social insects more than one queen is reproducing in a colony. This leads to a decrease in relatedness of workers to the sexual brood they are rearing, so that other cost benefit trade-offs than relatedness need to be considered to explain the evolution and stability of these eusocial systems. Environmental factors affecting survival and reproduction of queens are likely to play a role and if so, social and reproductive behaviour is expected to be plastic and to respond adaptively to changing environmental conditions.

Like the majority of its congeners, *Myrmica sulcinodis* NYL. has extensive variation in queen number, both between colonies within populations, and between populations. In this study we have examined the social and genetic structure of colonies from different habitats of the same population, using genetic information at nine polymorphic allozyme loci.

The study population inhabits two adjacent different habitat types. The main habitat is densely covered with heather. Here, *M. sulcinodis* occupies almost all suitable nest sites, which are rare patches of bare ground scattered across the heathland. The other marginal habitat is sparsely vegetated throughout, due to a recent fire. Here, most sites are unoccupied by ants. The genetic relatedness among nestmate workers, among worker brood, between workers and brood, between queens and workers, and between queens and brood was considerably higher for colonies in the marginal habitat than in the main habitat. However, the mean number of queens present in the nests did not differ between these habitat types.

From these observations it can be hypothesised that *M. sulcinodis* pursues two different reproductive strategies within the same breeding population. If free nest-sites exist, one or a few queens can establish new colonies on their own and reside as egg-layers for several seasons. Alternatively, if all nest-sites are already occupied, queens are adopted back into highly polygynous and polydomous (multi-nest) colonies that reproduce through budding. In these colonies queen turnover is fast and occurs even within the same season of egg-laying. Males are probably produced by workers whereas queens serve as the source of replacement queens and workers. The differences in social structure suggest that both queen and worker reproductive behaviour of *M. sulcinodis* are plastic and respond to the environmental constraints of changing population densities.

13-061

IS KIN CONFLICT EXPRESSED IN THE COLONY CYCLE OF THE BUMBLE BEE *BOMBUS TERRESTRIS*?

M.J. Duchateau

Dept. of Comparative Physiology, Ethology and Socio-ecology Group, Utrecht University, Utrecht, The Netherlands.

The kin selection theory predicts that in the social Hymenoptera a conflict will arise between parent and offspring concerning the production of males. This study focuses on the production of males and the effects on the colony and discusses male parentage.

In *B. terrestris* the queen mates only once. After hibernation the solitary queen lays diploid eggs which produce the workers of the first and second brood. At some point in the third brood phase the queen switches to laying haploid eggs, from which males develop. These are nourished by the workers. The workers were expected to respond to the appearance of males by laying eggs themselves because they are related with the males of the queen for 0.25 only, but this does not occur. Worker behaviour does not change in response to male production by the queen either.

The workers start laying eggs after a eusocial phase of about a month. This transition is called the competition point. It is highly correlated with the moment at which queens, instead of workers, reared from diploid eggs. After the competition point only a few of the eggs, laid by workers and queen develop into adults. Most of the eggs are eaten. The queen plays an important role in the egg eating. The colony disintegrates and workers desert the colony.

By crossing two morphologically different sub-species of *B. terrestris* and taking measures to maintain brood rearing conditions after the competition point, it was possible to determine the share of the workers and the queen in male parentage after the competition point. It could be shown that, even after the competition point, the queen remains reproductively dominant. Matricide, a possible way in which workers can increase their fitness, occurred infrequently, and was not correlated with the competition point. The inclusive fitness of the workers is low not only because of a low direct fitness, most of the sexuals being derived from queen-laid eggs, but also because of the male-biased average sex ratio in the colonies, males being 4 times more frequent than queens.

13-063

SEX ALLOCATION OF *MYRMICA RUGINODIS* DEPENDS ON RELATEDNESS ASYMMETRY AND LOCAL RESOURCE COMPETITIONLaura Walin¹ & Perttu Seppä²¹Department of Ecology and Systematics & ²Department of Biosciences, University of Helsinki, FINLAND

The sex allocation of individual ant colonies may depend on the worker/queen ratio, different dispersal ability of the sexes or on the relative relatedness asymmetry of the colony. According to the inclusive fitness theory it is expected that the workers control the sex allocation of their colonies using these parameters when deciding on the optimal sex ratio. We studied the sex allocation of the red ant *Myrmica ruginodis*, which is known to have two morphologically and behaviourally distinct forms. Microgyna form is known to have more queens and nest formation often takes place by a simple budding of old colonies, whereas macrogyna colonies are usually monogynous and individual queens usually act as independent nest-founders.

A total of 35 whole colonies from a single population were excavated and sociogenetic organization and brood production were studied. Our results indicate that at the population level the sex allocation pattern is mostly affected by local resource competition due to poor dispersal of microgyna females. No indication of worker male production was found. When colonies were divided into two classes, mothered either by one queen or many queens, we could show that in the former class a significantly more female-biased sex ratio (as investment) was produced. Furthermore, the relatedness of nestmate workers was significantly higher in monogynous colonies.

13-064

PATTERNS OF REPRODUCTION IN SLAVE-MAKING ANTS

J. Herbers and R.J. Stuart²

Department of Biology, Colorado State University, Fort Collins CO USA - 2 Department of Entomology, Rutgers University, New Brunswick NJ USA

We examined reproductive allocation in three slavemaking leptothoracine ants (*Leptothorax duloticus*, *Harpagoxenus canadensis*, and *Protomognathus americanus*). Because sex ratios in slavemaking ants have been proposed as a critical test case for the hypothesis that eusociality evolved via kin selection, we wished to test the hypothesis that slavemaker sex ratios reflect the queen's interests. We found little evidence to support the hypothesis, but instead our data showed evidence of conflict between the slavemaker queen and her workers. Furthermore, explicit comparisons of slavemaker sex ratios with their conspecific hosts showed that the slaves themselves may exert strong influences over sex allocation decisions in their parasites.

13-066

INSEMINATION REGULATES REPRODUCTION IN QUEENLESS COLONIES OF THE PONERINE ANT *GNAMPTOGENYS* SP. (PONERINAE: FORMICIDAE)

B. Gobin¹, C. Peeters² and J. Billen¹

¹K.U.Leuven, Laboratory of Entomology, Leuven, Belgium

²Université Paris Nord, Laboratoire d'Ethologie Expérimentale et comparée, Villetaneuse, France.

14 queenless colonies of an arboreal *Gnamptogenys* sp. were completely collected and workers individually marked for observation. In these 1 to 14 inseminated reproductive workers (gamergates) were present, while most of the virgin workers laid trophic eggs of variable shape. We observed frequent reciprocal antennal boxing among the gamergates, but these or other aggressive interactions were rare among virgin workers and from gamergates to virgin workers. When virgin worker groups were created, this resulted in strong aggression among most individuals. This aggression led to a non-linear hierarchy with an alfa-worker at the top, but none of the workers ever started laying reproductive eggs. Dissections of workers of unmanipulated colonies as well as virgin worker groups confirmed that none of the virgin workers produced reproductive oocytes. Gamergate ovarian development was higher and only in these were yellow bodies found, thus indicating that insemination controls the type of eggs produced (trophic or reproductive). In 3 of the virgin worker groups that were observed for several weeks, dominant workers would eventually go out of the nest to perform sexual calling behaviour. When a single male was left in the arena of one such group, the alfa-worker got mated. This result suggests that dominance interactions regulate insemination. During the observations it became clear that virgin workers could recognize the gamergate from a short distance. However when two additional virgin worker groups were created by splitting one colony with a single mesh and the other with a double mesh, in both cases strong aggression followed. These results suggest that only in absence of physical contact aggression starts.

13-065

QUEEN DIMORPHISM IN THE NEOTROPICAL PONERINE ANT *ECTATOMMA RUIDUM* ROGER (HYMENOPTERA, FORMICIDAE)

B. Schatz^{1,2}, J.-P. Lachaud^{1,2}, C. Peeters³, G. Pérez-Lachaud², G. Beugnon¹

¹ LEPA, URA-CNRS 1837, Université Paul-Sabatier, 31062 Toulouse cedex (France) - ² ECOSUR, Apdo Postal 36, 30700 Tapachula, Chiapas (Mexico) - ³ LEEC, URA-CNRS 667, Université Paris-Nord, 93430 Villetaneuse (France)

Known till now principally in Myrmicinae but also in Pseudomyrmecinae and Formicinae, this is the first report of the coexistence of two forms of reproductive females (microgynes and macrogynes) in a ponerine ant: *Ectatomma ruidum* Roger. The morphological study indicates the absence of intermediates between both forms. While similar in size and weight to the workers, the microgynes present a wider and longer thorax with functional wings and a wider head with three ocelli. In natural conditions as in laboratory, both forms are able to initiate a new colony using the semi-claustral mode of colony foundation typical for ponerine ant species. The relation "wing surface / body weight" is in favor of the microgynes suggesting a better dispersal capacity compared to the macrogynes. Nevertheless, with a number of ovarioles varying from 2 to 4 (median 3) vs. 3 to 12 (median 6), the fecundity of microgynes is less than macrogynes and the success rate of the colony foundation by microgynes is more limited as proved by the study of the colonies development from foundresses of both forms. The presence of microgynes seems to be associated with a reduced size of the colony, but there is not any evidence of a direct relationship with a variation of the population density or with the availability of food sources. Present in about 20% of the nests of *E. ruidum* collected in Mexico in the Rosario Izapa zone (Chiapas), the hypothetical biological function (i.e. an adapted strategy of reproduction) of the microgynes is discussed under a phylogenetic viewpoint in reference with what is known in myrmicines.

13-067

SOCIAL FACTORS AFFECTING ENDOCRINE MEDIATED REPRODUCTIVE DEVELOPMENT IN WORKERS OF *BOMBUS TERRESTRIS*.

Guy Bloch and Abraham Hefetz

G.S.Wise faculty of life sciences, Department of Zoology, Tel Aviv University, 69978 Tel Aviv.

Colonies of *B.terrestris* are characterized by two major social phases. The eusocial phase in which the queen is the only reproductive female and a competition phase in which at least some of the workers reproduce, contributing to the male offspring's of the colony. A decrease in queen inhibition ability was proposed as an explanation for the onset of worker reproduction. In this study we compared the effect of queens from various social environments on worker reproduction and aggressive behavior.

Using a radio chemical assay (RCA) for JH biosynthesis by corpora allata (CA) *in vitro* that was optimized for *B. terrestris* we demonstrated that ovarian development are positively correlated with elevated JH biosynthesis. Young workers in queenright colonies had low JH biosynthesis rates, and their ovaries developed slowly. In contrast, some of the workers of the same age that were kept as small queenless groups had high JH biosynthesis, their ovaries developed fast and they were aggressive toward nestmates. These workers generally oviposited as early as six days old.

To verify whether queen inhibition declined with time we constructed groups that included callow workers with either virgin queens or queens of colonies before or during the competition phase. Queenless groups served as control in these experiments. There were no differences in the rates of JH biosynthesis by CA of young workers confined with mated queens from colonies before or after the onset of worker reproduction. Furthermore, threatening behaviors and overt aggression were similar and low in these groups. In contrast, some of the workers confined with virgin queens or in queenless groups demonstrated a significantly higher rate of JH biosynthesis threatening behaviors and overt aggression. When callow workers were introduced into intact colonies before or during the competition phase or into mature queenless colonies, they all demonstrated low rates of JH biosynthesis.

These results do not support the hypothesis that a decline in queens inhibition capacity leads to the competition phase.

13-068

THE ROLE OF INDIVIDUAL AND SOCIAL EXPERIENCE
IN EARLY DEVELOPMENT OF ANT BEHAVIOUR

Zh. Reznikova

Inst. of Animal Ecology, Frunze, 11, Novosibirsk, 630091, Russia

A great deal of the flexibility observed in the behaviour of individual ants can be attributed to learning and this raises the question as to how development of their behaviour is affected by early experience.

Species with different foraging systems were compared: *Formica polyctena* Foerst. and *F. sanguinea* Latr., with collective organization of foraging, and singly foraging *F. cunicularia glauca* Ruzs. The latter two species are said to be the pair of slave-makers and slaves.

Experiments in which the individual and the social experience of naive lab reared ants were manipulated, indicated that: 1. many of such activities as terrestrial locomotions, simple patterns of area-related search behaviour and of brood care behaviour as well as simple recruitment activity seem to be innate to ants; 2. when compare equally aged workers during the first hours and days of their lives, *cunicularia* individuals appear to be able to active operations much earlier than the other two species; 3. the main factor promoting changes of the ant behaviour is poor / rich environmental rearing conditions; 4. cross-social rearing conditions (young workers of *F. cunicularia* with older workers of *F. sanguinea* and vice versa) do not influence the behavioural parameters in slave-makers (*F. sanguinea*), but only in slaves, by modifying their shape according to slave-makers. 5. preliminary results show that a "peck order" system is innate to ants, while delicate social relations and the very complex forms of communications such as distant homing, seem to be determined mainly by learning processes.

13-069

DIVISION OF LABOR BETWEEN FORAGING
CASTES OF THE BLACK MARCHING TERMITE
HOSPITALITERMES MEDIOFLAVUS (ISOPTERA:
TERMITIDAE)

T. Miura, T. Matsumoto

Department of Biology, University of Tokyo

3-8-1 Komaba, Meguro-ku, Tokyo 153, Japan

Castes and division of labor in the black marching termite *Hospitalitermes* were examined in this study.

Instar-related polyethism between workers was discovered in *Hospitalitermes medioflavus*. The genus distributed over tropical rain forests in Southeast Asia is one of the open-air foraging termites. It makes long journey with continuous column to the foraging sites. There, workers make food balls cooperatively. Task allocation between workers is seen at the foraging sites; workers gnawing food materials and workers carrying food balls to the nest. In foraging workers, there were three peaks of size; major, medium and minor. Gnawers were composed of medium and minor workers, while carriers were of major and medium workers. And it became clear that the trimorphism was related to post-embryonic development, because there were no white larval instars corresponding to medium and major workers, and because molting workers were also found in the nest.

The temporal dynamics in foraging activities of the open-air foraging termite *H. medioflavus* was also investigated. Especially we focused on the dynamics of caste ratio during the activity. From the results differences of behavior between soldiers, major, medium and minor workers were identified. It is considered that soldiers play the roles of scout, defender and messenger and workers divide tasks to collect foods and carry them to the nest.

COLONY SOCIAL ORGANISATION, FORAGING COSTS AND
PONERINE ANT FORAGING STRATEGY.

F.D. Duncan and R.M. Crewe

Department of Zoology, University of the
Witwatersrand, Johannesburg, South Africa.

Two closely related ponerine ant species, *Ophthalmopone berthoudi* and *Megaponera foetens*, are both obligatory termite hunters, and overlap in their distribution, but use different foraging strategies; solitary hunting and group raiding respectively. This study investigated the constraints on these two foraging strategies by looking at the foraging costs of each strategy in relation to attributes of the ants' life histories.

The energy cost of an individual *O. berthoudi* forager was approximately 0.3% of the average foraging reward. In *M. foetens* the cost of a raiding party was approximately 30% of the foraging reward. Yet, *M. foetens* has raiding parties of approximately 300 workers while *O. berthoudi* has an average of 38 workers foraging during peak activity.

To evaluate an ant foraging strategy fully, the cost of producing sexuals has to be considered. *Ophthalmopone berthoudi* do not possess a queen but have laying workers (gamergates), only males need to be produced for the colony to reproduce by fission. However, in *M. foetens* both ergatoid queens and males are required for colony reproduction by fission. Thus the need for a greater net energy gain for production of sexuals may have contributed to the development of a more complex and efficient foraging strategy with a larger number of workers foraging.

EFFECT OF PERORALLY GIVEN BIOLOGICALLY ACTIVE SUBSTANCE OF ANIMAL ORIGIN ON MICROSPORIDIOSIS INFECTED HONEY BEES (*APIS MELLIFERA*)

Tatiana M. Yefimenko

Petro Prokopovitch Apiculture Research Institute, Kyiv, 252627, Ukraine

Biologically active substances (BASs) isolated from different animal systems and organs possess stimulative effect permitting to use them in medicine and veterinary. In this report we present some data concerning a BAS preparation, RBS, isolated from cattle embryo tissues and its effect on healthy and Microsporidia-infected (MI) honey bees (HB), both insects infected in laboratory and naturally infected having been used. In our laboratory experiments HBs were twice fed with 0,1 % RBS containing 50 % sucrose syrup (immediately after infection and 10 days post MI); in field experiments HBs were fed with RBS three times with 14 days intervals. In laboratory tests insects of the same age were infected in July-August (10,000 spores/HB); our field experiments were made with HB families with natural infection occurred in May-June. We found that RBS had no therapeutic effect in laboratory experiments. Furthermore, some MI stimulation took place accompanied by higher mortality of RBS-treated infected HBs comparing to untreated infected ones, the latter having smaller spores according to morphometric data. These facts are well correlated with a conception of obligatory parasitism postulating that factors favourable for a host organism are also favourable for its parasites, the disbalance developed in host-parasite system killing one of this system members.

The use of RBS in natural HB families with low MI frequency stimulated rather host than parasite organism, the treated families became stronger comparing to control ones. So it is necessary to be careful when treating parasites-carrying insects with BASs. Such preparations are to be used in apiculture only for HBs slightly infected or treated previously with antinosemic drugs.

13-073

AN ETHOLOGICAL CONTRIBUTION TOWARDS THE PHYLOGENETIC RELATIONSHIPS IN THE *Trigana* - *Tetragana* COMPLEX (APIDAE, MELIPONINAE).

E.V. Silva-Matos¹, R. Zucchi

Departamento de Biologia, Faculdade de Filosofia, Ciências e Letras de Ribeirão Preto, Universidade de São Paulo (USP), Brasil. 1 - Bolsista Recém-Doutor - CNPq.

The cell provisioning and oviposition process (POP) of the stingless bees proceeds along a behavioral syndrome ruled by highly group-specific queen-workers interactions. The POP and related aspects involve 42 ethological characteristics of which 16 were used aiming a analysing the ethological phylogenetic relationships among representatives of the *Trigana* - *Tetragana* complex, namely the genera *Oxytrigana*, *Tetragana*, *Trigana* and *Cephalotrigana* of which only representative species was analysed. Such results (consistency index 0,88) may contribute to solve the polytomous approach used by Michener (1990) because they separate *Trigana*, *Tetragana* and *Cephalotrigana* (05 synapomorphies involved) and suggest *Oxytrigana* as the sister-group of the involved monophyletic clade. A comparison between such results and the positions held by Michener (1990) and Camargo & Pedro (1992 a,b) are provided.

VALIDATION OF THE DOUBLY LABELLED WATER TECHNIQUE FOR BUMBLEBEES *BOMBUS TERRESTRIS* (L.)

Thomas J. Wolf
Department of Zoology, University of Cambridge, U.K.

In the doubly labelled water DLW technique, hydrogen and oxygen isotopes (deuterium or tritium and ¹⁸O, respectively) are added to an animal's body water. Isotope concentrations decrease exponentially with time through the natural 'washout' of CO₂ and water. The hydrogen isotope is lost as water only, and the oxygen isotope as both water and CO₂. Therefore, the apparent turnover rate of ¹⁸O is higher than that of deuterium (or tritium) and the difference between the two apparent turnover rates reflects the CO₂ production rate. The most outstanding feature of the DLW method is the ability to estimate the rates of body water turnover and the energy expenditure of free-living animals with minimal interference with their natural behaviour. This technique has liberated the study of vertebrate energetics from the artificial environment of the laboratory but has not yet been successfully validated for insects.

Here, I report its validation for the bumblebee *Bombus terrestris* (L.), using respirometry (RESP) from tethered roundabout flights. We injected small volumes (1 µl) of a mixture containing low concentrations of deuterium and ¹⁸O isotopes and withdrew 1-2 µl of haemolymph to determine initial ¹⁸O concentration. The injected isotopes were equilibrated with the body water pool after 10 min, and high material turnover allowed the analysis of final blood isotope concentrations after 5-7 h. On average (n=16), values measured using the DLW technique exceeded values using RESP by 3.1±9.9%, a difference which was statistically not significant at the 99% confidence level. The absolute error was 7.4±7.1% (mean ± S.D.). Isotope dilution spaces of both deuterium and ¹⁸O were almost identical with the body water pool.

The accuracy of DLW measurements allows its further use in field experiments. This could help to liberate the study of insect flight energetics from the restricting and unnatural environment of the laboratory. Energetic assumptions underlying many ideas in insect ecology could be tested directly. The small quantities of isotopes needed will help to restrict the costs of such studies, simultaneously allowing larger sample sizes.

13-074

LYSOZYME - AN IMMUNE FACTOR IN SECRETION OF SALIVARY GLANDS OF *APIS MELLIFERA* L

I.M.Nagornaya, I.A. Levchenko

Institute of beekeeping P.I. Prokopovich, Kiev, Ukraine

We have found that apart from the previously known enzymes and pheromones each of three pairs of salivary glands of worker honeybees produces lysozyme (EC 3.2.1.17). This protein is able to lyse cell walls of bacteria. When entering the digestive tract of a bee, lysozyme imparts antibacterial properties to it, thus normalizing the microflora. Bees supply larval food, nectar, pollen, wax and propolis with lysozyme. It has been established that a high level of lysozyme secretion falls on the period of optimal functional activity of glands. Hypopharyngeal and mandibular glands produce the greatest quantity of lysozyme. The maximal activity of lysozyme in hypopharyngeal glands is revealed in nurse-bees on the 9th day of their life and also in field bees.

Since lysozyme is a factor of humoral immunity of insects, it is possible to conclude about the existence of a singular mechanism of the resistance formation in a honeybee colony.

The basic role in the production of lysozyme and saturation by this protein both of larval food and of food which is stored for wintering bees belongs to workers of summer generation.

USE OF STRIDULATION IN FORAGING LEAF-CUTTING ANTS: MECHANICAL SUPPORT DURING CUTTING OR SHORT-RANGE RECRUITMENT SIGNAL?

F. Roces, B. Hölldobler

Theodor-Boveri-Institut, Lehrstuhl für Verhaltensphysiologie und Soziobiologie der Universität, Würzburg, Germany

Foraging leaf-cutting ant workers stridulate while cutting a leaf fragment. Two effects of stridulation have recently been identified: i) attraction of nestmates to the cutting site, employing substrate-borne stridulatory vibrations as short-range recruitment signals, and ii) mechanical facilitation of the cut, because the vibrating mandibles of a stridulating forager stiffen the tender leaf tissue like a vibrating knife. We asked whether foragers actually stridulate to support their cutting behavior, or whether the mechanical facilitation represents an epiphenomenon correlated with the use of stridulation as a short-range recruitment signal. To differentiate between both alternatives, workers of *Atta cephalotes* were presented with tender leaves of invariant physical traits, and their motivation to initiate recruitment was manipulated by varying the palatability of the leaves and the starvation of the colony. The lower the palatability of the harvested leaves, the lower the percentage of workers that stridulated while cutting, irrespective of the leaf's physical features. After intense feeding, no workers were observed to stridulate while cutting tender leaves, and the percentage of stridulating workers increased with deprivation-time. When confronted with familiar and unfamiliar leaves after intense feeding, while only 5 % of workers stridulated while cutting familiar leaves, as expected due to satiation effects, 60% of them stridulated while cutting unfamiliar leaves of similar physical traits. Results support the hypothesis that leaf-cutting ants workers stridulate while cutting leaves in order to recruit nestmates, and that the observed mechanical facilitation of stridulation during cutting represents a by-product of recruitment communication.

13-076

ENERGY EXPENDITURE DURING CUTTING AND LOAD-SIZE DETERMINATION IN LEAF-CUTTING ANTS

F. Roces

Theodor-Boveri-Institut, Lehrstuhl für Verhaltensphysiologie und Soziobiologie der Universität, Würzburg, Germany

Leaf-cutting ants cut vegetation into small fragments that they transport to the nest, where the material is processed by the ant colony's resident fungal garden. Here I report measurements on the energetic costs of leaf-cutting, and their relationship with the worker's decision about the size of the leaf fragment to be cut. Using open-flow respirometry, leaf-cutting energetics was measured in individual workers of *Atta sexdens*. The leaf-cutting metabolic rate (MR) was stable and dramatically above the post-cutting locomotion metabolic rate. Both leaf-cutting MR and post-cutting MR were strong functions of body mass. The aerobic scope (MR/StandardMR) of post-cutting locomotion was 7, and that of leaf-cutting was far larger, at 31. By comparison, the maximum sustainable metabolic rate in non-flying animals ranges from 8-12 times resting or standard metabolic rate, which increases to 20 - 100 for flying animals. Based on the observation that foragers cut smaller fragments, the harder the leaf tissue, similar measurements were performed by presenting ants with leaves of different toughness. Measurements of cutting speed, load-size selection and metabolic rate in individual foraging workers revealed that the total energy expenditure per fragment increased with increasing leaf toughness, and reached a maximum for a given leaf toughness which depended on ant body size. When workers harvested even harder leaves, they selected smaller leaf fragments, in such a way that the total energy expenditure per fragment remained similar for leaves of different toughness.

13-077

TEMPORAL POLYETHISM IN THE TERMITE *RETICULITERMES FUKIENENSIS* (ISOPTERA, RHINOTERMITIDAE)

M.W.J. Crosland, C.M. Lok, M. Shakarad, J.H. Zhang, T.C. Wong, J.F.A. Traniello

Biology Dept., Chinese University of Hong Kong, Shatin, N.T., Hong Kong. - 1 Biology Dept., Boston University, 2 Cummington Street, Boston, MA 02215, U.S.A.

Measurements of head widths of workers and larvae from two colonies of *Reticulitermes fukienensis* revealed 5 size categories that could be readily distinguished. We termed the size categories WL1 to WL5. Larger individuals are on average older than smaller ones, since they have gone through more moults. WL1 and WL2 were typical larval morphology, with very white soft bodies, virtually unsclerotized mandibles, and clear gut contents. WL4 and WL5 were "worker" morphology with sclerotized mandibles (especially in WL5) and dark gut contents. WL3 was intermediate. Most behaviours monitored to date were carried out at highest frequency by WL5, the oldest individuals. Examples are given below:

- Scouting. When equal numbers of WL4 and WL5 individuals were placed under dark paper in a corner of the Petri dish, over 90% of the time WL5 ventured from under cover before WL4.
 - Tunneling. Tunnels made by isolated groups of WL5 individuals were over 10 times the length of those made by WL4.
 - Alarm behaviour. This behaviour was nearly 10 times more frequent in WL5 than in WL3 (WL4 was intermediate).
 - Burying corpses. Worker corpses were buried by WL5 individuals in 8 of the 10 replicates of WL5 but none of the ten replicates containing either WL3 or WL4.
- Current experiments are concentrating on larval rearing behaviours to determine whether younger individuals (e.g. WL3 and WL4) are involved more in these tasks or whether virtually all tasks are carried out mainly by older individuals.

13-078

DIVISION OF LABOUR WITHIN HONEYDEW COLLECTORS IN ANT SPECIES WITH DIFFERENT COLONY DESIGN

Zh. Reznikova, T. Novgorodova

Inst. of Animal Ecology, Frunze, 11, Novosibirsk, 630091, Russia

Field observations and laboratory experiments have shown that adjustment of foraging efforts and task switching within a specialized category in an ant colony is connected with a level of social organization.

In the high social species *Formica polyctena* Foerst. each of an aphid colony is tended by a constant team including different groups. "Aphid ants" collect honeydew droplets and each member attend to about 3 individual aphids. "Watch ants" scare predators and alien ants away and they also protect aphids from drops in the rain. "Transporting ants" carry honeydew to the nest. "Discovering ants" search for new aphid colonies and sometimes they may take the place of other members.

In *Camponotus saxatilis* Ruzs. with more simple territorial structure, a lower level of individual specialization is revealed. One individual play a role of a "host" at the aphid colony and it combines the tasks of the "aphid ant" and the "watch ant" attending to about 15 individual aphids. There are also 2 - 3 "transporting ants". *Saxatilis* do not protect aphids from unfavourable influences.

Singly foraging *F. cunicularia glauca* Ruzs. may share aphid colonies with other species and each worker acts independently.

Preliminary results enable us to hypothesize that, at least in some ant species communities, when attending the same species of homopterans, ants species with more simple colony design may "steal" the honeydew from the homopterans without rendering any service in return and thus use "efforts" of high social species.

13-079

MORPHOLOGICAL CASTE DIFFERENCES IN *CHARTERGELLUS COMMUNIS* (HYMENOPTERA, VESPIDAE, EPIPONINI)**S. Mateus, F.B. Noll and R. Zucchi** (Financial support by Fapesp and CNPq)

Universidade de São Paulo, Faculdade de Filosofia, Ciências e Letras de Ribeirão Preto, Ribeirão Preto - SP, 14049-901, Brazil

Neotropical swarm-founding polistine, in which polygyny is a rule, have remained less explored, mainly due to the difficulty for studying them continuously under both experimental and natural conditions. On the other hand, some sociological and other biological information on these wasps can be obtained, though partially, by analyzing a sample of wasps taken from a particular nest. This is especially true for the caste differentiation an related phenomena.

Caste differentiation analysis on *Chartergellus communis* evidenced a non-clear dimorphism among queens (inseminated egg-layers), workers (uninseminated with no ovary development) and intermediates (uninseminated with any ovary development). The measurements of 8 body parts and counts of hamulus number in a sample of 100 wasps showed that all characters of queens (n=19) were not significant larger than those of workers (n=54). Intermediates were significantly larger than workers in 6 caracteres and larger than queens in 7 caracteres (Kruskal-Wallis One Way Analysis of Variance on Ranks, $p < 0.05$). Canonical discriminant analysis showed intermediates with higher values in the first canonical variable (CAN_1) (-1.0 to 2.3) than workers (-2.7 to 1.8) and queens (-3.2 to 1.0). The most discriminant character was the basal width of the tergite II. The Mahalanobis's distances were 1.80 between queens and workers, 2.33 between queens and intermediates and 1.38 between workers and intermediates. These results evidence that caste differentiation in *C. communis* is not pronounced but intermediates are preferentially larger then the other kind of females. A closer analyses in the color patterns of frons, clypeus, mandibles and other related morphological body parts did not evidence inter caste differences.

13-081

SEXUAL INVESTMENT AND POLYANDRY IN THE LEAF-CUTTING ANT *ACROMYRMEX HEYERI* FOREL (HYMENOPTERA: FORMICIDAE)**E. Diehl-Fleig**

Laboratório de Genética, Universidade do Vale do Rio dos Sinos, São Leopoldo, RS, Brasil

Some of the most interesting problems in the evolutionary biology of formicids are related to the investment of colony resources in the reproductive brood, sexual rates of the colonies and populations, as well the colony social organisation. We aimed to analyse these questions in the leaf-cutting ant *Acromyrmex heyeri*. The males and gynes of three colonies at Torres (29°20'S; 49°43'W) and of three others at São Leopoldo (29°45'S; 51°08'W) were all numerically quantified. The energetic cost to produce each sex was estimated by the dry weight. As complementary data in other 22 colonies the sexual rate was qualitatively evaluated. The social organisation of each colony was obtained by means of five isoenzymic systems (MDH, α -GPDH, AMY-1, AMY-2 and AMY-4) analysed by horizontal electrophoresis.

Considering the number of adults of each sex, 67% of the colonies have a male bias production. However as the males' weight is lower than the females', only 33% of the colonies invested more resources in the male production. The low weight of the males can be reflecting not their small size only, but also a reduced quantity of sperm, that would be insufficient for the spermateca capacity. The isoenzymic analysis showed that 67% of the colonies are monogynous or polygynous, with the female mating with multiple males. The male bias production by the colonies reduces the energetic cost of the sexual production and can favour polyandry. The polyandry augments the genetic variability and as consequence favours a bigger adaptive plasticity. We did not find differences between the two sampled populations related to the sexual investment and social organisation of the colonies.

13-080

CASTE DIFFERENTIATION AND ITS RELATION TO THE COLONY CYCLE IN *POLYBIA (MYRAPETRA) PAULISTA* (HYMENOPTERA, VESPIDAE, EPIPONINI).**F. B. Noll and R. Zucchi** (Financial support by Fapesp and CNPq)

Departamento de Biologia, Faculdade de Filosofia Ciências e Letras de Ribeirão Preto, Universidade de São Paulo, Ribeirão Preto 14040-901 SP, Brazil

Among the social insects, Epiponini tribe has challenged the students of behavioral social evolution because they generally present incipient caste differentiation and polygyny. These characteristics are sometimes interpreted as a complication to the evolution of social behavior via kin-selection theory (Hamilton 1964 a,b). However, recent studies (West-Eberhard, 1978) demonstrated that polygynous wasps colonies have their queen number diminished according to the cycle progression. Such facts seem to be related to population viscosity raising (Queller et al., 1990; Hughes et al., 1993).

Individuals from three colonies of *Polybia (Myrapetra) paulista* were morphometrically analysed in different phases of the colony cycle (foundation, worker production and sexuals production). Principal component analyses (PCA) indicated that larger queens are preferentially selected, what provokes caste differentiation increase according to colony age. In contrast, significant variation in worker morphology was not detected. In addition, generalized Mahalanobis distances (D^2) for each colony revealed the same trend in queen/worker differentiation previously observed (2.50 for foundation, 6.68 for worker production and 21.60 for sexuals production phases). Other fact is related to the appearing of intermediates (Richards and Richards, 1951) that were restricted only in the sexual production phase suggesting queen control decrease. These data imply that the colony cycle of epiponine reflects Polistinae phylogeny: Queens' morphology is initially undistinct from workers becoming statistically different later on. Such process recapitulates the evolutionary steps found in other related taxa.

13-082

MULTIVARIATE ANALYSIS APPLIED TO CASTE DIFFERENCES IN *SCHWARZIANA QUADRIPUNCTATA* (HYMENOPTERA, APIDAE, MELIPONINAE)**E. H. Nogueira-Ferreira, R. Zucchi & V. L. Imperatriz-Fonseca**

Depto de Biologia, Faculdade de Filosofia Ciências e Letras de Ribeirão Preto - USP, Av. Bandeirantes, 3900, 14040-900, Ribeirão Preto, SP, Brasil. (Financial support by FAPESP).

Among the caste determination systems in stingless bees, namely interaction of genes and environment (Meliponini), and purely nutritional (Trigonini), the position of *Schwarziana* is outstanding because their gynes range from large (normal potential queens) until very small (miniature queens, same sized as true workers) (Imperatriz-Fonseca & Zucchi, 1995 and ref. therein). From 3 *Schwarziana* colonies, 42 queens (38 virgins, 3 physogastrics, one pupa from royal cell) and 39 workers were collected and measured from 11 morphological characteristics. Data were PCA (principal component analysis) treated using Systat programs, version 6.0. From the queens' sample 3 principal components were extracted which encompassed 79.6% of variance found. Graphically three distinct groups emerged, that are: 36 virgin gynes, 2 virgin gynes and 3 physogastric queens plus the analysed pupa. Among the analysed morphological characters, head width and maximum interorbital distance were the most discriminant ones. By including workers sample in the analysis, the 3 extracted components composed 76.6% of the variance found, and this time hind tibia length and malar area length are the characters that better express inter-caste separation. The analysis suggest: a- larger gynes have better chances of reaching the queen status and b- morphologically, such prospective queens are intermediate between workers and other kinds of gynes. Actually, it seems that caste determination in *Schwarziana* lies just in the border-land between the Meliponini system (abundant small gynes) and the Trigonini system (few, but larger gynes), irrespectively of the opinion held by Campos & Costa (1989).

13-083

ASPECTS OF SOCIAL BIOLOGY OF *EUGLOSSA TOWNSENDI* (HYMENOPTERA, APIDAE, EUGLOSSINI).

S.C. AUGUSTO, C.A GARÓFALO

Departamento de Biologia - Faculdade de Filosofia, Ciências e Letras de Ribeirão Preto - USP, Ribeirão Preto, SP, Brasil.

Nests of *Euglossa townsendi* are founded by a single female that lays 4-13 eggs. After the last oviposition the foundress stays in the nest. When female daughters emerge, some leave the nest while others stay together with the mother in the natal nest and begin to reactivate it. The daughters (=foraging females) build, provision and oviposit their own cells. The foundress oviposits in cells provisioned and laid by foraging females and she dies before the second reactivation is started. The oviposition by the foundress is always preceded by oofagy. In five reactivation processes observed the number of foraging females varied from 1 to 4 and the number of cells oviposited by them from 3 to 10. After these females stop their ovipositions they may stay in the nest until the next reactivation. During the new reactivation processes those females perform oofagy and oviposition in cells laid by new foraging females. According to the number of those females, oviposition in a single cell occurs several times; the ovipositions are preceded by oofagy. Some new females may stay in the nest and perform only oofagy and ovipositions in cells laid by foraging females. The results obtained up to now suggest that unlike *E. cordata*, in *E. townsendi*, neither the presence of a single dominant female nor the aggressive interactions among the females in the nest occur.

13-085

TAXONOMY OF JAPANESE *RETICULITERMES* (ISOPTERA: RHINOTERMITIDAE) - MORPHOLOGICAL AND CHEMICAL APPROACH

Yoko Takematsu

Entomological Laboratory, Faculty of Agriculture, Kyushu University, Fukuoka, Japan

The genus *Reticulitermes* (Holmgren) is widely distributed in the northern temperate zone, and it occurs from Hokkaido to the Ryukyus in Japan.

In Japan, 3 species of *Reticulitermes* were recorded; *R. speratus* (Kolbe), *R. flaviceps amamianus* Morimoto and *R. miyatakei* Morimoto, and there is an undescribed species which is distributed around Yamaguchi area. *R. speratus* was subdivided into 5 subspecies based on the characters of soldiers and alates. Although, the morphological characters which were used to distinguish these species are continuous and Japanese *Reticulitermes* cannot be divided distinctly by these characters.

Recent studies on the cuticular hydrocarbons have suggested that components of them would be a variable taxonomic characters.

In this study, I identify the cuticular hydrocarbons of Japanese *Reticulitermes* and make comparison of these components, and re-evaluate the morphological characters. From this results, I suggest that there are 6 species of *Reticulitermes* in Japan. In addition, I discuss about these speciation.

13-084

FORAGING ACTIVITY OF THE LEAF-CUTTING ANT *Atta sexdens rubropilosa* Forel (FORMICIDAE: ATTINI) TO TEMPERATURE, HUMIDITY, AND ILLUMINATION

M.A.L. Bragança, A. Tonhasca Jr.

Laboratório de Proteção de Plantas - CCTA, Universidade Estadual do Norte Fluminense, Campos dos Goytacazes, RJ, Brazil

This study describes the diurnal and nocturnal foraging patterns of the leaf-cutting ant *Atta sexdens rubropilosa* Forel in response to temperature, humidity, and illumination in a forest of eucalyptus (*Eucalyptus* spp.) located in Rio de Janeiro State, Brazil. There was no difference in average mass between diurnal and nocturnal foragers. However, nighttime foragers carried significantly lighter burdens than daytime foragers. It is suggested that daytime foragers carry heavier plant fragments to compensate for their low density on foraging trails when compared to nighttime foragers. Load, defined as (ant mass + fragment mass)/ant mass and fragment mass were significantly and negatively correlated with ant mass, although r^2 -values were low. The roles of temperature, humidity, and illumination on foraging activity of *Atta sexdens rubropilosa* are discussed.

13-086

TERMITES BIODIVERSITY ON DATE PALMS IN KHUZESTAN, IRAN AND PRELIMINARY STUDIES ON COLONY FOUNDATION IN ANACANTHOTERMES VAGANS (H.) IN LABORATORY CONDITIONS (ISOPTERA: HODOTERMITIDAE)

K. Kamali, B. Habibpour

Department of Entomology, College of Agriculture, Shahid-Chamran University Ahwaz, Iran. During 1992-1994 a faunistic investigation was carried out on termites (Isoptera) infesting date palms in Khuzestan (southwestern province of Iran). In this study a total of 5 species from 2 families were collected and identified in the province. Three species namely *Microcerotermes diversus* (S.), *M. buettikeri* (Ch.&B.) and *Amitermes vilis* (H.) were mostly collected and associated with date palm trees in the area. Whereas two other species namely *M. gabrielis* (W.) and *Anacanthotermes vagans* (H.) were generally found in the soil and in pasture lands respectively. They were not directly associated with date palm trees. Observations on colony foundation in *A. vagans* (H.) in lab. conditions revealed that the queen was able to lay first series of eggs about 7 days after colony foundation. Mean number of eggs which were laid during 9 and 28 days were 24 and 32 respectively. The time required for eclosion of the eggs and appearance of the larvae was observed to be 35 days. After 7 weeks from oviposition, the first workers of *A. vagans* (H.) were appeared in the colony. The rate of egg laying was declined and a second phase of oviposition was then initiated about 15 to 20 days after last eggs were hatched.

13-087

POPULATION DYNAMICS AND NUTRITIONAL BEHAVIOUR OF *MICROCEROTERMES DIVERSUS* (S.) IN AHWAZ, IRAN (ISOPTERA: TERMITIDAE)

B. Habibpour, K. Kamali

Department of Entomology, College of Agriculture, Shahid-Chamran University, Ahwaz, Iran

Some aspects of biology of *M. diversus* (S.) including relationship of foraging activity to seasonal cycle of nymph production, their development into alates, density of larval stages and temperature were studied.

An experiment was carried out in a piece of termite infested land burying paper rolls as source of food. Weekly collections were made of workers and nymphal instars 3-5 from buried paper rolls.

Also 10 more colonies were chosen in different localities in Ahwaz. They were inspected at 10 days intervals for a complete year, and all of the termites including larval stages, unpigmented workers and nymphal instars 3-5 were counted. Preliminary studies were also made on colony foundation in *M. diversus* (S.) in lab. conditions to help understand some aspects of nutritional behaviour of the species in the field.

It was observed that the first eggs were laid in breeding containers 8 to 9 days after colony foundation.

The times required for eclosion of eggs and appearance of workers were between 18 to 26 and 36 to 37 days respectively.

The result of investigation revealed that high activity of colony for production of alates and workers (presence of nymphs and larvae in large numbers in samples) from April through mid-November (indicating population increase in colony) correlated positively with foraging activity of the termite.

13-089

THE DRUMMING BEHAVIOUR OF THE CARPENTER ANT *CAMPONOTUS LIGNIPERDA* - INDIVIDUAL REACTIVITY AND GROUP BEHAVIOUR

U. Raub, J. Tautz

Theodor-Boveri-Institut, Lehrstuhl für Verhaltensphysiologie und Soziobiologie, Universität Würzburg, 97074 Würzburg

Old colonies of the carpenter ant *Camponotus ligniperda* usually live in nests inside of pinetrees build by gnawing out the soft wood of the annual rings and constructing thin concentric cylinders of wooden plates. When receiving any disturbing stimuli (CO_2 -Puff, ground vibration) they display a typical behavior (running in circles, mandibel gapping, biting attacks) and produce vibrational signals by alternately drumming with mandibel and gaster on the ground. This signal is perceived by nestmates up to a distance of 15cm and is discussed as a part of a "modulatory communication system" (Fuchs 1976).

We examined the meaning of individual behavioural variability for the performance of group-demands in an experimental setup simulating natural conditions. In individual and group-tests slowly walking workers receiving a simulated drumming signal show a startling response (standing still with stretched antenna) lasting several seconds. There is evidence that

1. the individual quality and duration of the startling response is a individual stable trait.
2. the response threshold for a second stimuli (different levels of CO_2) following the perception of the vibrational signal is modulated.
3. the perception of and the reaction to a drumming signal is influenced by species-specific chemical signals.

The drumming behaviour is discussed as a modulatory communication signal, fine tuned to physical features of a wooden nests and as a part of a elaborate multi-component alarming system.

Fuchs, S.: The Response to vibrations of the substrate and reactions to the specific drumming in colonies of Carpenter Ants (*Camponotus*, Formicidae, Hymenoptera). *Behav. Ecol. Sociobiol.* 1, 155-184 (1976)

The work is supported by SFB 251 of the Deutsche Forschungsgemeinschaft

SWARMING AND FORAGING ACTIVITY OF SUBTERRANEAN TERMITE, *PSAMOTERMES HYPOSTOMA*, DESNEUX (RHINOTERMITIDAE) IN THE NEW VALLEY, EGYPT

A.M. Ali, M.M. Rizk, A.K. El-Sayed, A.A.S. Ahmad

Department of Plant Protection, Faculty of Agriculture, University of Assiut, Egypt

Flight and surface activity of *Psamotermes hypostoma* Desn. was investigated in the New Valley, Egypt. This termite species has two main periods of swarming. The first period lasted from February to May and the other extended from August to November. No swarming was recorded during hot (temp. $> 35^\circ\text{C}$) or cold ($< 10^\circ\text{C}$) months. Temperature, relative humidity, wind speed and certain biological factors were found to be the most important factors affecting flight activity of *P. hypostoma*.

Concerning the surface activity of this species, two peaks of foraging have been recorded. One was observed during March-April and the other during July-August. The lowest foraging periods were recorded during December-January and May-June. Low temperature during winter months was the main factors of reducing the foraging activity, whereas high temperature and the swarming activity were the main factors of reducing foraging during summer months.

TERRITORY, FORAGING ECOLOGY, LIFE HISTORY, TRANSPORT SYSTEM AND LONG DISTANCE RECRUITMENT OF THE GIANT ANT *CAMPONOTUS GIGAS* IN THE RAINFOREST OF SABAH, BORNEO

Martin Pfeiffer & K.E. Linsenmair

Department for Tropical Zoology and Animal Ecology, Biozentrum, Julius-Maximilians-Universität Würzburg, Würzburg, Germany

The giant forest ant *Camponotus gigas* is one of the largest ant species in the world, with the spectacular major workers reaching occasionally 30 mm in length. This common inhabitant of the dipterocarp forest in Borneo, Sumatra and Peninsular Malaysia is mostly active by night, living in underground nests between the roots of overmature trees. At dusk hundreds of ants are climbing up the trunks, to forage in the forest canopy. In the 44 000 m^2 of our research plot, we observed 4 polydomous colonies of *C. gigas*. Each of the colonies had up to 14 nests, one of them covering a territory of 8000 m^2 . Not more than 8000 foragers were found in the colony. The foraging behavior of this ant species is highly organized. Specialized subcastes are working as hunters, transport workers or herdsmen. Its logistic functions according to the central-place foraging theory. 90% of its diet consists of honey dew from the homopteran *Bythopsyrna circulata* (Flatidae) and other trophobionts including true bugs (Coreidae) and Fulgoridae. As a source of nitrogen it uses dead arthropods and birds droppings. According to our observations at one colony, mating flight takes place only twice a year with intervals of approx. 188 days. We observed 4 flights comprising between 40 to 200 reproductives, mostly males. The territorial behavior of this ant is highly ritualized, with small groups of Majors (up to 5) involved in permanent fighting („boxing“). Interspecific borders to other *Camponotus* species are guarded by sentinels. To observe the cascade like long distance recruitment we constructed about 400 m artificial trail, mostly made of bamboo. To supervise this routes we used a data logger connected to light barriers.

13-091

EXPERIMENTAL REMOVAL OF MAIN PREY FORAGERS IN A PAPER WASP, *POLISTES JADWIGAE* (HYMENOPTERA: VESPIDAE)

S. Makino

Forest Entomology Laboratory, Kyushu Research Center, Forestry and Forest Products Research Institute, Kurokami 4-11-16, Kumamoto, 860 Japan

In post-emergence colonies of a paper wasp, *Polistes jadwigae*, main prey foragers were experimentally removed in order to learn how other wasps would respond to the reduction of prey brought into colonies, and to possible increase in larval hunger level resulting from it. The experiment was made with four colonies containing the queen and 8 to 12 workers, and 2 orphan colonies containing 11 or 12 workers. The colonies were each observed for 12 hours on three consecutive days: on the first and the third day, wasps were observed for behavior under undisturbed conditions; on the second day, 2 to 4 workers that most frequently came back to the nests with prey loads on the first day were removed early in the morning and behavior of other wasps was observed (the removed workers were released after the observation).

Removal of main foragers did not affect foraging activity of other wasps: number of prey loads brought into the nests by non-removed workers did not change between the first and the second day. Likewise, their activity level (proportion of time spent in acts other than grooming, fanning, and standing (=motionless)) or the number of their foraging trips did not change. In addition, in the 4 queenright colonies, queen activity level did not increase after the worker removal. These results contrast with those of Gamboa et al. (1990; *Ethology*, 85: 335-343), who suggest that queens are sensitive to brood needs, and that they behaviorally regulate worker foraging to match brood needs by increasing their level of activity in *Polistes fuscatus*. Regulation of worker foraging, if any, seems to be accomplished by agent(s) other than queen control in *Polistes jadwigae*.

13-093

STUDY ON AN AGGREGATED NEST OF THE BEE *ANDRENA AGILISSIMA* (HYMENOPTERA: ANDRENIDAE)

A. Martinoli, M. Giovanetti, S. Amonte, F. Rigato, F. Andrietti
Dipartimento di Biologia, Sezione di Zoologia e Citologia,
Università degli Studi di Milano, via Celoria, 26 Cap 20133,
Milano, Italy

A nest site of *Andrena agilissima* was studied at the beginning of May of the years 1993/95 at Isola d'Elba (Toscana). This species shows a strong trend towards nesting in aggregation, with a nest density of more than 100/m². During this research several hundred bees were marked. The observation of their behaviour gave the following results:

1. Foraging activity shows two peaks at mid morning and early afternoon, with a reduction of the foraging trips around noon;
2. Every nest is inhabited by several bees. Females move from one nest to another using underground tunnels;
3. Data about any level of sociality were not available. Yet threats or aggressions of any kind were not observed at all among interacting females, nor differences in the development of ovarians.
4. Parasitism by the bee fly *Bombylius fimbriatus* (Diptera, Bombyliidae) was detected.

13-092

DIFFERENTIATION OF THE STINGING MECHANISMS IN QUEEN AND WORKER HONEYBEES, *APIS MELLIFERA*: FUNCTIONAL AND STRUCTURAL ANALYSES

M. Sasaki, K. Suzuki, T. Sonezaki and M. Kato
Laboratory of Entomology, Faculty of Agriculture,
Tamagawa University, Machida, Tokyo, Japan

Female honeybee differentiates into worker or queen. Virgin queen stings her reproductive rivals (sister queens) and workers do intruding (non-nestmates) workers and animals which disturb their nest. We compared the caste-specific differences in the stinging mechanism and venom function.

1) Aged workers showed active stinging response to mechanical stimuli but young ones within 24 h after emergence showed no response. Queens responded weaker than aged workers. However, decapitated bees showed strong response even in day 0, revealing the implication of inhibition from head, probably by brain. The inhibition can be cancelled by JH treatment.

2) Rhythmic movements of muscular systems (M197, M198 and M199) of the sting apparatus were recorded with electromyography (EMG): While mechanical stimuli caused similar rhythmic movements in both castes, sensory inputs from proprioceptors distributing over sting surface and/or the nerve severance between 6th and terminal abdominal ganglion (simulating sting autotomy) caused the movements only in workers. Quick and repetitive injections of the limited amount of venom by queen sting seemed to be under central control.

3) Ether-washed queen or isolated queen abdomen was enough to release the stinging response of assaultive queens. Neither 9ODA nor 9HDA released the behavior. Instead, the cuticular surface structure was found to play critical role in the queen-queen recognition. The cuticular surface dimorphism was found in *A. cerana* and *A. florea* also.

4) In comparison to worker venom, queen venom was 3 times more in amount and 50% higher in LC₅₀ when injected to worker bees.

13-094

FUNGUS-GROWING TERMITE IN JAPAN

Kazuhiko Kinjo, Choyu Shinjyo and Shiryō Yaga (Department of Bioscience and Biotechnology, University of Ryukyus, Nishihara-cho Okinawa, Japan 903-01)

Seventeen species of termite were distributed in Japan. The fungus-growing termites belong to genera: *Hypoterme*s, *Macrotermes*, *Microtermes*, *Odontotermes*, *Canthotermes* and *Prototermes*. Only one species *Odontotermes formosanus* Shiraki was known in Japan. This termite makes fungus comb under ground. They inoculate mycelium to the nest. The mycelium spread in the nest and forms nodules. The mycelium and nodules were used as food for termite.

In rainy season (from the last seven days of May to July), the pseudorrhizae of the fungus developed on the comb. They break through the soil and forms carpophore on the ground. This mushroom was known *Termitomyces clypeatus* and *Termitomyces eurhizus*.

In order to cultivate this mushroom, the analysis of comb was done.

The combs were collected from Okinawa, Ishigaki and Iriomote island. The comb have the appearance of sponges, brains and corals. The comb floor is flat or little arched, the ceiling is domed. The diameter and weight of collected combs were about 25cm, 250g. The combs took out under ground was soft and brittle, but dried comb were very hard.

13-095

MORPHOLOGICAL DIFFERENCES AMONG FEMALES OF THE EUSOCIAL ALLODAPINE BEE, *EXONEURELLA TRIDENTATA* (HYMENOPTERA: APIDAE).

P. S. Hurst and M. P. Schwarz

School of Biological Sciences, The Flinders University of South Australia, Adelaide, Australia.

Exoneurella tridentata is the only allodapine bee in which females fall into one of two groups based on size and morphology. Female pupal weights are strongly bimodal with, on average, the larger females (majors) being twice the weight of the smaller females (minors). Also, majors have reduced scopae on the hind legs and enlarged metasomas. Brood are not raised in cells but in a communal undivided chamber, yet by the pupal stage females fall into two distinct weight groups. This suggests that there is a developmental switch from the minor morphology, which is typical of allodapines, to the unusual major morphology.

The majority of *E. tridentata* colonies are multifemale. Colony size ranges up to 37 females per nest, which for allodapines is very large. Minors are more numerous than majors but most nests contain at least one major. When nests are opened the first bee encountered is frequently a major. In other bees morphological differences are associated with foraging or egg laying, rather than with guarding.

E. tridentata does not excavate its own nest, unlike most other allodapine bees, but utilises the burrows created by beetle larvae in the dead wood of long lived semi-arid trees. Other invertebrates also use beetle burrows which suggests that burrows may be a limiting resource. In *E. tridentata* the major morph may have evolved as an adaptation to colony defence with reproductive division of labour evolving later and resulting in eusocial colonies.

13-097

CLIMATE-MEDIATED SOCIALITY IN ALLODAPINE BEES.

A.L. Cronin and M. Schwarz

School of Biological Sciences, Flinders University of South Australia, GPO Box 2100, Adelaide, S.A. 5000, Australia

Opportunities for sib-rearing and the exploitation of high levels of relatedness among haplodiploid sisters arise only if some brood reach imaginal stages when younger dependent brood are still in the nest. In most insects, this requires that adults are long lived (> one year) or that multiple broods are produced in a single year. Studies of Australian allodapine bees have provided some evidence of sib-rearing in warmer, northern habitats, but this appears to be precluded in cooler climates where development rates may be lower. This suggests climate may be an important constraint in the development of eusociality. The current study investigated life-cycles and social behaviour in a number of allodapine bees along the east coast of Australia, where habitats ranged from sub-tropical in the north to temperate in the south. Voltinism and opportunities for sib-rearing varied with latitude such that eusociality was common in northern habitats but not in cooler, southern regions. Similar variation has been observed for other bcc taxa in other continents and demonstrates the importance of large-scale physical factors on social behaviour, and raises considerations for their impact on the evolution of sociality.

13-096

THE ECOLOGY AND SOCIAL BEHAVIOR OF AN ARID-ZONE ALLODAPINE BEE, *EXONEURELLA EREMOPHILA* (HYMENOPTERA: APIDAE: ALLODAPINI)

N.L. Watiniasih, M.P. Schwarz, and S.G. Reyes

School of Biological Sciences, Flinders University of South Australia, GPO Box 2100, Adelaide, S.A., Australia

Social variation among allodapine bee species provide unrivalled material for comparative studies of social evolution. The endemic Australian genus *Exoneurella* comprises four species which range from highly eusocial to subsocial. *E. eremophila* is a distal species in the *Exoneurella* clade. It is unusual in that it lives in a strongly xeric environment and multifemale colonies are very rare during brood rearing periods. Both these traits appear to be derived; nearly all other Australian allodapines are predominantly social and have a southern temperate distribution, probably reflecting a Gondwanaland origin. *E. eremophila* nests in the dead stalks of several herbaceous plants and grasses; these substrates deteriorate rapidly, limiting the potential for multifemale colonies to develop via re-use of natal nests by subsequent generation. Multifemale colonies occur primarily as "pre-reproductive assemblages", although some multifemale colonies may develop in sturdy nesting substrates. *E. eremophila* provides an opportunity to study behavior in a species where solitary nesting is a derived trait and where sociality is largely precluded by physical constraints.

13-098

SOCIAL EVOLUTION IN THE ALLODAPINE BEE GENUS *EXONEURELLA* (HYMENOPTERA: APIDAE): INSIGHTS FROM PHYLOGENY.

M.P. Schwarz, S.G. Reyes, P.S. Hurst, T. Neville, Z. Steen, N. Watiniasih

School of Biological Sciences, Flinders University of South Australia, GPO Box 2100, Adelaide, S.A., Australia

Interspecific variation in sociality in allodapine bees provides an opportunity to study patterns and processes of social evolution. Of the four endemic Australian groups, *Inquilina* is socially parasitic, *Exoneura s.s.* and *Brevineura* display well-developed forms of social organization, and members of the group *Exoneurella* span the range from largely solitary to highly eusocial. *Exoneurella eremophila* and *E. setosa* are largely solitary, *E. lawsoni* is weakly social, and *E. tridentata* is highly eusocial with morphologically differentiated castes. Phylogenetic reconstruction indicates that *E. tridentata* is basal to this group and *E. eremophila* and *E. setosa* are distal. The characteristic of predominantly solitary nesting in the distal members of this group appears to represent a reversion from more social life-cycles, rather than being an ancestral trait. This reversion coincides with a radiation into xeric and saline environments where nesting substrates deteriorate rapidly, limiting colony growth over time. The potential for nesting substrates to limit expression of social behaviour has also been demonstrated for some species of *Exoneura s.s.*. It has previously been assumed that the range in sociality of Australian allodapines provides an opportunity to study early steps into sociality; our findings suggest that the opposite may be closer to the true situation.

13-099

SOCIAL AND SOLITARY BEHAVIOUR IN THE ALLODAPINE BEE *EXONEURELLA SETOSA*. (HYMENOPTERA: APIDAE)

T. Neville and M. Schwarz

School of Biological Sciences, Flinders University of South Australia, GPO Box 2100, Adelaide, S.A. 5000, Australia

The allodapine bee group *Exoneurella* provides unequalled opportunities for comparative approaches to social evolution. *Exoneurella setosa* is a phylogenetically distal member of this group and is largely solitary. Solitary nesting appears to be a derived rather than ancestral character. Solitary behaviour is linked to occupation of coastal saline environments where nesting substrates rarely persist long enough to permit colony growth over more than one generation. Other factors associated with solitary nesting include a high level of physical disturbance affecting nest sites and low levels of ant predation compared to social allodapine bee species. Evidence for relictual caste differentiation in the small percentage of multifemale colonies that occur is presented and discussed with respect to phylogeny. Despite the rarity of social colonies during brood rearing, pre-reproductive assemblages during winter are common and the selective pressures maintaining these are discussed with respect to sex allocation patterns and Local Fitness Enhancement.

13-100

INTRA-COLONY AGGRESSION AND HIGHLY EUSOCIAL BEHAVIOUR IN AN ALLODAPINE BEE, *EXONEURELLA TRIDENTATA*.

Z. Steen

School of Biological Sciences, Flinders University, GPO Box 2100, Adelaide, S.A. 5001, Australia.

Examination of a native Australian allodapine bee, *Exoneurella tridentata* provides an opportunity for understanding processes in the evolution of morphological castes in social insects. *Exoneurella tridentata* has the largest known colony sizes during brood rearing periods for any allodapine bee. The species is also unique in that it displays morphological caste differentiation which is more extreme than in other social bee species. A behavioural study of *E. tridentata* revealed that unlike other allodapines, a high level of aggressive interaction (in the form of biting) was displayed between individuals within a nest. Agonistic behaviours have not been recorded for any other *Exoneura* species, and only rarely in other allodapines. Surprisingly, analyses of behavioural repertoires did not show that morphological caste was clearly linked to any particular behaviour(s), and that within nests only weak behavioural specialization occurred. The behaviour of *E. tridentata* within nests is very different to that observed for other highly eusocial species; it appears that this species is facultatively highly eusocial. It is suggested that morphological differentiation in this species probably arose from selective factors associated with nest defence, and reproductive specialization arose in the majors as a secondary function for this morph. These morphological castes may be the evolutionary outcome of a dichotomy in selective pressures - selection for guarding ability, and selection for more general tasks such as foraging. Selection for a morph which is effective at guarding may have lead to a morph which is also able to exert reproductive dominance.

13-101

OPPORTUNITIES FOR DISPERSAL AND SOCIALITY IN THE ALLODAPINE BEE, *EXONEURA BICOLOR*: COOPERATIVE NESTING IS NOT MAKING THE BEST OF A BAD SITUATION.

N. Bull and M. Schwarz

School of Biological Sciences, Flinders University of South Australia, GPO Box 2100, Adelaide, S.A., Australia

Several factors thought to be important for the evolution of cooperative breeding in vertebrates have received little attention in facultatively social insects. One of these, Selander's (1964) 'habitat saturation hypothesis', predicts that colony sizes will be greater in breeding units where dispersal opportunities are limited, suggesting that group living is a secondary option to independent reproduction. The Australian allodapine bee *Exoneura bicolor* exhibits a number of traits that occur in cooperatively breeding bird species, including long life-span, repeated opportunities for reproduction, and vulnerability to brood predation and parasitism. The effect of a potentially limiting environmental factor, nesting substrate availability, was experimentally examined as an agent influencing the sociality of *Exoneura bicolor*. We manipulated nesting substrate availability in two separate locations during a time when foundress dispersal is common. No significant difference was found between colony sizes in cases where dispersal options were abundant and cases where dispersal options were limited. We found that provision of abundant opportunities for dispersal did not lead to higher rates of independent nesting, suggesting that cooperative nesting is a preferred strategy regardless of costs of dispersal. Reproductivity per female and brood survival were examined as factors selecting for group living. Low survival of brood in single-female nests has the potential to select for cooperative nesting in this bee.

13-102

THE ROLE OF TERMITE (ISOPTERA) DIVERSITY IN ECOSYSTEM PROCESSES

Paul Eggleton, Richard Davies, Luc Dibog, David T. Jones

Termite Research Group, Biodiversity Division, Entomology Department, The Natural History Museum, London, UK

Termites are increasingly being recognised as the dominant decomposer insects in tropical ecosystems. However, there are still relatively few studies that explore the complex ecological roles of termites in such systems. For example, we have little idea of the effect and influence of termite diversity on large scale ecosystem processes. In this talk I will outline studies being undertaken as a part of the work of the Natural History Museum's Termite Research Group that attempt to make the role of termite diversity in such processes clearer. I will describe work underway in Cameroon, Congo, Thailand and Malaysia, involving experimental and semi-experimental manipulation of termite assemblages in tropical forests. Special emphasis will be placed on the role of termites in carbon fluxes and decomposition, and how this may be affected by long term historical and short term ecological factors.

13-103

TERMITE SPECIES RICHNESS AND FUNCTIONAL DIVERSITY IN SOUTHEAST ASIAN FORESTS

D.T. Jones & R.G. Davies
Department of Entomology
The Natural History Museum
London, United Kingdom

Termites are the dominant detritivorous arthropod group in tropical forests, and play a central role as mediators of nutrient and carbon fluxes. However, due to their diverse feeding habits the precise extent of their influence over decomposition processes depends on the functional composition of the local assemblage. A standardized sampling protocol was used to measure termite species richness in primary lowland dipterocarp forests in Thailand, Peninsular Malaysia and Borneo. Differences in species richness between sites is related to latitude while shifts in the dominance of taxonomic and functional groups are discussed in relation to biotic and environmental factors. Changes in the frequency of occurrence of the fungus-growing termites (Macrotermitinae) appears to be influenced by rainfall and moisture levels.

13-105

ANTIBACTERIAL ACTIVITY OF SOME EXUDATES OF ANA-CANTHOTERMES AHNGERIANUS JACOBSON (ISOPTERA: HODOTERMITIDAE)

L.I.Ljutikova, T.G.Judina
Biological Faculty, M.V. Lomonosov Moscow State University, 119899, Russia

The inside of galleries and living chambers of termite nest have special coating consisting of liquid and water-free feces of termites. It seems, the secret of salivary, sternal and other glands may be included in composition of this coating. We reported before, that the chamber coating from natural nest and its analog from artificial nest show the fungistatic activity. The tests were carried out to determine the antibacterial activity of chamber coating analog (the filter paper impregnated with exudates, which are released and accumulated during maintenance of colony in laboratory). The sterile water extracts from termite-treated paper were prepared and sensitivity of the 28 bacterium species to them was tested by agar diffusion method. On the whole the test extracts showed bactericidal effect on the 14 bacterium species including 5 subspecies of entomogenous bacterium *Bacillus thuringiensis* and also bacteriostatic effect on the 2 species. We suppose, that termites *A. ahngerianus* support "sterile" conditions within the nest by own metabolites inclusion in its structure.

13-104

STUDY ON A BIONOMICS OF ASIAN MITE(*TROPILAEELAPS CLAREAE* DELFINADO AND BAKER), MAJOR PARASITE OF HONEYBEES(*APIS MELLIFERA* L. AND *APIS CERANA* FABRICIUS) IN KOREA

K.-S. WOO, J.-H. LEE

Department of Agricultural Biology, College of Agriculture and Life Sciences, Seoul National University, Suwon, South Korea.

Since the asian mite(*Tropilaelaps clareae* Delfinado and Baker) was introduced from China in 1992, it has caused great damages to Korean beekeeping industry and expanded its distribution. Even worse, it was reported recently that *T. clareae* could overwinter at greenhouse or southern parts of Korea. To set the effective control scheme, a life history of *T. clareae* was examined. After capping of brood cells, eggs were first found in 48-51 hours. The protonymph and the deutonymph were first detected after 66-69 hours and 120-123 hours, respectively. Also, limit of overwintering temperature was studied. According to a survey, *T. clareae* could overwinter above 2°C in Korea.

13-106

MATING SYSTEM IN TWO ANT SPECIES OF THE EUROPEAN SUBGENUS COPTOFORMICA

SCHNEIDER MARC-ANDRE & DANIEL CHERIX
Museum of Zoology, Lausanne, Switzerland

Dispersal strategies in ants has been the subject of many studies this last ten years. In the european subgenus *Coptoformica*, male sexuals of at least three species (*F. exsecta*, *F. bruni* and *F. pressilabris*) are characterized by a bimodal distribution of their size (micraners and macraners). In *F. pressilabris*, both morphs, micraners (small males) and macraners (big males), exhibit different behaviours during nuptial flight. Micraners have a significantly higher relative wing surface and relative glycogen content than macraners and may represent the dispersing form. Mating behaviour experiments, including small and big males, show non significant differences in the number of mating attempts when separated. But micraners seem to be more successful in matings than macraners when in competition. Detailed results about mating system of the following two species, *F. pressilabris* and *F. exsecta*, will be presented, including sperm counts of micraners and macraners, sperm transfer in single, double and treble mated females, and the frequency of insemination by both morphs.

13-107

HYDROCARBON PATTERN VARIATIONS IN THE PAPER OF *POLISTES BIGLUMIS BIMACULATUS* NESTS USURPED OR NOT BY THE SOCIAL PARASITE *POLISTES ATRIMANDIBULARIS* (HYMENOPTERA: VESPIDAE)

M. C. Lorenzi and A. G. Bagnères¹

Dipartimento di Morfofisiologia Veterinaria, Università di Torino, Torino, Italy - 1 Laboratoire de Neurobiologie, CNRS, Communication Chimique, Marseille cedex 9, France

In social wasps of the genus *Polistes* nest paper odour is thought to be important for the process of nest and nestmate recognition (Gamboia, 1996).

Comparing the odour of parasitized and non-parasitized colonies, Lorenzi et al. (1996) showed that by the end of colony cycle the hydrocarbon pattern of the two kinds of nest differed: nest paper was covered by alkanes in non-parasitized colonies while it contained both alkanes and alkenes in parasitized colonies.

Fragments of the paper of field colonies of the social wasp *Polistes biglumis bimaculatus* were collected at different moment during colony cycle from both "normal" colonies controlled by the original queen and colonies usurped by the social parasite *Polistes atrimandibularis*. Aim of the present research was to identify the moment in the colony cycle when nest odour begins to vary in colonies usurped by the social parasite. Nest paper fragments were extracted with organic solvent and extracts analysed by GC and GC/MS. Multivariate statistical analyses (PCA and cluster analysis) of the results of the chemical analyses showed that nest odour varies continuously during colony cycle both in parasitized and in non-parasitized colonies. Parasitized colonies do differ from normal colonies regarding nest paper hydrocarbon pattern but parasite-specific compounds (alkenes) appear late in the colony cycle, more than one month after host nest invasion by the parasite queen. The moment when nest paper hydrocarbon pattern of parasitized colonies begins to differ from that of normal colonies correspond to the moment when the parasite brood are at the stage of pupae while host workers are going to emerge.

13-108

Symbiotic Relationship and Genetic Analysis between Ants and Two Epiphytic Myrmecophytes *Hydnophytum moseleyanum* and *Anthorrhiza caerulea* (Rubiaceae: Rubiales) in Papua New Guinea

T. Maeyama, T. Matsumoto

Department Biology, the College of Arts & Sciences, the University of Tokyo, 3-8-1, Komaba, Meguro, Tokyo, 153, Japan

The Rubiacerous epiphytic ant-plants which are distributed in/around New Guinea Island belong to Hydnophytinae including five genera. They have the swollen tuber with the complicated cavities. Some arboreal ant species are known to colonize in the cavities. The interaction between ants and the plants is considered as the mutualism because the plants can absorb the nutrients from the debris stored by ants on the cavities through the surface of specialized cavities. However, the ecological interaction of their symbiotic relationship is still unclear. Also, the genetic interaction between ant colonies and the population of these ant-plants are not studied at all.

We investigated the species compositions of ants living in *Hydnophytum moseleyanum* and their territory. The dominant ant was *Philidris* sp. and their colony occupied many ant-plants on plural (mostly two or three) trees. We compared total leaf area of the plants, the number of flowers, of fruits, of seeds, the weight of seeds and the rate of seed germination between the plants occupied and unoccupied by *Philidris* sp. In result, the occupied plants produced bigger seeds significantly and their seeds showed higher germination rate. The ant occupation will be beneficial for their host plants.

The other rubiacerous ant-plant *Anthorrhiza caerulea* was always occupied by the ants of *Dolichoderus* sp. We investigated the genetic interaction of the population of both ants and plants. The result suggested their close relationship.

13-109

THE ROLE OF 9-ODA [(E)-9-KETODEC-2-ENOIC ACID] FOR WORKER DOMINANCE HIERARCHIES IN *APIS MELLIFERA CAPENSIS*

U. Bögemann¹, R.F.A. Moritz¹, R. Crewe², M. Allsopp³

1 Institut für Biologie und Ökologie, TU Berlin Germany; 2 Department of Zoology, University of the Witwatersrand RSA; 3 Plant Protection Research Institute, Stellenbosch RSA

The presence of the queen in a honeybee colony is perceived by the workers through a blend of fatty acids secreted by the queens mandibular glands. Its major compound (9-ODA) has been shown to inhibit the development of worker ovaries. In queenless colonies this signal is absent, the depression ceases and some workers initiate ovary development. In *Apis mellifera capensis* this process is very swift and as soon as two days after queen loss eggs can be found. Furthermore these workers produce a queenlike pheromone with high 9-ODA levels. We here report on preliminary data of the role of 9-ODA in worker-worker interaction in small experimental groups.

13-110

PHYLOGENY OF THE SWEAT BEE TRIBE AUGOCHLORINI (HYMENOPTERA: HALICTIDAE), WITH IMPLICATIONS FOR SOCIAL EVOLUTION

M.S. Engel

Department of Entomology, Comstock Hall, Cornell University, Ithaca, NY USA

Phylogenetic relationships of the genera and subgenera of the New World sweat bee tribe Augochlorini are explored. Eighty characters of adult external morphology are used in cladistic analysis of the thirty-nine recognized genera and subgenera of the tribe (seven of which are new). An attempt is made to include the fossil augochlorine genus, *Oligochlora*, however placement of this taxon is problematic due to the dearth of codable characters.

This phylogeny has implications for the evolution of behavior within this tribe of bees. Both nocturnal foraging and cleptoparasitism have each apparently evolved more than once in the augochlorines. Particularly noteworthy for sociobiology, the primitively eusocial genera - *Augochlora* (*Oxytroglossella*), *Augochlorella*, and *Pereirapis* - form a monophyletic group. Eusociality apparently evolved once in the common ancestor of this complex, with a reversal back to solitary living in *Augochlora* (*Augochlora*).

13-111

NEW DATA ON LARVAL KIN RECOGNITION BY *Apis mellifera* L.WORKERS

A. Mohammedi¹, Y. Le Conte¹, A. G. Bagnières², A. Paris¹ and D. Crauser¹.

¹ Station de Recherches de Zoologie et d'Apidologie, INRA, Site Agroparc, Domaine St Paul, F-84914 Avignon Cedex 9.

² Laboratoire de Neurobiologie- Communication Chimique. CNRS-LN-8., 31, Chemin J. Aiguier, F-13402 Marseille Cedex 09.

In social insects, kin recognition has been studied most intensively in honeybees and has been treated with different approaches. The common context is the queen rearing because it is one of the few times that workers have an opportunity to control the genotype of future reproductive (Breed et al.1984).This authors found that when worker honeybees were given a choice of rearing queens from related rather than unrelated larvae, the worker didn't prefer to rear sister larvae over unrelated larvae whereas Visscher (1986) obtained positive results with similar techniques.

In our studies, we performed 3 different experiments to test the hypothesis that honeybees can favor closely related individuals when rearing queens. We used colonies of *Apis mellifera mellifera* (dark colored) and *Apis mellifera ligustica* (yellow colored) with queens that were open mated. In a first experiment, worker bees were given the opportunity to choose between one sibling and one unrelated larva grafted in the same cup. We recorded the results by using the color phenotypes of queens after emergence. In a second experiment queenless bees were given the choice of rearing related or unrelated old larvae (4 days after hatching). In a third experiment, we tested the hypothesis that workers selectively feed related larvae by providing them more and/or best quality of royal jelly.

In the two first experiments, workers were unable to make a choice between related and unrelated larvae but in the third experiment one colony of *mellifera* has a tendency to feed favorably the sibling larvae. We are also testing the effect of external resources on the worker's ability to rear selectively larvae.

QUEEN-WORKER CONFLICT OVER REPRODUCTIVE SEX RATIO AND BROOD MALE RECOGNITION IN THE ARGENTINE ANT

L. Passera, S. Aron

Laboratoire d'Ethologie et Psychologie Animale, Université Paul-Sabatier,Toulouse, France

Inclusive fitness theory predicts that workers enhance their inclusive fitness by biasing reproductive sex ratio towards females. This can be reached by eliminating queen's male offspring. That workers recognise juvenile forms of males is a prerequisite for this assumption. This study tests this possibility. Using queenright societies which elicit elimination of male brood, we regularly took away batches of larvae sorted according to their size. We reared these larvae in queenless societies and we checked sex and number of the resulting pupae in order to determine the ratio of male larvae still alive when the rearing colony status was changed. The results indicate for the first time sex larval recognition followed by male brood elimination. Half of the latter was cannibalised after hatching and the remaining when the male phenotype becomes recognisable. The results are discussed with regards to conflicts concerning sex investment ratio and sexual deception theory

CHEMICAL AND VISUAL CUES USED BY DEFENDING HONEY BEES TO RECOGNIZE MAMMALIAN PREDATORS

J.O. Schmidt

Carl Hayden Bee Research Center, ARS-USDA, Tucson, AZ USA

I collected data from a mass attack of honey bees on a dog and tested the following hypotheses: 1) attacking honey bees target the victim's eyes and oral-nasal area; 2) breath directionally orients the attack; 3) dark colors elicit attack; 4) furriness enhances attack vigor. The highest density of stings on the dog's body were in the anterior muzzle and the eyelids (see Table), a density several times higher than in neighboring areas. Dark areas of the dog's body received over twice as many stings as light areas. Indirect evidence supports the correlation of attack vigor with furriness. The overwhelming role of breath in directing the attack is obvious when 7.8 stings/cm² in the muzzle are compared to 0.02 stings/in² for the feet/lower legs. These

Table — Sting pattern data for dog killed in bee attack

Stings	# Received	Stings/cm ²
Total	3305	
Head	2460	
Face (ears & anterior)	2227	1.8
Anterior muzzle	565	7.8
Eyelid area	79	6.1
Inside mouth	233	
Body (excluding head)	845	0.080
Feet/lower legs	7	0.022
Body stings by fur color		
Black & dark grey	506	0.13
Yellow & yellow-grey	339	0.053

data demonstrate that bees target mammalian breath and eyes, with dark areas and furry textures being auxiliary attracting factors.

INTRASPECIFIC CLEPTOBIOSIS: AN OPTIMAL FORAGING STRATEGY IN THE NEOTROPICAL PONERINE ANT *ECTATOMMA RUIDUM* ROGER

J.-P. Lachaud^{1,2}, P. De Carli^{1,2}, B. Schatz^{1,2}, J.A. Lopez Méndez², G. Beugnon¹, M.A. Moreno Prospero², J.A. Garcia Ballinas².

1 LÉPA, URA-CNRS 1837, Université Paul-Sabatier, 31062 Toulouse cedex (France) - 2 ECOSUR, Apdo Postal 36, 30700 Tapachula, Chiapas (Mexique)

Due to their extremely high nest density per hectare (up to 11300), the hunting areas of neighboring colonies of the ponerine ant *Ectatomma ruidum* partly overlap and some workers can enter a foreign nest to rob food reserves. The real ecological impact and function as an efficient foraging strategy of this usual cleptobiotic behavior remain uncertain. Intraspecific food competition between colonies of *E. ruidum* on numerous small and light prey was studied in a coffee plantation in Mexico. For each of the three replications of this experiment, separated by a two-day interval, 1000 dead fruit flies (*Ceratitis capitata*) were used as a unique food source. The species *E. ruidum* realized 90-95% of its exploitation. The predatory activity of each colony, the general kinetics of prey items disappearance and the distances between each colony involved in a cleptobiotic interaction were recorded. The exploitation was done both at a direct and an indirect level, so called "first-hand" and "second-hand" cleptobiosis, with some colonies which never had any direct relation with the food source. Along the three replications, the number of nests exploiting directly the food source did not really change (8, 11, 10 respectively) while the number of nest involved in indirect exploitation increased significantly (8, 11 and 16). The average distance for the direct exploitation of the food source weakly increased between the first and the subsequent repetitions (162 cm vs 196 and 188 cm) while the average distance between the colonies involved in cleptobiosis interactions highly increased during the second and third replication (182, 211 and 253 cm). Such a strategy for the exploitation of an important and unique food source optimizes the foraging efficiency under high nest density conditions. Firstly because direct predation is very high, secondly because the food robbing by ants from the more distant nests on nests located closer to the food source induces an increase of the direct exploitation resulting in a super-exploitation of the food source.

13-115

POLYETHISM IN THE ANT *GNAMPTOGENYS* SP. (FORMICIDAE, PONERINAE)

A. Colles, B. Gobin and J. Billen

K.U.Leuven, Laboratory of Entomology, Leuven, Belgium

Gnamptogenys sp. is an arboreal Ponerine ant with a colony structure in which either queens or gamergates -inseminated, egg-laying workers- can be reproductives.

The division of labour in 1 queenright and 2 queenless colonies of this species was studied through observations of nests with individually marked workers of well known ages from eclosion up to four months.

A clear polyethism among the workers was found in all three colonies, in which two clear categories can be distinguished. A first group of mostly young workers is generally found within the nest, where they are mostly involved in brood care. A second group comprises foragers, that generally represent older workers. An additional intermediate group can be found and is formed by individuals performing a wide range of tasks inside the nest (such as allogrooming, nest maintenance and brood care) while they may also be found outside the nest. Alate and dealate virgin queens can be produced in both colony types, and unexpectedly perform tasks similar to workers like brood care, nest maintenance and foraging.

Although our data suggest that most workers go through an evolution from nurses to foragers, there seem to be no fixed ages of this transition. This suggests that absolute age may not be a good measure in age-polyethism studies for this species. Since in some cases an early specialization to foraging occurred in very young ants, we believe that other mechanisms might influence task choice.

13-117

DIVERSITY OF TERMITES (INSECTA:ISOPTERA) IN PRIMARY TERRA FIRME FOREST IN CAXIUANÃ SCIENTIFIC STATION, PARÁ, BRAZIL.

M.L.J. Macambira

Department of Zoology/Entomology, Museu Paraense Emílio Goeldi/CNPq, Belém, Pará, Brazil

Species lists are presented for these area in Amazonian forest. Sixty-four species of termites belonging to 28 genera in three families, were found in a primary terra firme forest, in Caxiuanã Scientific Station "Ferreira Penna" (1° 42'30"S; 51° 31'45" W), Pará, Brazil..

The Nasutitermitinae subfamily especially the genus *Nasutitermes*, were the dominant group in number of species. The majority of the species (36) were wood-feeders, many of them restricted to rotten-wood. The humus-feeders were the second group in number of species (16).

The cohabitation of different termite species in the same nest was more common.

13-116

DOMESTICATION OF THE LEAF-CUTTING ANT: REPRODUCTION OF *ATTA OPACICEPS* BORGMEIER, 1939 (HYMENOPTERA: FORMICIDAE)

F.J.M. SALES, J.O.L. OLIVEIRA JUNIOR, R.A. MOREIRA

Laboratory of Agricultural Entomology, Plant Science Dept, Federal University of Ceará, Fortaleza, CE, Brazil

The northeast leaf-cutting ant, *Atta opaciceps* is a widespread species of the Brazilian northeast ecosystems. This attini is extremely resistant to density independent factors such as drought and high temperatures. *A. opaciceps* is also a useful insect which produces: Phytoalexins, organic and mineral fertilizers and a high-quality protein which tastes better than the finest caviar. This investigation aims to elucidate the insect reproductive behavior. It was conducted on a 5ha plot covered with arboreal and arbustive vegetation infested with nests of the formicid in Fortaleza, CE, Brazil from 1991 to 1995. Thirty mature nests, 15-year old and more, were directly and daily inspected for three times, v.g., 09:00, 17:00 and 19:00 GMT. It was disclosed that less than 50% of the nests engage in nuptial flights which last from late December to middle February. This activity starts right after 17:00 and finishes up by 18:15, approximately. From those nests, all produce both male and female in different ratios. Females start flight first and stay from 60 to 80m above the ground level and are followed by males of different nests. They mate during the flight.

13-118

WORKER TASK AND WORKER SIZE OF *AZTECA* ANTS

H. C. Morais

Pós Graduação em Ecologia, Instituto de Biologia, UNICAMP, CP 6109, 13081-970, Campinas, SP, Brasil (Departamento de Ecologia, Instituto de Biologia, Universidade de Brasília, 70910-900, Brasília, DF, Brasil)

Azteca cf. *lanuginosa* (Hymenoptera: Formicidae: Dolichoderinae) is found in the cerrado of Central Brazil where it makes cardboard-like nests on the tallest trees (around 6 m tall). The nests are oval in shape, reaching 33 x 40 cm in diameter, and contain a large number of workers (50,000 to 80,000). There is a continuous variation in size of the workers, with their cephalic capsule width ranging from 0.58 to 1.43 mm. This species is predations on insects, and capture their prey either patrolling actively the plant or waiting for larger prey such as butterflies, beetles and grasshoppers, in coordinated group ambush. Although there is variation in the size of the workers outside of the nest, there is no apparent differentiation in terms of their activities. However the smallest workers (cephalic capsule width between 0.58 and 0.68 mm) were only found within the nest. This result indicates a specialization of the smallest ants to tasks inside the nest.

13-119

NESTMATE DISCRIMINATION IN *LEPTOTHORAX LICHTENSTEINI* BONDROIT ANTS: A KIN-BIASED BEHAVIOR ?

E. PROVOST

Laboratoire de Neurobiologie, Equipe Communication Chimique, C.N.R.S., Marseille, France

To test the kin recognition ability of *Leptothorax lichtensteini*, closely related colonies were set up in which the foundress sisters were fertilized by their brothers, and ethological experimentation was carried out in which workers from a colony were transferred into a related or a nonrelated colony. Intruders related to the host colony were licked and participated in trophallactic contacts more frequently, as well as being bitten less frequently than intruders which were unrelated to the host colony. Workers turned out to be capable of recognizing individuals which they had never encountered previously, on the basis of their kinship.

Does kin recognition rank high among the mechanisms whereby the members of a colony recognize each other? A worker which had been removed from its nest for 70 days along with four sisters was subsequently attacked by its nestmates on being returned to its colony. Likewise, a worker which had spent 45 days in an alien colony attacked its own previous nestmates, and vice versa, when the two colonies were brought into contact. In both cases, the workers seem not to have been recognized, as if the genetic cues they carried had been masked by social environment cues.

In this species, recognition among the members of a colony is probably based on a whole complex set of coexisting mechanisms, involving both genetically determined chemical cues and environmental factors (including social factors). The preponderance of one type of cue might vary depending on the context (nestmate or nonnestmate kin recognition).

13-121

HOW DO WORKERS OF THE ANT *FORMICA RUF*A COPE WITH SPATIAL INFORMATION DISRUPTIONS IN THEIR ENVIRONMENT?

A. Loureiro Henriques, R. Campan, V. Fourcassié

Laboratoire d'Ethologie et Psychologie Animale, Université Paul Sabatier, Toulouse, FRANCE

Workers of the ant *F. rufa* are known to use chemical trunk-trails as well as visual landmarks to orient to familiar food sources. However, spatial information disruptions between the two types of cues as well as within visual landmarks can sometimes occur whenever some landmarks are temporarily hidden or permanently displaced by natural agents (fog, wind, etc...) or when they altogether disappear under the action of man. The aim of our study was to investigate the behaviour of ants facing such information disruptions.

In order to work in a fully controlled visual environment our experiments were carried out in the laboratory. The orientation performance of the ants was studied by recording and analysing their trajectories. Previous to all experiments, ants were first allowed to establish a chemical trail between their nest and a permanent food source. In a first series of experiments, no landmarks were placed on the area and the environment was manipulated in three different ways: the whole experimental set up could remain unchanged, be rotated by 180° or surrounded by a white curtain so as to mask the visual landmarks. For each of these situations the chemical trail was either in its usual position or rotated by 90°. In a second series of experiments visual landmarks were placed directly on the area and the location of the food source was associated with one of these landmarks. This particular landmark was then moved at different locations whereas the location of the other landmarks remained unchanged, thus introducing a conflict both between the chemical and visual cues as well as within the visual ones.

Preliminary results show that ants are able to orient successfully when only chemical or visual cues are present but that, on average, the orientation was always better when the two types of cues were present, suggesting the existence of a cross-potential process between the two types of sensory input. The worst performances were observed when the information given by the proximal (within-area) and the distal visual landmarks (experimental room) was reversed.

13-120

DEMOGRAPHIC CHANGES AND TEMPORAL POLYETHISM IN COLONIES OF *ECTATOMMA TUBERCULATUM* (HYMENOPTERA: FORMICIDAE: PONERINAE)

R. Fénérón

Laboratoire d'Ethologie Expérimentale et Comparée. Université Paris-Nord, Villetaneuse, France

Ant societies are biologically dynamic structures: their population size and composition change throughout their life cycle. Such demographic fluctuations were examined in mature colonies of *Ectatomma tuberculatum* (Ponerinae) reared under constant laboratory conditions. Three different demographic situations were then characterised by the value of the ratio "workers to brood". In each situation, the behavioural ontogeny of workers was studied from emergence to death. We compared the age at which tasks (i.e. brood care, nest maintenance, guarding the nest entrance, foraging) were first displayed and the rate of their performance. When the ratio "workers to brood" was inferior to 1, workers foraged at the mean age of 22 days old and were engaged over a longer period of time in brood care. When the ratio was superior to 2, the first foraging trip occurred later, at approximately 66 days old, and was usually preceded by a guarding stage. Differences between groups were observed as early as the first week of imaginal life; they mainly concerned alimentary activities and social interactions. It appears that actual colony needs affected by demographic situations greatly influence the behavioural ontogeny of workers. Social stimulations, especially those originating from older nestmates, might partly control the maturation rate of callow workers and as such temporal polyethism.

13-122

EGG-MARKING IN THE BUMBLE BEE *BOMBUS TERRESTRIS*

J.S. Birnbaum, M. Ayasse, J. Tengö¹, A. van Doorn², T. Taghizadeh³,

W. Francke³

Institute of Zoology, Dept. of Evolutionary Biology, Vienna, Austria

- 1 Ecological Research Station of Uppsala University, Färjestaden, Sweden

- 2 AR Berkel en Rodenrijs, Netherlands - 3 Institute of Organic Chemistry, University of Hamburg, Germany

In bumble bees "elite workers" often show developed ovaries, but since they do not mate, they only produce haploid male eggs. In the honey bee *Apis mellifera*, the haploid eggs produced by workers are eaten by their nestmates, but those layed by queens are left intact due to an odour marking from the Dufour's gland, which is deposited on the eggs and is recognised by the workers. We investigated whether similar egg-marking occurs in the bumble bee *Bombus terrestris*. Volatile markings were obtained by washing individual eggs in pentane and the resulting odour samples were analysed by gas chromatography and mass spectrometry.

Eggs produced by queens and workers showed significantly different odour bouquets. Furthermore, the volatile patterns were colony-specific. In the odour bouquets, n-alkanes and alkenes were the major classes of compounds. Since the odour composition of the Dufour's glands differed from those of the egg-markings, females of *B. terrestris* obviously mark their eggs with secretions other than only those of the Dufour's gland. Whether the egg-markings of bumble bees encode colony-, caste- or even patriline-specific recognition signals is presently under investigation.

13-123

NEST MATE RECOGNITION OF WORKERS AND THEIR HYDROCARBON PROFILES IN JAPANESE, ASIAN AND EUROPEAN HONEYBEE.

Hiromi Sasagawa, S. Matsuyama¹, M. Sasaki², T. Suzuki¹

Department of Insect Physiology and Behavior, National Institute of Sericultural and Entomological Science, Tsukuba, Ibaraki, Japan,
 -1 Institute of Applied Biochemistry, University of Tsukuba, Tsukuba Ibaraki, Japan, -2 Tamagawa Univ, Machida, Tokyo, Japan.

The Japanese honeybee (*Apis cerana Japonica* Rad.:Acj) and the European honeybee (*Apis mellifera* L.:Am) share the same habitat in Japan. Workers of both species were experimentally introduced to their own hive, to different hives of the same species, or to hives of the other species. Am hives accepted 52% of the trials of day-0 Am workers and 87% of the Acj foragers. On the other hand, Acj hives accepted almost all foragers from the other hive (96% average) and day-0 Am workers as well (90%). Hive mates as well as non-hive mates accidentally damaged during experiments were rejected, even in the case of the friendly Acj. As a result, nest mate recognition in Acj among different colonies and against different species was milder than that of Am.

Hydrocarbons were analyzed by GC and GC/MS, and were compared among 3 species, using wax and body surface extracts from workers and drones. Each species was distinguishable not only by a combination of components, but also by occurrences of specific components. Acj workers contained C₂₃, C₂₅, C₂₇ and Am workers contained C₂₅, C₂₇, C₂₉, C₃₁ and C₃₃ with various degrees of unsaturation (0 to 3). Alka-6,9-dienes (C₂₅ to C₂₉) was present in Acj, while Am possessed dienes with (CH₂)_n (n > 3) between double bonds.

Hydrocarbon profiles (HCP) among individual workers and drones of a hive or with age were different in Acj, Am in Japan and Asian bee (*Apis cerana indica*) in Nepal. HCP of workers were divided into groups of 3 to 10, whereas those of drones were divided into groups of 1 or 2. These results could be explained by queen's multiple mating and/or inbreeding in honeybee society and suggest that these drones are homozygotes.

13-125

WHAT ROLE FOR KIN SELECTION IN COMMUNAL BEE SOCIETIES? THE CASES OF SOME EUROPEAN ANDRENIID BEE SPECIES (HYMENOPTERA: ANDRENIDAE)

R.J. Paxton¹, P.A. Thoren, J. Tengö¹

Department of Genetics, Uppsala University, Sweden - 1 Ecological Research Station of Uppsala University, Öland, Sweden

Bees (Apoidea) exhibit a wide diversity of social organizations and they therefore provide suitable material with which to test theories for the evolution of sociality. One such theory, invoking kin selection, has been the major paradigm for understanding the evolution of sociality in the Hymenoptera because of the inherent asymmetries of relatedness in eusocial societies of ants, bees and wasps. Yet rarely has relatedness been measured in facultatively social species, those in which one can measure the factors favouring the evolution of sociality.

We examine the potential importance of kin selection in facultatively communal bee species, that is, species with amongst the lowest levels of social organization within Hymenoptera involving little more than the use of a shared nest entrance. We do so by measuring genetical relatedness of nestmate females using microsatellite DNA markers. Estimates of relatedness in established nests are generally low, and not significantly different from zero.

Inclusive fitness benefits may nonetheless be important in nest initiation, when small numbers of females join together to construct a communal nest. Field manipulative experiments suggest that, even in this situation, kin selection is of little importance in communal bee societies.

13-124

A GENERAL APPROACH TO THE VISUALISATION AND ANALYSIS OF DOMINANCE INTERACTIONS: THE PONERINE ANT *GNAMPTOGENYS* SP. AS A CASE STUDY

T. Wenseleers, B. Gobin and J. Billen

K. U. Leuven, Laboratory of Entomology, Leuven, Belgium

Dominance hierarchies are traditionally represented using dominance matrices and statistically analysed using Appleby's test for linearity. These methods were however mainly developed for species where the repertoire of agonistic interactions can easily be pooled together and clear-cut conclusions on the outcome of encounters are obvious, e.g. in chickens. Dominance orders are however also known to occur in various social insects. In the primitive ponerine ants where actively reproducing inseminated workers (gamergates) occur, evidence for dominance-regulated reproduction has recently accumulated. However, the use of dominance matrices implies the reduction of temporal and sequential information of interactions. Also, additional data on the difference in status of the interacting individuals can be deduced from the reaction (aggressive vs. submissive) of the aggressed individual. As a model for our research on improving the analysis, the arboreal ponerine ant *Gnamptogenys* sp. of Sulawesi was used. A generally applicable computer program was developed allowing a visual representation of interaction-type data-sets. An automated representation of the interactions between all individuals is obtained, with the simultaneous display of type of action and the type of reaction. This approach has many advantages: apart from giving a perfect representation of temporal dynamics of hierarchies, it provides a framework for gaining insight in factors which have so far not been considered in research on dominance hierarchies in ants. Currently, attempts are made to include this additional data in the analysis in order to maximise the correlation between egg-laying rates or ovary development and the obtained dominance hierarchy - models which could then be tested on different colonies. Ultimately we hope to provide a tool for assessing the most accurate picture of the dominance hierarchy based on interaction data.

13-126

ACTIVITY CYCLES OF EXOCRINE GLANDS OF *BOMBUS TERRESTRIS*Monica Brozzoni¹, Hayo Velthuis², Marie José Duchateau², Johan Billen³ and Eric Schoeters³

1. Istituto di Entomologia, University of Pavia, Italy

2. Dept. of Comp. Physiology, Univ. of Utrecht, The Netherlands

3. Lab. of Entomology, K. U. Leuven, Belgium

Bumblebees use pheromones in sexual (Kullenberg et al., 1970; van Honk et al. 1978) as well as in dominance communication (van Honk et al. 1980; Röseler et al. 1981). Two glandular systems are involved, the labial and the mandibular gland.

We studied the changes of the glandular morphology during the aging of males and queens, using light and electron microscopic techniques. While both glands are present in either sex, only one has prominent secretory activity. In the male it is the cephalic labial gland, in the queen the mandibular gland that demonstrates (ultra)structural changes related to the secretion of pheromones.

The labial gland is composed of many acini made up of polygonal cells. The acini are empty in newly emerged males but they are totally filled with secretion at 5-10 days of age, so they become very much enlarged while the cells flatten. Later (15-30 days old males) the gland is not producing pheromones any more, the acini become smaller again due to the discharging of the secretion and the cytoplasm attains a vacuolar disrupted appearance.

The mandibular gland of the queen shows two distinct periods of activity: the first coincides with the mating age, before hibernation, the second with the development of the colony. In between a reactivation of the secretory cells takes place. The ultrastructural changes are very obvious near the site of the end apparatus. At the end of the colony cycle we observed clear sign of degeneration of the secretory cells, such as the occurrence of primary and secondary lysosomes together with lamellar inclusions.

13-127

CHEMICAL 'DISGUISE' BY THE QUEEN OF THE SLAVE-MAKING ANT *POLYERGUS RUFESCENS* DURING COLONY FOUNDATION.

C. Errard ¹, P. D'Ettorre ², C. Vienne ¹, F. Le Moli ²

¹ Laboratoire d'Ethologie Expérimentale et Comparée, Université Paris Nord, Villetaneuse, France. ² Dipartimento di Biologia Evolutiva e Funzionale, Università degli Studi, Parma, Italy.

Polyergus rufescens is an obligatory slave-making ant species that depends entirely (for food, brood rearing and colony maintenance) on the slaves species *Formica cunicularia*. After mating, the newly fecondated *Polyergus* queen enters a *Formica* nest where she kills the host queen, appropriates the brood and gets adoption by adult workers. To understand how the queen *Polyergus* can introduce into the *Formica* colony, the cuticular hydrocarbons of the queen (before and after usurpation) are compared to those of the slaves (queen and workers) living in monospecific or mixed colonies. It appears that the pattern of the *Polyergus* queen before entering the *Formica* nest, differs from that of the *Polyergus* queen after usurpation. Before usurpation, the *Polyergus* queen has small amount of cuticular hydrocarbons. It seems that the slave-keeping queen synthesizes the minimal necessary amount of her own cuticular hydrocarbons. Chemical changes are observed when the queen enters the slave's nest where she obtains the cuticular hydrocarbons from the slaves which keep their original pattern. In fact, the cuticular profile of the queen *Polyergus* becomes more similar to that of the monospecific *Formica* queen. We will discuss on this parasitism strategy.

NEUROPEPTIDES REGULATING METAMORPHOSIS OF THE SILKWORM, *BOMBYX MORI*

Hiroshi Kataoka, Akinori Suzuki

Department of Biotechnology, Graduate School of Agriculture and Agricultural Life Sciences, The University of Tokyo, Bunkyo-ku, Tokyo 113, Japan

Insect molting and metamorphosis are regulated by various neuropeptides. During past 10 years, these neuropeptide, such as prothoracicotropic hormone, eclosion hormone, and bombyxin have been purified from the silkworm, *Bombyx mori* and chemically characterized. Furthermore, the cDNAs and/or genomic DNAs of these hormones have cloned and sequenced. In this talk, Our research on these neuropeptides is reviewed.

14-002

ECDYSTEROIDS AND JUVENOIDS CONTROLLING GROWTH AND DEVELOPMENT OF THE SILKWORM *BOMBYX MORI*

Bernard Mauchamp and Hervé Monconduit

Unité Nationale Séricole, INRA, 69350 La Mulatière, France

Numerous pioneers of insect endocrinology used the silkworm *Bombyx mori* as a model insect for the studies of the control of post-embryonic development and reproduction. In 1900 an organ was described in the larva only. This organ was termed "prothoracic gland" by Ke (1930) but its function was elucidated by S. Fukuda in 1940. During this decade J.J. Bounhiol (1936) published several papers on the role of corpora allata in the onset of metamorphosis. During a long period the function of these different glands was only revealed by removal or implantation of the gland at various periods of the development. We had to wait until 1963 to have the ecdysone chemical structure by Karlson *et al.*, and 1967 to obtain the first insect juvenile hormone structure by Röller *et al.*. As soon as chemical elucidation occurred it became possible to develop techniques for hormone titration. With such tools, hormone fluctuations during the development were established. From this period, numerous studies were achieved to determine the factors that regulate the balance between the different hormones. Both *in vivo* and *in vitro* studies gave information on the responsiveness of the glands. Important data were obtained on the different routes in biosynthesis and metabolism of hormones. Ohnishi and his group purified several ecdysteroids in silkworm ovaries and in embryos but their role remains to be clarified. Molecular approaches and genetics are an important means for clarification of the regulation of the development. The elucidation of the hormone structures and available biological assays allow the discovery of hormone analogs that were suggested to be used as insecticides (Williams 1967) or in sericulture.

14-003

DIAPAUSE HORMONE OF THE SILKWORM, *BOMBYX MORI* (LEPIDOPTERA: BOMBYXIDAE)

Okitsugu Yamashita¹, Kunio Imai²

¹ School of Agricultural Sciences, Nagoya University, Chikusa, Nagoya 464-01, ² Faculty of Bioresources, Mie University, Tsu 514, Japan

The silkworm, *Bombyx mori* enters diapause at the early embryonic stage. Diapause is a physiological phenomenon controlling the life span, so that many physical, chemical and biological informations are used to determine diapause character. Diapause hormone (DH) plays a central role for induction of diapause, and the secretion of DH is controlled by temperature and photoperiod experienced at maternal stages.

The temperature function is elucidated by measuring the DH gene expression at 15 °C and 25 °C conditions. A high temperature induced DH gene expression at the specific stages of embryonic and post-embryonic development. This temperature stimulus provided a high coefficient value between DHmRNA content and diapause egg incidence. Diapause hormone enhances trehalase activity in developing ovaries, that is the initial biochemical process leading to diapause metabolism. An RT-PCR determination of trehalase mRNA in ovaries clearly demonstrated that DH induced trehalase gene expression as early as 1 h after hormone treatment.

The recent advances on regulation mechanisms of DH gene expression and molecular action of DH will be considered.

14-004

PEPTIDES REGULATING PHARATE LARVAL
DIAPAUSE OF *ANTHERAEA YAMAMAI*

K. Suzuki
Department of Bioscience and Technology, Faculty of Agriculture, Iwate
University, Morioka 020, Japan

By ligation experiments, this study ascertained that a repressive factor (RF) produced in the region of the mesothorax (Suzuki *et al.*, 1990, 1994), is indispensable for diapause maintenance in pharate larvae of the wild silkworm, *Antheraea yamamai*. To identify the factor, extracts from prothoracic glands, mesothoracic ganglia, suboesophageal bodies and the mesothoracic part of the foregut were compared with *Bombyx* diapause hormone in a diapause termination bioassay. Only the foregut extract delayed, and in a double application assay, prevented diapause termination. This RF activity was heat stable and destroyed by proteinase. By analogy with Bom-DH, I propose that RF is named Any-diapause hormone. This study also identified a maturation factor inducing post-diapause development, using the methods practiced in the silkworm for eclosion hormone. This peptide-like hormone and Any-DH are different from the FXPRL amide peptides by some results of bioassay. Then a complete isolation of these two hormones is necessary to understand the mechanism controlling diapause in insect pharate larvae.

14-006

IN VIVO AND IN VITRO ANALYSES OF FENOXYCARB
INTERACTION WITH THE ENDOCRINE SYSTEM OF THE
SILKWORM, *BOMBYX MORI*.

H. Monconduit and B. Mauchamp
Unité nationale séricicole, INRA, 69350, La Mulatière,
France

Fenoxycarb, an insect growth regulator with juvenile hormone (JH) mimic effects, acts at very low doses on last-instar larvae of the silkworm, *Bombyx mori*. Last-instar larvae treated with only some picograms of fenoxycarb are unable to spin their cocoon and to undergo metamorphosis, but stay as dauer larvae and continue to feed. JH and its classical analogs are known to delay or inhibit spinning and pupation at higher doses in the silkworm. Such chemicals prevent normal commitment to metamorphosis by inhibiting ecdysone production in the prothoracic glands and PTTH release from the brain-corpora cardiaca-corpora allata complex. Fenoxycarb does not involve a modification in JH production since corpora allata ablations do not restore the normal development of treated larvae. However, Enzyme Immuno Assay(EIA)-detected ecdysteroid peak, which triggers spinning and pupation in normal larvae, is absent in permanent larvae. Therefore, fenoxycarb seems to interfere on mechanisms controlling ecdysteroids titers in last-instar larvae, as does JH. In vitro cultures of prothoracic glands will permit to determine whether fenoxycarb, like JH, can inhibit ecdysone production by acting directly on the gland, or at an upstream step, on the PTTH-producing neurosecretory cells. In addition, a highly sensitive EIA for fenoxycarb is being prepared in order to establish the kinetic of its activity.

EFFECTS OF TEBUFENOZIDE, AN IGR WITH ECDYSTEROID-LIKE ACTION
ON THE SILKWORM *BOMBYX MORI* L.

B. Mauchamp, H. Monconduit and Valérie Tournadre
Unité Nationale Séricicole, INRA, 69350 La Mulatière. France
In spite of the large number of insecticides available for pest protection, the search for new insect control agents is continuing. Among the approaches to develop new safer insecticides, the development of insecticides based on the insect endocrine system is greatly improved. Numerous hormone agonists have been synthesized, but only a few have been developed into useful insecticides. Recently a non-steroidal ecdysone agonist (Tebufenozide) has been registered as an insecticide (Confirm^R or Mimic^R). According to the very high sensibility of the silkworm to the IGRs possessing JH activity, we first improved the sensitivity of the silkworm against this IGR possessing an ecdysone-like activity. The ED50 is around 1µg/larva, a value too high to act as a contaminant on the mulberry leaves. Then the Tebufenozide action was evaluated on different ecdysteroid-regulated biological systems and compared with the effects of the ecdysteroids. The first biological event observed after tebufenozide administration was the arrest of feeding followed by the apolysis. The treated worms were unable to molt and they died in their unshed larval cuticle. As with ecdysone, tebufenozide elicits wing disc evagination. We never observed the beginning of spinning but the posterior region of the silk glands revealed precocious histolysis quite independently from the developmental stage of the larvae. The dauer larvae induced by JH mimic treatment do not undergo an extra larval molt if injected with Tebufenozide. We also evaluated the effects of tebufenozide on growth and maturation of ovaries since it was demonstrated that in silkworms ecdysteroids replace the function of juvenile hormones.

DIFFERENTIAL SYNTHESIS AND UPTAKE OF
STORAGE PROTEIN (SP) BY VARIOUS FAT BODY
TISSUES DURING DEVELOPMENT OF *BOMBYX MORI*

V. Vanisree and M. Krishnan, Department of
Biotechnology, Bharathidasan University, Tiruchirappalli
620 024. INDIA

Insect fatbody is a versatile tissue performing myriad of functions. Depending on their locations, the tissue has been traditionally recognised as peripheral and perivisceral and frequently compared to mammalian liver and adipose tissue. Since structural changes take place rapidly during larval development, it is difficult to distinguish between regional or developmental differences. Recently, in 1992, it was established that in *Heliothis zea* the fat body that turns blue, due to the sequestration of the blue colored storage protein, is the perivisceral tissue that is assigned the role of storage and the colorless peripheral tissue is the synthetic tissue. The punch line of their report was a fact that such specialised tissues exist in other insect species that lack a colored storage protein. Our search in this direction in *Bombyx mori* revealed that fatbody tissues at different locations differ in their morphology from the last instar stadium through adult life. Our *in vitro* and electrophoretic studies revealed the differential storage protein synthetic capacities of these tissues and the specialised organ of storage during prepupal stages in *B. mori*. Studies pertaining to the levels of SP mRNA transcripts in different fat body tissues are under progress.

EXTRACTION, CLONING AND SEQUENCING OF DNA FROM *NOSEMA BOMBICIS*X. Y. ZHANG, K. M. LU, C. X. Zhunag, W. M. Hu, X. Y. Xu, Z. R. Huang¹ and H. S. Chen²

South China Agricultural University, Guangzhou, Guangdong, P. R. China, 510642-1. Department of Microbiology, Sun Yat Sen University of Medical Science, Guangzhou, P. R. China, 510089-2.

This article reports the experimental results of extraction, cloning and partial sequencing of *Nosema bombycis* DNA. The total nucleic acids were extracted from purified *N. n.* spores by SDS-proteinase method. After digested with RNase and DNase, the ethidium bromide stained pattern of agarose electrophoresis showed *N. b.* spore's nucleic acids contain a high molecular weight of RNA. The *N. b.* spore DNA cleaved with restriction endonuclease EcoR I and Hind III were demonstrated smear pattern in AGE. Using plasmid pTZ18R as vector, *Escherichia coli* DH5 as host cell, the EcoR I cleaved DNA of *N. b.* were cloned by shot gun method. Four recombinant plasmids were screened and isolated. They were temporarily named as pTZ18RN. b. 1, pTZ18RN. b. 2, pTZ18RN. b. 3 and pTZ18RN. b. 4. The insert DNA size in the four recombinants were 1.0, 1.2, 1.8 and 1.9kb respectively. The DNA fragments were labelled with ³²P-dCTP by random primer labelled method as a specific probe. Hybridization of these probes with the DNA of *N. b.* spore, MG1, *Nosema cyathia* and *Nosema phyllostactica* showed strong hybridization signals only in *N. b.* spore DNA. A Part of insert DNA fragments were sequenced with dideoxy chain termination method.

CHITIN FROM SILKWORM: ITS PREPARATION AND APPLICATIONS

M.-X. Cao, R.-J. Jiang, J. Yuan, H. Ying, Z. Li¹

Shanghai Institute of Entomology, Academia Sinica, Shanghai 200025, China-1 Hangzhou Silk Printing and Dyeing Joint Plant, Hangzhou 310015, China

Chitin from erisilkworm, *Philosamia cynthia ricini* and silkworm, *Bombyx mori* was prepared from larvae and pupae. The mild procedure was tested and chosen for the deproteinization and decalcification of the cuticles, since it minimizes both chain hydrolysis and deacetylation.

As a natural polymer, chitin is a ideal medical macromolecular material. Chitin fibers having suitable denier and higher tensile strength are produced by wet-spinning and finishing. A chitin suture for medical use is made with such fibers. It has the advantage of histocompatibility and can be degrades and absorbed in vivo.

A system of subdermal implants that release a steady dose of levonorgestrel for long term, reversible contraception is being developed. It consists of a biodegradable chitin capsule with a rod composed of the drug and chitin.

Chitin and its derivatives exhibited antigenic activity against bacteria and fungi. They are successfully used for freshness preserving of some kinds of fruits and vegetables.

14-009

TRANSFERRING SYNTHETIC ANTIBACTERIAL PEPTIDE GENE FROM CHINESE OAK SILKWORM INTO MULBERRY PLANT BY USING TI PLASMID FROM *AGROBACTERIUM TUMEFACIENS*Z. W. Guo, Q. J. Zhang, C. X. Zhuang, Z. R. Huang¹, A. Y. Chen, L. W. Kong².

South China Agricultural University, Guangzhou, P. R. China, 510642-1 The Sericultural Research Institute, Chinese Academy of Agricultural Science, Zhenjiang, P. R. China, 212018-2.

Transferring mulberry plant, *Morus alba*, by infection of Ti plasmid from *Agrobacterium tumefaciens* was studied. Plants selected on kanamycin containing medium were confirmed to express the introduced 35S-synthetic antibacterial peptide gene (ABG) from Chinese oak silkworm, *Antheraea pernyi*. The introduced gene was obtained by fusion of CaMV 35S promoter with ABG. Using the kanamycin resistant gene in Co24 plasmid, the mulberry leaf discs of adventitious bud formed from infected tissues were selected on the MS medium containing kanamycin at 25µg/ml. When they were transferred to the selection medium at 4-5 days, the nopal synthetase activity was detected by electrophoresis. The transformation was confirmed in 40 days with kanamycin resistance by DNA dot blotting. The results showed the synthetic antibacterial peptide gene was transferred into mulberry plant.

14-011

COMPARATIVE ULTRASTRUCTURES OF COCOON FILAMENT FORMATION IN SILK SPINNING INSECTS

H. Akai, T. Nagashima

Tokyo University of Agriculture, Setagaya, Tokyo, Japan

Ultrastructures of the liquid silk materials and cocoon filaments of *Bombyx mori*, *Antheraea yamamai*, *Antheraea pernyi*, *Antheraea mylitta*, *Antheraea assama*, and *Attacus atlas* were studied by both transmission and scanning electron microscopy. In *Bombyx mori*, the elementary fibroin fibers in the fibroin globules in the gland cells are released into the silk layer by exocytosis, forming masses of tangled fibroin fibers 1-5 µm in diameter; these are stored in the silk layer for 30 to 60 minutes. Lysosomal materials, frequently discharged into the silk layer from the gland cells, are completely digested in this layer without transfer into the lumen, passing through the outer cuticular membrane. Therefore, the fibroin column is composed solely of masses of fibroin fibers.

All of the wild silkmots mentioned above, however, have no silk layer because there is no cuticular intima. Therefore, the elementary fibroin fibers in the fibroin globules are directly released into the lumen by exocytosis and form small masses of fibroin fibers 0.5 to 1 µm in diameter, then accumulate on the surface of the fibroin column in the central lumen. During the maturing and spinning periods, numerous lysosomal materials are released into the fibroin column. By digestion they become various sized vacuoles ranging 0.5 to 5 µm in diameter, and all contain small amounts of fine fibrous materials. The fibroin column is thus a mixture of the masses of fibroin fibers and the vacuoles.

In TEM cross sections of *Antheraea mylitta*, the columnar fibroin contains more than 4,000 vacuoles (from 1 µm diameter up) and also many vacuoles of small size. Shapes of the vacuoles change greatly from globular to long tubular shapes in the space between the middle and the anterior silk glands. In the cross section of cocoon filaments of *Bombyx mori*, the filament is rather triangular in shape, and there are no vacuoles in either fibroin or sericin areas. Most of *Antheraea* insects have numerous tubular vacuoles in their cocoon filaments, although the numbers differ by insect species.

14-012

MECHANISM OF LIGHT INDUCED GREEN COLORATION OF THE COCOON IN THE JAPANESE OAK SILKWORM, *ANTHERAEA YAMAMAI*

H.Yamada, Y.Kato¹
Department of Chemistry, Kyoto University, Kyoto, Japan - ¹ Department of Biology, International Christian University, Mitaka, Tokyo, Japan

The cocoon of the Japanese oak silkworm, *Antheraea yamamai*, is green in nature, whereas it is yellow in darkness. Previously, we revealed that this phenomenon is based on light irradiation at pre-spinning stage, and light acts directly on the hemolymph to bring an accumulation of "cocoon blue pigment" in the silk-gland. In the present work, HPLC analysis of the larval hemolymph showed the followings: (a)the larvae reared in darkness did not contain the blue pigment in their hemolymph, (b)after light irradiation on the larvae for 60 minutes, the pigment appeared in the hemolymph, (c)light irradiation on the isolated hemolymph also caused the formation of the pigment, (d)light irradiation before gut-purge was not effective for the formation of the pigment.

14-014

A NEW COMPONENT OF THE SILK FIBRE PRODUCED IN THE MIDDLE AND POSTERIOR SILK GLANDS

M. Žurovec, C. Yang, F. Sehnal, K. Scheller¹
Institute of Entomology, Academy of Sciences, and Faculty of Biological Sciences, University of South Bohemia, České Budějovice, Czech Republic - ¹Theodor-Boveri-Institute, University Würzburg, Germany

Analysis of water-insoluble cocoon proteins of the wax moth, *Galleria mellonella*, revealed presence of an 18 kDa component that could not been identified with known silk proteins. An oligoprobe derived from partial N-terminal sequence of this protein was used to screen a cDNA library prepared from the silk gland RNA. A clone was isolated that encodes a protein of 166 amino acids, including the N-terminal region identified by cocoon protein sequencing. The protein differs from all known constituents of lepidopteran silk. With the use of the cDNA clone we found that the corresponding gene, called *seroin*, is expressed in the middle and, to a lesser extent, in the posterior silk glands, but in no other tissue. The content of seroin mRNA in total RNA is high in the silk glands of feeding larvae, declines at the time of larval ecdysis, and reaches a maximum during cocoon spinning. Expression of the *seroin* gene is apparently hormonally regulated: application of a juvenoid to mobile prepupae prevented the drop in seroin mRNA content associated with pupation, whereas application of 2 µg 20-hydroxyecdysone to explanted silk glands caused an abrupt decline of the content.

14-013

PURIFICATION AND CHARACTERIZATION OF INSECTICYANIN FROM THE LARVAL HEMOLYMPH OF *RHODINIA FUGAX* (LEPIDOPTERA: SATURNIIDAE)

H. Saito
Department of Insect Genetics and Breeding, National Institute of Sericultural and Entomological Science, Tsukuba, Ibaraki 305, Japan

Fifth-instar larva of the saturniid silkworm, *Rhodinia fugax*, resembles a leaf of the host plant, *Quercus serrata*, in color and shape. The spectral reflectance of the larval integument of *R. fugax* corresponded with that of *Q. serrata* leaf. To examine the relationship between the biliverdin-binding protein and the larval coloration of *R. fugax*, blue biliprotein, (insecticyanin, INS) was isolated from the hemolymph of fifth-instar larvae using hydrophobic interaction chromatography and ion-exchange chromatography. The purified INS showed a native molecular weight of approximately 37,000 in gel-filtration, whereas the apoprotein was found to be a single polypeptide of a Mr of 27,000 in SDS-PAGE. The blue coloration of INS was due to the presence of biliverdin relative pigment, which was non-covalently bonded with the apoprotein. N-terminal sequence of *Rhodinia* INS showed about 40% homology to other biliverdin-binding proteins, such as *Samia* BBP, *Pieris* BBP, *Manduca* INS and *Agrius* INS. *Rhodinia* INS was found not only in the larval hemolymph but also in the epidermis and cuticle. These results suggest that INS plays an important role in the protective camouflage in *R. fugax*.

PRIMARY STRUCTURE OF WILD SILKMOTH FIBROINS ESTIMATED FROM NUCLEOTIDE SEQUENCE

T. Tamura, K. Yukuhiro
Department of Insect Genetics and Breeding, National Institute of Sericultural and Entomological Science, Tsukuba, Ibaraki 305, Japan
It is of interest to study how different types of fibroin are distribute in wild silkmoths and utilize commercially. According to X-ray diffraction analysis, *Antheraea* and *Philosamia* fibroins belong to β(3a) and β(3b) types, respectively. We already reported that fibroin genes of Japanese oak silkworm, *Antheraea yamamai*, and Chinese tusser silkworm, *Antheraea pernyi*, were cloned and partially sequenced. The comparison of amino acid sequence deduced from the coding region between two silkworms shows that the both fibroins consist of two types of motif following poly alanine sequence. We analyzed the gene structure of other wild silkworm fibroins by southern blotting and found that there are significant homology among these fibroin genes. This result strongly indicated that there are some relationships concerning to the origin of fibroin genes. In this presentation, we report the summary of these recent data and possibility of further works using wild silkmoth fibroin genes.

14-016

UTILIZATION OF A CELL LINE ESTABLISHED FROM CHINESE OAK SILKWORM FOR PLAQUE-PURIFICATION OF THE *ANTHRAEA PERNYI* NUCLEAR POLYHEDROSIS VIRUS AND CONSTRUCTION OF A NOVEL BACULOVIRUS EXPRESSION VECTOR SYSTEM

J. Kobayashi, S. Wang*, S. Miyajima

Faculty of Engineering, Mie University, Tsu, Mie, Japan - *Shenyang Agricultural University, Shenyang, China

In the baculovirus expression vector system using the *Bombyx mori* nuclear polyhedrosis virus (BmNPV), expression of some proteins is much higher in silkworm larvae than in *B. mori* cell lines. Therefore, it is expected that the similar or much higher level of foreign gene expression would be obtained using the giant wild silkworm, *Antheraea pernyi*, and *A. pernyi* NPV (ApNPV). Additionally, pupal diapause of *A. pernyi* is an advantage over *B. mori*, because diapausing *A. pernyi* pupae can be stored for several months until infecting them with recombinant ApNPVs. Recently, a cell line, NISES-AnPe-428 (AnPe), was established from *A. pernyi* embryos. Using this cell line, we started to construct an ApNPV vector system and obtained following results.

1. We demonstrated that AnPe cells are susceptible to ApNPV. It was also demonstrated that AnPe cells do not support the BmNPV replication and that BmN4 cells derived from *B. mori* do not support the ApNPV replication.
2. Three clones of ApNPV were plaque-purified using AnPe cells. When DNA genomes of these clones were digested with restriction endonucleases, some differences in the electrophoretic profile among their restriction fragments were observed.
3. Diapausing *A. pernyi* pupae were infected well with each ApNPV clone. It took more than one week before the pupae infected with each clone began to die and within 25 days after infection all the infected pupae died.
4. The polyhedrin gene of ApNPV was successfully identified by the Southern hybridization using genomic DNA of ApNPV clone A and a DNA probe containing the polyhedrin gene of BmNPV. The 6.6 kbp *Pst*I fragment containing the polyhedrin gene of ApNPV was cloned.
5. Partial DNA sequences of the ApNPV polyhedrin gene and its flanking regions were determined.

Construction of a transfer vector plasmid is now in progress.

14-017

ON THE INHERITANCE OF NEW COCOON COLOR "EMERALD GREEN (EG)" IN THE JAPANESE OAK SILKWORM, *ANTHRAEA YAMAMAI*

T. Nakada and K. Sahara

Faculty of Agriculture, Hokkaido University, Sapporo 060, Japan

A new cocoon color strain of Japanese oak silkworm was found in our laboratory and it has been maintained as "Emerald Green (EG)" strain. It is the first report of spontaneous mutant in this insect. The cocoon of this strain appears to be more bluish green colored than that of normal strain "Normal Green (NG)". By earlier study of biochemical analysis, it is recognized that the normal strain has yellow and blue pigments. This yellow pigment is originated in the plant leaves as food and it is transferred into the silk gland of larvae, and the blue pigment is synthesized in vivo under light condition.

We clarified a deficiency of yellow pigment in EG cocoon, by the method of biophysical colorimetry. As a result of progeny test after crossing between two strains, we confirmed the genetic control by a single recessive gene, and the statistical inference by use of cluster analysis was carried out to make clear the variance component within and between phenotypes in the color difference among individuals.

14-018

A METHOD IMPROVED FOR ARTIFICIAL HATCHING IN EGGS OF THE WILD SILKMOTH, *ANTHRAEA YAMAMAI*

K. Suzuki, E. Kuwano¹

Department of Bioscience and Technology, Faculty of Agriculture, Iwate University, Morioka 020, Japan - ¹ Department of Agricultural Chemistry, Kyushu University, Fukuoka 812, Japan

The method of artificial hatching with an imidazole derivative KK-42 has been developed in eggs of the wild silkworm, *Antheraea yamamai* and in the gypsy moth, *Lymantria dispar japonica*. Particularly this compound was effective to break diapause of pharate larvae in the intact eggs and in the naked pharate larvae removed from chorions. In the latter case, KK-42 concentration was 100-fold lower (0.1 µg/pre-larva) than in the former. KK-42, however, was sometimes harmful to induce died individuals. To overcome this point, we examined some imidazole derivatives to break pharate larval diapause. As a result, TH-27 was unharmed and effective for diapause breakdown in naked individuals.

Additionally, we analyzed the mode of action of imidazole derivative in diapausing and diapause-terminated pharate larvae. This study can indicate a model of its function.

14-019

THE SATRUNIID INSECT IN NEW ZEALAND

K. Okui Center of Liberal Arts & Science, Kitasato University, Sagami-hara, Japan

At present, three species of Satruniid insect are known living in New Zealand. But originally, it is considered that there are no live under the native condition in this country. However about 1920s one of Satruniid, Gum emperor moth (*Antheraea eucalypti*), was looked and immediately it has spread throughout the north Island and in south Island. This caterpillar feeds on leaves most varieties of eucalyptus and also on pepper tree. Now, it is most popular moth in this country.

The other one is north american silk moth, cecropia (*Hyalophora cecropia*). This insect was found as a caterpillar feeding on a apple leaves in a part of north Island in first of 1980s. And it is consider as feeding on a wide variety of plants so the absence of its natural enemies. The next one is new species of silk moth, *Samia cynthia*, it found at the cocoon stage on the chinese tree of heaven in Auckland city. On these two silk moths, the Ministry of Agriculture & Fisheries of New Zealand has great interest therefore they have able to pest insect on orchards in this country. In this time, the author report mainly on life style of Gum emperor caterpillar.

APPLICATION OF SILK-SPINING INSECTS TO EDUCATION AND WELFARE
M.Hattori
Japanese Society for wild silkmooths,Tsukuba,Ibaragi,Japan

- 1.Application to education
It can help the intellectual curiosity and the scientific reserch spirit bud out in infants to use bombyx silkworm and wild silkmooths as teaching materials for infant education.
- 2.Application to welfare
In the welfare facilities where there are people advanced in age or suffering from dementia, it can be applied to the activities for their worthy life. The bombyx silkworm, which used to commune with people, can help dementia people refresh their memories and find out joy and support to live.
- 3.Application to the conservation of nature and the propulsion of tree planting
According to the breeding study of *Attacus atlas* done in the welfare facilities for the aged, the results of scientific reserches of its ecology and the development of artificial diet make a contribution to protection and preservation of *Yonagunisai*, a natural monument in Okinawa prefecture. With this approach to protection and preservation of the insects in enviromentally critical condition in the facilities for the aged who are the social weak, we can give to children a welfare education for understanding of the significance of life as well as the enviromental education. It will lead to the combined education of welfare and enviroment. Also it is useful for cooperation in the study and industrialization on *Attacus atlas* in Indonesia. And it would give a contribution to tree planting of necessity for planting to breed it.

STUDIES ON CERTAIN ASPECTS OF MUGA SILKWORM (*ANTHERAEA ASSAMA* WESTWOOD) CULTURE ON DIGHLOTI (*LITSAEA SALICIFOLIA* ROXB.)

B.Gogoi, B.C.Goswami.¹
Department of Botany, Sonari College, Sonari, Sibsagar, Assam, India-1 Department of Botany, Gauhati University, Guwahati- 781 014, Assam, India.

The unique natural silk fibre golden yellow muga is produced by muga silkworm (*Antheraea assama* Westwood) which is exclusively produced in Assam, a state of North-Eastern Region of India and nowhere else in the world. The polyphagous muga silkworm is mainly reared outdoor on som (*Machilus bombycina* King) and soalu (*Litsaea polyantha* Juss). Dighloti (*Litsaea salicifolia* Roxb.) has certain advantages of muga silkworm rearing that is due to bushy and evergreen nature of the plant and good response to pruning. Despite tremendous potentialities, the plant has been neglected so far as a food plant of muga silkworm.

The present paper highlights the comparative biochemical composition of the leaves and rearing performance of the muga silkworms on the plant. The findings of the study may help in establishing it as an important primary food plant of muga silkworm both for outdoor and indoor rearing.

14-021

THE DISTRIBUTION OF SILK PROTEIN/PEPTIDES IN THE SILK GLAND REGIONS OF MUGA SILKWORM *Antheraea assama* DURING DEVELOPMENTAL STAGES
B.G.Unni,P.Das,P.G.Saikia,A.Choudhury, A.C. Ghosh, Biochemistry department (Insect Biochem. Cell), Regional Research Laboratory, (CSIR), Jorhat- 785006. Assam. INDIA
Like any other proteins, silk protein is also a polymer of aminoacids. It is composed of two kinds of protein-Sericin and Fibroin. During the fifth instar, fibroin synthesis occurs in large amounts in the posterior silk gland and then translocated into the middle silk gland where it is stored. Recent analysis of the silk gland protein during IVth to Vth instar by SDS-PAGE has revealed 6-19 bands within 24-67 Kda. Differential peptide synthesis was studied with late fifth instar larvae. Anterior silk gland gives ten peptides which are equally distributed in both low (24-45 Kda) and high (45-67 Kda) molecular weight regions. Both middle and posterior silk gland exposed 12 bands at high molecular wt region where as 3 bands were detected at this region for posterior silk gland. Among all three regions of the silk gland, middle one showed the presence of the heaviest peptide. Analysis of the silk gland excluding the anterior part at 24 Hrs after spinning revealed 7 peptides in the same positions as observed for middle and posterior gland and other 4 peptides were detected at high molecular wt region. The significance of this studies will be discussed. (Supported by Department of Biotechnology and Central Silk Board, Govt.of India)

DETERMINATION OF SUSCEPTIBLE AGE FOR COLD TREATMENT FOR THE EXTENSION OF PUPAL DIAPAUSE IN TROPICAL TASAR SILKWORM, *ANTHERAEA MYLITTA* DRURY.

BY
N.G.Ojha, S.K.Sharan, M.K.Singh, B.R.R.Pd.Sinha and S.S.Sinha
Silkworm Seed Technology Laboratory,
Central Tasar Research and Training Institute,
PO. PISKA-NAGRI : 835 303, RANCHI, INDIA

A B S T R A C T

Bivoltine brood of Indian tropical tasar silkworm *Antheraea mylitta* Drury (Lepidoptera:Saturniidae) undergoes pupal diapause from mid November to mid June (passing tropical winter and summer). A substantial portion of the adults start emerging from 1st week of June. However, due to severe summer up to 3rd week of June, the rearing of larvae hatched from eggs laid by these females is uneconomical. To overcome this problem, it is imperative that the adult emergence is delayed up to the onset of monsoon (around 20th June), when the atmosphere cools down enough to rear the larvae profitably. In the present study diapausing pupae of various ages (60 to 175 days) were subjected to low temperature (7±2°C) treatment for 15 days. The response was most pronounced on the pupae having age between 150 to 165 days as the peak adult emergence was delayed by 15 days. Pupa of ages less than 120 days did not respond to the treatment. The findings were further substantiated with biochemical assessment which is reported.

14-024

AGE-RELATED CHANGES IN COUPLING APITUDE, OVIPOSITION BEHAVIOUR AND FERTILITY IN THE FEMALE MOTH OF *ANTHRAEA MYLITTA* D. (LEPIDOPTERA : SATURNIIDAE).

Rath S.S., B.R.R.Pd. Sinha and S.S. Sinha

Central Tasar Research and Training Institute,
P.O. Piska Nagri- 835 303, Ranchi, Bihar, INDIA.

ABSTRACT

Reproductive senescence was studied in the short-lived species *Antheraea mylitta* D. Virgin female moths of various ages (in days) were mated with newly eclosed males (day 0) for 8 h. under prevailing conditions of temperature and humidity. The coupling aptitude (i.e mating success) of the female moths decreased significantly with advancing age so as the coefficient of egg laying and fertility. The mated females laid maximum number of eggs within first 24 h of depairing, but the egg laying of the virgin females were found to be slow, erratic and delayed. The survivality of the moths during oviposition significantly decreased with the advancing age in both mated and virgin females.

A MODEL FOR A COMMON INTEGRATION MECHANISM OF THE RETROTRANSPOSON , BMC1, AND RETROPOSON, BM2, OF *BOMBYX MORI*

H. Maekawa, Y. Nakajima¹, K. Hashido, K. Tsuchida and N. Takada

Division of Radiological Protection and Biology, National Institute of Health, Tokyo, Japan - ¹ Laboratory of Gene Technology, Univerity of Ryukyus, Okinawa, Japan

We isolated a retrotransposon, BMC1, which was a member of the LINE family without LTR and is present in about 3500 copies per haploid genome. This element is considered to be integrated into the genome through an RNA intermediate without including any ORF for reverse transcriptase. Short SINE-like repetitive elements designated as Bm2 (~10⁴ copies) are homologous to the 3' end of BMC1. One of three types of Bm2 element was identical to the 3' end of BMC1 and hence both elements may be derived from the same ancestor. The same member (3.7kb) containing the complete ORF for reverse transcriptase was reported in the intron of amylase gene. This suggests that an active reverse transcriptase and integrase complex recognizes and integrates defective RNA intermediates into the genome. If this integration complex recognizes the 3' end of the corresponding RNAs, the same mechanism could occur in the integration of both elements. We will talk about the possible evolutionary origin and model for integration of both elements. Ogura,T.et al., Chromosoma 103, 311 (1994)

A HIGH-EFFICIENCY, NON-LYTIC EXPRESSION SYSTEM FOR PRODUCTION OF RECOMBINANT PROTEINS IN INSECT CELLS

M. Lu, P.J. Farrell¹, L.A. Behie¹ and K. Jatrou

Departments of Medical Biochemistry and ¹ Chemical Engineering, The University of Calgary, Calgary, AB T2N 4N1, Canada.

This expression system is based on the utilization of the cytoplasmic actin promoter of the silkworm *Bombyx mori*, which is constitutively expressed in virtually all cell types, including all available silkworm cell lines and many cell lines derived from other lepidopteran insects. The actin promoter is coupled to two genetic elements of BmNPV that enhance dramatically its activity and the expression of any genes linked to it. The first element is an enhancer that stimulates the actin promoter in *cis*. The second one is a gene encoding a transcriptional regulator. This stimulates the expression of the actin promoter in *trans*. Each of the two genetic elements increases the level of expression of genes cloned in the actin promoter-based expression cassette by approximately two orders of magnitude relative to that obtained from the basic actin expression cassette. Supplementation of the actin promoter with both genetic elements results in an increase of 2,000 to 5,000-fold in the transcriptional activity of the actin promoter and in a corresponding increase in the expression of recombinant proteins encoded by genes cloned under its control. A comparable degree of enhancement in the activity of the silkworm actin promoter occurs also in cell lines derived from other lepidopteran species.

When coupled with a hygromycin-resistance selection scheme allowing stable chromosomal integration of the recombinant expression cassettes, and with a cell cloning procedure resulting in the acquisition of cells expressing uniformly high levels of the recombinant proteins, this system yields quantities of recombinant proteins comparable to those achieved through conventional infection of insect cells by baculovirus expression vectors. To avoid cell poisoning caused by accumulation of large quantities of foreign proteins that are not normally secreted out of the expressing cells, we have also constructed a modified expression cassette containing a synthetic signal peptide sequence that directs recombinant protein secretion.

This non-lytic expression system has several advantages over baculovirus-based expression systems, including the capacity for production of recombinant proteins from both cDNA and intron-containing genomic sequences. These advantage will be discussed.

14-027

XANTHINE DEHYDROGENASE GENES IN THE OILY MUTANTS OF SILKWORM, *BOMBYX MORI*

N. Komoto, Y. Yasukochi, K. Yukuhiro, T. Kanda, T. Tamura

Department of Insect Genetics and Breeding, National Institute of Sericultural and Entomological Science, Tsukuba, Ibraki 305, Japan

In order to develop a transgenesis in the silkworm, construction of suitable vector contained dominant marker gene would be very useful. In the silkworm, it is well known that many different morphological mutants are maintained. Among them, three different oily mutants located on *og* and *oq* loci are caused by low level or deficiency of xanthine dehydrogenase (XDH) activity. The mutant skin becomes translucent because no uric acid globules are formed in the epidermal cells. We recently succeeded to clone two XDHcDNA in the silkworm. The sequence of two genes shows reasonable similarity with other organism's XDH genes. Therefore, we call them BmXDH1 and BmXDH2. In this report, we analyzed the structure of two genes in the oily mutants by southern blotting. The comparison between the normal and mutant from *og* strain showed no significant difference. However, mutant specific BmXDH1 and BmXDH2 bands were detected in *oq* strain. We are now analyzing the meaning of these mutant specific bands and the low level of enzyme activity by using long PCR.

14-028

INTEGRATED GENETIC MAP OF THE *BOMBYX MORI* GENOME
 Toru Shimada, Shuntaro Yano and Masahiko Kobayashi
 Department of Agricultural and Environmental Biology
 University of Tokyo, Yayoi, Bunkyo-ku, Tokyo 113, Japan

We constructed a linkage map of random amplified polymorphic DNAs (RAPDs) in *Bombyx mori* consisting of 168 loci on 29 chromosomes which we are integrating with a linkage map of restriction fragment length polymorphisms (RFLPs) by another group. We are also overlapping these molecular maps with the conventional linkage map for phenotypic loci, which requires large scale crossing experiments. The correlation of 14 chromosomes between the phenotype linkage map and our RAPD map is already known. For chromosomes 13 and 22, we have made integrated maps of a single line which carries both molecular and phenotypic loci. Our final goal is to find DNA markers that are closely-linked to phenotypic loci of interest, i. e., disease resistance, diapause, embryogenesis, behavior and so on, and to obtain the genes by positional cloning. Toward this end, we are determining the nucleotide sequences of RAPDs, and are designing specific primers to amplify the loci they represent.

We are also trying to map genes whose function and nucleotide sequence are known. We have mapped the gene encoding prothoracicotropic hormone at 2.5 cM on chromosome 22 and the gene encoding the diapause hormone and the pheromone biosynthesis activation neuropeptide at -2.2 cM on chromosome 11. We have found a polymorphism of the gene coding for the ecdysone receptor, and are looking for the chromosome on which it is located. The aim of these efforts is to know the relationship between growth-regulating molecules and already localized phenotypic mutants.

14-030

STRUCTURE AND FUNCTION OF THE SILK FIBROIN MOLECULAR COMPLEX
 S. Mizuno, K. Tanaka
 Department of Applied Biological Chemistry, Faculty of Agriculture,
 Tohoku University, Sendai, Japan

Western blot analysis of the silk fibroin secreted into the lumen of the posterior silk gland or in the cocoon of *Bombyx mori* with polyclonal antibodies against synthetic peptides corresponding to segments in the fibroin L-chain and P25 or against the whole L-chain has demonstrated that L-chain is a major and P25 is a minor small protein components in the fibroin molecular complex. Combined approaches with gene cloning and peptide analysis have demonstrated that Cys190 in L-chain and Cys 20 (from the C terminus) of H-chain form a disulfide bond. The homozygous *Nd-sD* mutation, mapped to the *Fib-L* locus on the 14th chromosome, causes severe deficiency of secretion of fibroin and the naked pupa phenotype. Studies on this mutation by cloning and sequencing of the mutant L-chain cDNA and its gene reveal that the H-L disulfide linkage can not be formed because the mutant L-chain has a completely different C-terminal half sequence created by intronic recombination and exon shuffling in its gene. These results suggest strongly that the disulfide linkage of H and L-chains is essential for the efficient secretion of fibroin. On the other hand, P25 is not covalently bound to H-chain. Its association with either H or L-chain is suggested to be through hydrophobic interactions. P25 is characterized by extensive intramolecular disulfide linkages and glycosylation. Electrophoretic mobility of P25 as revealed by the reaction with Con A is altered in the *Nd-sD* mutant silkworm, suggesting that the state of glycosylation of P25 is affected when the H-L linkage is not formed. Presence of homologues of L-chain and P25 in distantly related fibroin-producing insects implies that formation of the molecular complex as shown in *B. mori* is a common strategy for producing a large amount of fibroin among different species of insects.

14-029

TRANSOVARIAN TRANSMISSION OF A FOREIGN GENE IN THE SILKWORM, *BOMBYX MORI*, BY *AUTOGRAPHA CALIFORNICA* NUCLEAR POLYHEDROSIS VIRUS
 H. Mori

Department of Applied Biology, Faculty of Textile Science, Kyoto Institute of Technology, Kyoto 606, Japan.

When the silkworm *Bombyx mori* cell line, BmN cell, was inoculated with *Autographa californica* nuclear polyhedrosis virus (AcNPV), the increase of progeny viruses in the culture medium was observed. The silkworm survives inoculation with AcNPV, however, pupal-adult metamorphosis of AcNPV-infected pupae was arrested and the metamorphosis was induced by administration of ecdysteroid hormone. The titer of progeny viruses in the hemolymph of AcNPV-infected pupae was 7.3×10^5 PFU/ml at 20 days p.i. We introduced a firefly luciferase gene, expressed under control of *Drosophila* heat shock protein gene or AcNPV immediate early gene promoter, into AcNPV DNA. When the 5th instar larvae of the silkworm were inoculated with the recombinant virus, luciferase activities were detected in the virus-infected larvae and pupae (F0), and in the newly hatched larvae of the next generation (F1). The silkworm larvae were reared on an artificial diet and successively mated. The genomic DNA was extracted from 5th instar larvae of each generation (F0 to F3). A polymerase chain reaction (PCR) was carried out using 5' and 3' primers derived from the luciferase gene. The PCR amplification and Southern blot hybridization analysis demonstrated that the luciferase gene was transmitted through at least the F3 generation. The luminescence in the hemocytes from the 5th instar larvae of the F0 to F3 generation were also detected. These results show that AcNPV can be utilized as vector for the transovarian transmission of foreign genes in the silkworm.

14-031

EXPRESSION OF FOREIGN GENES IN THE SILKWORM *BOMBYX MORI* USING BACULOVIRUS VECTORS
 S. Maeda
 Department of Entomology, University of California, Davis, CA USA

The nuclear polyhedrosis viruses (NPVs), comprise a genus within the Baculoviridae. Due to numerous advantageous characteristics as vectors, NPVs have been widely used for the expression of foreign genes using insect cell cultures. Whole insects (e.g. silkworm larvae using the *Bombyx mori* NPV (BmNPV) vector) have also been used to produce large quantities of specific polypeptides. For secreted polypeptides, the expression rate (mg of protein per ml of medium or hemolymph) in silkworm larvae is often over 100-fold higher (e.g. 1 mg mouse IL-3 compared to a few ug in cell culture) than that in in vitro culture. Post-translational modifications (e.g. C-terminus amidation) which occur in mammalian cells also occur normally in larvae and the expressed product can be purified by traditional biochemical procedures. An improved strategy for the collection of hemolymph from silkworm larvae and commercial-scale production of feline interferon alpha for use as a veterinary medicine will be discussed.

POTENTIALITIES OF THE DENSOVIRUS-DERIVED EXPRESSION VECTORS FOR INSECT TRANSGENESIS

C. Royer (1), C. Romane (2), P. Couble (3), A. Handler (4), M. Bergoin (2)

(1) Unité Nationale Séricicole, INRA, 25 quai J.J. Rousseau, 69350 La Mulatière, France - (2) Unité de Virologie Moléculaire, Station de Recherches de Pathologie Comparée, 30380 Saint Christol-lez-Alès, France - (3) Centre de Génétique Moléculaire et Cellulaire du CNRS et de l'Université Claude Bernard, 43 Bd. du 11 Novembre 1918, 69622 Villeurbanne cedex, France - (4) Insect Attractants, Behavior, and Basic Biology Research Laboratory, USDA/ARS, Gainesville, Florida, USA

By inserting different reporter or selection genes (*lacZ*, CAT, luciferase, *neo^R*) in the cloned sequence of the *Junonia coenia* densovirus (*JcDNV*) genome, we succeeded in expressing these genes under the control of the promoter of either the structural (S) or the non structural (NS) viral genes in Lepidopteran cell lines. An unexpected result of these vectors was the observation that the recombinant viral genome could maintain in cells from generation to generation, leading to the stable constitutive expression of the reporter gene. Analysis of the DNA extracted from clones of transformed cells revealed that the recombinant *JcDNV* sequence could integrate into the cell DNA if the gene coding for the three NS polypeptides (NS1, NS2 and NS3) is functional. If this gene is deleted (Δ NS vectors), the complete plasmidic sequence containing the recombinant genome is maintained as an episome. We recently observed that the deletion of the sequence coding for NS3 resulted in a 10 fold increase of cell transformation efficiency which reached 10^{-3} - 10^{-4} . Thus, the *JcDNV*-derived expression vectors appear as good candidates for gene transfer in insects. To further investigate their potentialities in this domain, we micro-injected eggs of *Drosophila melanogaster*, *Ceratitis capitata* and *Spodoptera littoralis* with pBRJLacZ Δ NS3 plasmidic DNA, a construct expressing the *lacZ* coding sequence fused to the coding sequence of structural polypeptides. The results of expression of β -gal through larval stages of these insects will be presented.

14-034

MORPHOGENESIS OF THE PUPAL WINGS IN BOMBYX MORI: THE LEVEL OF A TRANSCRIPT ENCODING A LONG COLLAGENOUS DOMAIN IS REGULATED THROUGH CHANGES IN ITS STABILITY ?

P. Chareyre, M.T. Besson, S. Hachouf, G. Bosquet

Centre de Génétique Moléculaire et Cellulaire, UMR CNRS 106, Université Lyon I, Villeurbanne, France.

Morphogenesis of the pupal wings of *Bombyx mori* is triggered during spinning of the cocoon by a sustained peak of 20-hydroxyecdysone which elapses on 4 days. Analysis of the developmental patterns of some markers suggests that, contrary to what occurs in *Drosophila*, the differentiation of the pupal wing starts probably during the last larval molts.

One of these markers, *BmColl*, encodes for a protein of the collagen super-family and the structure of the known region corresponds to that of a non-fibrillar collagen. No strict homology with a known collagen can be established and the C-terminal domain of this protein has no counterpart in libraries. In wing discs as in epidermis the transcript level is closely correlated to that of ecdysone. During the larval life, the accumulation in response to the hormone is rapid, dose-dependent, and can be obtained in vitro in absence of protein synthesis. Conversely, no *BmColl* transcript is detected in pupal wings, whatever the in vivo hormone level. Both the structure of the 3' end of the transcript and its accumulation following protein synthesis inhibition alone suggest that this accumulation might result, at least for part, from the stabilization of the messenger controlled by the hormonal status. A model is presented. Ecdysone control of development mediated by changes in mRNA stability might be more important than generally estimated.

14-033

TRANSCRIPTIONAL TUNING OF THE GENE ENCODING THE SILK PROTEIN P25 IN THE SILK GLAND OF BOMBYX MORI

E. Julien, B. Horard, P. Nony, A. Garel and P. Couble

Université Lyon 1-CNRS, 43 boulevard du 11 Novembre 1918, 69622 Villeurbanne, France

In the silk gland of *Bombyx*, the genes encoding silk proteins are expressed in either the posterior or the median cells.

To understand the mechanisms controlling regional specialization of transcription, we examined the promoter of P25, a posterior cell-expressed gene encoding a fibroin-associated polypeptide. The spatial specificity of expression could be reproduced on extrachromosomal copies of P25-LacZ fusion genes by *in vivo* functional assays using biolistic as means to transfect DNA into silk gland cells. The test of a series of mutated promoters showed that posterior cell-specific transcription strictly depends on the proximal SGFB cis-acting element, but not one other suspected upstream cis-elements.

Comparative *in vivo* DNaseI footprinting of P25 chromatin by LMPCR of posterior and median silk gland cells revealed a protection of the SGFB cis-element and of a Forkhead/CAAT-like cis-element at -40 in the active cells. Both approaches led to conclude that P25 transcriptional activation via SGFB, a silk gland specific factor present in both median and posterior cells, requires the action of another factor that governs posterior cell specificity. The two factors are under cloning at the moment.

14-035

OVEREXPRESSION OF BOMBYX MORI PROTHORACICOTROPIC HORMONE ACCELERATES THE SPEED OF KILLING OF A BOMBYX MORI NUCLEAR POLYHEDROSIS VIRUS MUTANT LACKING THE ECDYSTEROID UDP-GLUCOSYLTRANSFERASE GENE

J. Kobayashi, H. Ishikawa, K. Fujita, D.R. O'Reilly¹, S. Maeda², H. Kataoka³, S. Miyajima

Faculty of Engineering, Mie University, Mie, Japan - 1 Department of Biology, Imperial College, London, UK - 2 Department of Entomology, University of California, Davis, CA, USA - 3 Department of Agricultural and Environmental Biology, The University of Tokyo, Tokyo, Japan

The speed of killing of host insects of *Autographa californica* nuclear polyhedrosis virus (AcNPV) is increased by deletion of the ecdysteroid UDP-glucosyltransferase (*egt*) gene from the AcNPV viral genome. However, when the prothoracicotrophic hormone (PTTH) gene of *Bombyx mori* is overexpressed in *Spodoptera frugiperda* larvae using both wild-type AcNPV and an AcNPV mutant that lacks a functional *egt* gene, any further increase in the speed of killing is not observed.

In this study, we prepared three BmNPV mutants, Bmegt⁻ (a mutant lacking the *egt* gene), BmPTTH (a mutant expressing the mature *B. mori* PTTH subunit under control of the polyhedrin promoter) and BmPTTHegt⁻ (a mutant lacking the *egt* gene and expressing the mature *B. mori* PTTH subunit), and compared their effects on the speed of the killing infected *B. mori* larvae.

When the 4th and 5th instar larvae were infected with wild-type BmNPV and these three mutants, Bmegt⁻ killed larvae more quickly than did wild-type BmNPV, as had been previously observed with AcNPV. BmPTTHegt⁻, however, killed much more quickly than did Bmegt⁻, although BmPTTH killed at the same speed as did wild-type BmNPV. In addition, 5th instar larvae infected with BmPTTHegt⁻ displayed wandering and spinning behaviors much earlier than those infected with the other mutant viruses.

The results indicated that the effects of overexpressed *B. mori* PTTH on the speed of killing were suppressed when the *egt* gene was functional and that the differences between results obtained in *B. mori* larvae and in *S. frugiperda* larvae probably reflected the species-specific functions of *B. mori* PTTH.

DEVELOPMENT OF NEW METHOD FOR ARTIFICIAL INSEMINATION OF THE SILKWORM, *BOMBYX MORI*

Y.Takemura¹⁾, T.Kanda²⁾, H.Shinbo²⁾, Y.Horie¹⁾

1)Institute of Silkworm Genetics and Breeding, Ami, Inasiki, Ibaraki, Japan

2)National Institute of Sericultural and Entomological Science, Tsukuba, Ibaraki, Japan

Little has been known about the artificial insemination in Lepidoptera including the silkworm since the reports by Omura(1936). Recently, we succeeded in the artificial insemination of the silkworm using a special instrument developed by Kanda & Tamura(1991). The instrument consists of capillary tube , gas-cylinder, pressure regulator, magnetic valve and foot-switch. The sperm was collected from vesicula seminalis of newly emerged male moth or from bursa copulatrix of female moth immediately after natural copulation. The each 4-6 μ l of sperm suspension with extract of glandula prostatica or of sperm from b.copulatrix were injected into b.copulatrix of newly emerged virgin female moth. The inseminated female deposited normally fertilized eggs just as that of natural copulation. Number of eggs laid and fertilized, and fertility were not different those from natural copulation significantly. The addition of the extract of g.prostatica was essential for both activities of sperm motility and fertilization.

The hatchability of eggs from artificial insemination was satisfactorily as high as that from natural copulation . The similar results to the sperm from v.seminalis were obtained when the sperm from b.copulatrix was injected to female moth. It is also confirmed by genetical method that fertilization by insemination was not caused by parthenogenesis but by sexual reproduction. Although the fertility was still low, the fertilized eggs were obtained from female inseminated artificially with semen which had been stored in liquid nitrogen with cryoprotectant.

14-038

IMPROVEMENT OF ARTIFICIAL DIETS FOR THE SILKWORM REARING ON ARTIFICIAL DIETS THROUGHOUT THE WHOLE INSTARS

H.Shinbo, C.Hirayama, K.Konno, K.Watanabe

Department of Sericulture, National Institute of Sericultural and Entomological Science, Tsukuba, Ibaraki, Japan

It was generally considered that artificial diets could not be used for silkworm rearing throughout the whole instars for silk production, due to the cost of the diets. With the development of low-cost artificial diets using a linear programming method and breeding of polyphagous silkworm races with a high adaptability to the diets this practice may become possible. However, low productivity of cocoon has been pointed out as one of problems to be solved in the silkworm rearing on artificial diets throughout the whole instars.

We found that the efficiency of conversion of ingested diets into the cocoon shell is lower in the absence of mulberry leaf powder in the artificial diets than in the presence. Moreover, the effect of dried grass powder, such as orchardgrass, added in the diets on the growth, cocoon quality and dietary efficiency of the silkworm was found to be almost the same as that of mulberry leaf powder, indicating that grass powder can be used for the feed ingredient instead of mulberry leaf powder.

Subsequently, we found that the growth of the larvae and cocoon quality are closely related to water content of the artificial diets. Cocoon quality, especially the weight of cocoon shell and the percentage of cocoon shell lowered with the increase in the water content of the diet. The suitable water content ranged from 60 to 65%, although it was found to be somewhat different between the two silkworm races, "Shin-Asagiri" and "Habataki"

On the basis of the above results, we developed a new type of artificial diet for the grown (5th-instar) larvae.

14-037

EFFECT OF THYROXINE ON THE GROWTH OF THE SILKGlands AND COCOON QUALITY IN THE SILKWORM, *BOMBYX MORI*

I. Ahmad and S. Manaf

Inter University Center for Life Sciences, and Dept. of Biology, Institut Teknologi Bandung, Bandung, Indonesia

The effects of feeding selected mulberry leaves treated with thyroxine on the growth of the silk glands and cocoon quality in the silkworm, *Bombyx mori* were analyzed. The results show that thyroxine greatly enhanced the growth of the middle division of the silk glands. Thyroxine treatment during the fifth instar larvae resulted in the highest quality of the cocoon filament.

14-039

METABOLISM AND UTILIZATION OF AMMONIA IN THE SILKWORM, *BOMBYX MORI*

C. Hirayama, K. Konno, H. Shinbo

Department of Sericulture, National Institute of Sericultural and Entomological Science, Tsukuba Ibaraki, Japan

Silk production is the most important character in the nutritional physiology of the silkworm, *Bombyx mori*. There has been great interest in nitrogen metabolism and utilization in the silkworm in connection with silk production. The present study was aimed at determining if ammonia , a principal waste of nitrogen metabolism, could be utilized for silk protein synthesis and excreted as cocoon filaments by the silkworm. When diammonium citrate was supplemented in a diet containing only essential amino acids as nitrogen sources, growth of 5th instar larvae fed the supplemented diet was improved. The supplement produced marked effect on the growth of silk glands and resulted in a remarkable increase of several non-essential amino acids as glycine, alanine, serine, glutamine in larval hemolymph. By a tracer experiment using ¹⁵N ammonium acetate, utilization of a considerable amount of ammonia for silk production was revealed.

Next, presence of the pathway of ammonia assimilation in the silkworm was examined. When methionine sulfoximine (MS), a specific inhibitor of glutamine synthetase in plants, was injected in matured larvae of silkworm, ammonia concentration in hemolymph rapidly increased. On the contrary, glutamine concentration decreased. Incorporation of ¹⁵N ammonia into larval tissue proteins, especially silk protein, was strongly inhibited in the presence of MS. Spinning and development of larvae was also inhibited by MS. These results suggest that ammonia may be assimilated into amino acids in the silkworm via GS-GOGAT pathway as in plants or bacteria and finally voided as cocoon filaments.

14-040

PRACTICAL APPLICATION OF ARTIFICIAL DIETS FOR THE SILKWORM, *BOMBYX MORI*

H. Yanagawa

Department of Sericulture, National Institute of Sericultural and Entomological Science, Tsukuba, Ibaraki, Japan

Artificial diets were applied for the first time in sericulture in Japan in 1977 for the rearing of young larvae of the silkworm, *Bombyx mori*, in cooperative rearing houses. Although, about 50% of the young silkworms are reared on artificial diets rather than on mulberry leaves in Japan, the cost of artificial diets accounts for about 50% of the total expenses for the silkworm rearing from the 1st to 3rd instars.

On the basis of the results of nutritional studies, low-cost artificial diets for the silkworm have been developed by applying a linear programming method to the formulation of the composition of artificial diets. In parallel with the development of the diets, studies on the feeding response of the silkworms to the diets and its inheritance have been carried out and polyphagous silkworm races with a high adaptability to the diets have been bred.

Development of a new type of silkworm rearing system based on these methods is deemed important.

14-041

AMINO ACID ABSORPTION IN THE SILKWORM MIDGUT
B. Giordana, G. Leonardi, M. Casartelli, G.M. Hanozet¹, P. Parenti¹
Dipartimento di Biologia, Università degli Studi di Milano, Italy -
¹Dipartimento di Fisiologia e Biochimica Generali, Università degli Studi di Milano, Italy.

Lepidopteran larval midgut absorbs amino acids through the coordinated activity of goblet cells and columnar cells. The former have a vacuolar-type H⁺-ATPase coupled to a K⁺/2H⁺ antiporter that generates a transepithelial voltage (DP) and a luminal K⁺ accumulation. In the latter the K⁺ electrochemical gradient is exploited by K⁺/amino acid symporters. These transport proteins operate in extreme chemical and physical condition, since pH value in the lumen reaches 12 units and DP across brush border membrane (BBM) exceeds 180 mV. We have measured the K⁺/leucine symport activity in BBM vesicles from *Bombyx mori* with varying pH and DP. The activity of the symport increases from pH 7.2 to pH 10.8, is poorly affected by intravesicular pH and is strongly activated by PD. Moreover alkaline pH also affects the efficiency of the transport, i.e. the accumulation of the amino acid. By fitting the data to a new implemented computer program that simulates the time course of amino acid uptake we evidenced that, in our experimental conditions, an important factor responsible for an increase in efficiency is the value of the initial uptake rate. Initial velocity increased more than 80% by passing from pH 7.2 to pH 10.8. The effect of external pH was qualitatively similar when analysing amino acid uptake in anterior, middle and posterior midgut. However, the symport is expressed unevenly along the midgut with the posterior region retaining the highest specific activity owing to higher efficiency and higher initial uptake rate. Several kinetic experiments support structural differences of the transport proteins along the midgut. The relevance of other factors able to modulate the symport activity in the silkworm (substrate specificity, hormones, and starvation) will be discussed.

14-042

UTILIZATION OF GRASS POWDER AS AN ARTIFICIAL DIET STUFF FOR SILKWORM (*BOMBYX MORI* L.)

K.Y.Seol and S.J.Hong

Department of Applied Entomology, Sericulture & Entomology Research Institute, RDA, Suwon, Korea

Utilization of some kinds of grass (ryegrass, Italian ryegrass, orchardgrass, alfalfa and white clover) was tried as a material of artificial diet for silkworm.

The nutrition value of the grasses used was analyzed for adjusting the diet composition in accordance with the nutritional requirement of silkworm. Mulberry leaf powder of a basal diet for silkworm was substituted by 10%, 20% or 30% of grass powder. Moisture content of the diets was ca. 74% and the pH in the range of 4.4 to 4.9, which were generally the same level as those of diet on the market.

Feeding the diets containing each of the grass powder from the 1st instar, the rearing results were superior to the feeding from the 2nd or 3rd instar, but the larval ingestion became deteriorated and the larval duration longer as the quantity of grass powder in the diet increased. On the other hand, the number of feces during the 5th instar was in negative correlation with the content of grass powder in the diet and in positive correlation with the cocoon quality.

In conclusion, the diet containing ryegrass or white clover was superior to those containing the other grasses in the larval ingestion. Therefore, the ryegrass and white clover powder were recommended to be utilized at the level of 10~20% in the diet as materials of artificial diet for silkworm.

14-043

DEVELOPMENT AND UTILIZATION OF ARTIFICIAL DIET FOR SILKWORM IN KOREA

K.Y.Seol

Department of Applied Entomology, Sericulture & Entomology Research Institute, RDA, Suwon, Korea

The earliest development of an artificial diet for silkworm was accomplished by a research team of KIST(Korea Institute of Science & Technology) in 1971. Since 1973, The cooperative rearing system for young silkworm with artificial diet has been studied in Sericultural Experiment Station(SES). Then, an automatic feeding machine was developed by KIST team and a new composition of artificial diet for silkworm was reported and named as SES-type diet by SES team.

In 1978, 4 varieties were selected as leading silkworm varieties suitable for artificial diet rearing and disseminated by SES. On the other hand, a mass application test of artificial diet in the farm was carried out with the scale of 150 boxes(silkworm eggs) in 1974, and the scale of the rearing with artificial diet has been increased year by year.

Besides, the present status, problems and outlook of the artificial diet rearing for silkworm in Korea will be presented and discussed.

14-044

SENSITIVITY OF FIBROIN IN SILK GLANDS OF *BOMBYX MORI* TO DIETARY PROTEIN LEVELS

X. Nirmala and **M. Krishnan**, Department of Biotechnology, Bharathidasan University, Tiruchirappalli 620 024. INDIA

Fibroin is the major silk protein produced by the posterior silk gland and stored in the middle silk gland during the fifth instar development. Fibroin gene expression is known to be under the control of hormones and nutrition. The evidence for the nutritional regulation of silk gene expression is the increase in cocoon weight and shell weight when silkworm larvae are supplemented with nutrients like aminoacids, carbohydrates or proteins. The present study is aimed to identify the effect of dietary protein levels on the accumulation of fibroin in *Bombyx mori*. Feeding the chosen hydrolysed soy protein to silkworm larvae at the rate of 2mg/female larva and 4mg/male larva/day during the fifth instar development increased the total weight of silk glands. Parallel to this an increase in the levels of fibroin heavy (H) and light (L) chains were also observed on a 4 - 15% SDS-PAGE and the same was confirmed by densitometric scanning. The homology of the H and L chain polypeptides in control and supplemented groups was confirmed by Western Blotting. Studies pertaining to the levels of fibroin (H & L) mRNA in silk glands with respect to dietary protein are under progress.

14-045

REARING THE SILKWORM LARVAE ON A NEWLY DEVELOPED ARTIFICIAL DIET, PELLET DIET

Y. Horie, **M. Sudo**
Institute of Silkworm Genetics and Breeding, Ami, Inashiki, Ibaraki, Japan

The new type of artificial diet for the silkworm, pellet diet, was developed. The new method for the preparation made possible to prepare the diet from the mixed powder in only one process of the twin-screw extruder under a high temperature and pressure for short time. This processing resulted in the formation of the pellet diet in which many babbles were contained. By dipping dry diet in an appropriate amount of water, the wet diet can be prepared instantly with ease. The basal composition of diet was designed by linear programming. Two kinds of diet in which the content of mulberry leaf powder was varied according to the silkworm strain, normal and polyphagous strains, were used. Using half-grown larvae reared on the wet diet during their young stages, the newly ecdysized 3rd or 4th-instar larvae were fed on the pellet diet. Then, the newly ecdysized 5th-instar larvae were continued to feed on the fresh mulberry leaves. The results were evaluated by comparing with those from the control in which the larvae were reared on the wet diet until the end of 4th instar by following on mulberry leaves in the 5th instar. The larval growth, survival and cocoon quality were not so much different between two groups. These results show that the pellet diet is practically available in the place of the usual wet diet, in particular for rearing the 3rd and 4th instar larvae. This diet is useful for making simple the diet processing and for labor saving in diet supply to the larvae.

14-046

STUDIES ON INTEGRATED PACKAGE FOR REARING OF TASAR SILKWORM, *ANTHRAEA MYLITTA* D.

S.K.Mathur, **V.K.Verma**, **C.M.Bajpeyi**, **B.R.R.Pd.Sinha** and **S.S.Sinha**
Central Tasar Research and Training Institute
Ranchi - 835 303 (Bihar) India.

A B S T R A C T

Based on research findings at Central Tasar Research and Training Institute - Ranchi, an integrated package has been developed for rearing of tasar silkworm, *Antheraea mylitta* D. in order to harvest considerable yield with quality cocoons. The package includes - methods for maintenance of chawki garden and economic plantation, control of gall infestation, foliar spray of urea to increase leaf quality, brushing schedule, pre-requisite for rearing, incubation of eggs, young age rearing on chawki garden under nylon net, late age rearing techniques, method of harvesting and storage of cocoons.

Rearing with the integrated package has shown a significant gain with regard to Effective Rate of Rearing (16.52%), cocoons/Dfl. (22 cocoons i.e., 60.31%) and absolute silk content per Dfl. (146.47%) over conventional technique.

The paper also contains comparative economics of tasar silkworm rearing which proves the advantages of the package of improved techniques vis-a-vis conventional technique.

14-047

BIODIVERSITY AND BIOGEOGRAPHY OF SILKWORM RACES IN THE NORTH-EASTERN REGION OF INDIA.

B.Gogoi, **B.C.Goswami**.¹

Department of Botany, Sonari College, Sonari, Sibsagar, Assam, India-1 Department of Botany, Gauhati University, Guwahati, Assam, India.

The North-Eastern Region of India is one of the most focal region of the world having maximum genetic diversity due to its congenial sub-tropical, eco-climatic and geographical position. The region has a distinctive position in the world sericultural map because of its commercial culture of all the four silkworm races namely Muga (*Antheraea assama* Westwood), Eri (*Philosamia ricini* Boisduval), Tasar (*Antheraea mylitta* Drury), and Mulberry (*Bombyx mori* L.). Among these, golden yellow muga silkworm is found nowhere in the world except in Assam, a state of the North-Eastern Region. It is noteworthy to emphasize that the Region is the homeland of all the wild counterparts of the domesticated forms of silkworms and their various host plants. Moreover, other wild silkworm races are also available in the Region. This has made this Region the most potential for sericultural development in the world.

The paper deals with the distribution pattern, intensity, collection, identification, rearing and evaluation of certain wild silkworm races and the domesticated forms. The findings of this study may help in breeding and conservation of silkworm races in the Region.

PRODUCTION OF THE SILKWORM (*BOMBYX MORI* L.) EGGS IN JIANGSU PROVINCEL. Li, Y. Z. Zhang¹, R. D. Lu¹

Development Division, Sericultural Research Institute, Chinese Academy of Agricultural Sciences, Zhenjiang, Jiangsu, China - 1 Jiangsu Silkworm Seed Corporation, Wuxi, Jiangsu, China

Jiangsu province, the home of the silk, is one of the largest suppliers of the silkworm (*Bombyx mori* L.) eggs in China. At present, there are 41 silkworm seed farms among which include two first class basic farms to maintain the grand-parent and the great-grand-parent seeds (P2-P3) and six second class basic farms to produce parent (P1) eggs. Every year, these farms can release 20,000 disease-free-layings(dfls) of P2-P3, 2,800,000 dfls of P1 and around 6 million cases of the hybrid (F1) silkworm seeds. The qualified eggs produced in Jiangsu supply not only local farmers but also those of other provinces, and even they are exported to foreign countries.

To strengthen the silkworm seed production management, Jiangsu Silkworm Seed Corporation is authorized in the egg production plan, the quality control especially in inspection of *Nosema bombycis* and the price decision province-wide. Generally, the Corporation arranges the silkworm seed production plans for 41 grainages according to the orders given by the each county sericulture extension station which is in charge of surveying on the demands of the seeds, incubating the all eggs of whole county in the specific rooms, distributing the incubated eggs to the villagers and guiding them to rear silkworm as scientific methods.

Recent 40 years, the silkworm seed breeding has been made a great progress due to the scientific and technologic development and the silkworm varieties have changed for 4 times in a large scale in Jiangsu areas. The cocoon shell ratio has increased from 20% in 1950s to 25% at present, meanwhile, the cocoon filament length and the raw silk percentage of fresh cocoon has respectively increased from 1,000 m to 1,400 m and 14% to 20% for the spring season. It has been statistically showed that the major silkworm varieties extended in Jiangsu mainly bred from Sericultural Research Institute, Chinese Academy of Agricultural Sciences in Zhenjiang city.

POSTEMBRYONIC DIFFERENTIATION OF THE GONADS IN HONEY BEE (*APIS MELLIFERA* L.) QUEENS, WORKERS AND DRONES

K. Hartfelder, C. Heppeler, I.C. Schmidt Capella, S. de O. Tozetto Klein, A. Rachinsky

Zoologisches Institut, LS Entwicklungsphysiologie, Universität Tübingen, Tübingen, Germany

Sex- and caste-specific morphogenesis of the larval gonad is a prerequisite for the realization of different reproductive strategies in drones and queens on the one hand, and for reproductive division of labor between a fully fertile queen and nearly sterile workers on the other. As compared to ovaries, development of the larval testes is considerably advanced. Already in the fourth larval instar, somatic and germ line cells in the testis tubules become distinguishable, and spermatogonia clusters with fusome-like structures can be found. Spermatocytes enter meiosis concomitant with the pupal moult, and shortly thereafter spermatids initiate spermiogenesis.

In contrast, differentiation of somatic and germ line cells in the ovary only occurs at the beginning of the fifth larval instar. A critical aspect of germ cell differentiation, the formation of syncytial germ-line cell clusters, was found to occur only in queens. Such clusters connected by a central fusome are not formed in most of the larval ovarioles in the worker ovary, instead histological signs of programmed cell death can be found. Formation of the fusomes coincides with caste-specific differences in juvenile hormone titers. Application of synthetic juvenile hormone induced cluster formation and prevented cell death in worker ovarioles. Whereas juvenile hormone appears to play a role in ovary differentiation at the cellular level, ecdysteroids were shown to be involved in the regulation of protein synthesis in the larval ovary. Makisterone A specifically inhibited the synthesis of a 29 kD heat shock-inducible protein. N-terminal microsequencing of this protein revealed homologies to actin-binding proteins, in particular the *Drosophila* Hu-li-tai-shao protein. Caste-specific ovary morphogenesis, thus, appears to depend on the correct timing of corpora allata and prothoracic gland activity.

COMPARATIVE STUDY ON MICROSPORIDIAS PATHOGENIC TO *BOMBYX MORI* L. (LEPIDOPTERA : BOMBYCIDAE)

K.W. HUANG, X.J. GUO, Z.Y. SHEN

Department of Pathology and Physiology, Sericultural Research Institute, Chinese Academy of Agricultural Sciences, Zhenjiang, Jiangsu, China

Four kinds of microsporidian spores were isolated from silkworms and wild insects, i.e. MA-1 and MD-1 from silkworm rearing production, Pha-M from a mulberry insect *Phyllobrotica armata* in Sichuan province and Ha-M from mulberry looper, *Hemerophila arilineata*, in Jiangsu province.

These microsporidian spores were compared in the following aspects respectively with *Nosema bombycis*, the typical pebrine pathogen of the silkworm. The results are as follows: 1) Spores size -- The spores of *Nosema bombycis* is ovoidal and $3.59 \pm 0.16 \times 2.07 \pm 0.12 \mu\text{m}$ in size, and the spores of MA-1 ovoidal and $3.79 \pm 0.17 \times 2.05 \pm 0.13 \mu\text{m}$, the spores of MD-1 elongate-ovoid and $4.06 \pm 0.20 \times 1.66 \pm 0.10 \mu\text{m}$, the spores of Pha-M ovoidal and $5.05 \pm 0.18 \times 3.07 \pm 0.13 \mu\text{m}$. 2) Exospore and total proteins of the spores -- The exospore protein of *Nosema bombycis* consists of 3 subunits with the molecular weight of about 32000, 26000 and 24500 Daltons respectively. The SDS-PAGE profiles of total proteins of *Nosema bombycis* spores contain at least 25 bands. Difference in protein components was found among those microsporidian (*Nosema bombycis*, MA-1, MD-1, Pha-M, Ha-M). 3) Pathogenicity to the silkworm and serological relationships -- Among these microsporidias, the Pha-M shows poorest pathogenicity to the silkworm while MD-1 shows the strongest pathogenicity. Except the Pha-M, other three microsporidias showed serological reaction with the antibody of *Nosema bombycis* spores. 4) Parasitizing site, pathological changes in infected tissues and cells and life cycle in the silkworm. Those microsporidias mentioned above can parasitize most tissues and organs in the silkworm. The cells parasitized with the microsporidias showed greatly hypertrophied, the nucleus smaller or squeezed to the edge of the cells, the cytoplasm not dyed by the Eosin because of cells full of the spores. The life cycles of the MA-1, MD-1 and Ha-M are similar to that of *Nosema bombycis* in the silkworm besides the spore formation of Pha-M was delayed slightly.

RACING FOR A QUEEN:

DRONE MATING FLIGHT AND MALE COMPETITION

Michael Gries

Institut für Bienenkunde (Polytechnische Gesellschaft),

Fachbereich Biologie, J.W.Goethe Universität, Frankfurt, Germany

Drones of the honeybee (*Apis mellifera* L.) perform mating flights under conditions of strong male competition. Often queens are pursued by large groups of drones, which persist behind her for some time. The subject of our study was the competitive behaviour of drones. A tethered queen dummy and stereoscopic video equipment were installed on a natural drone congregation area. The dummy was moved with constant speed on a circular trajectory. Drones were able to follow, mount and even copulate with the queen dummy. The size of the observed groups varied frequently. The behaviour of the drone during his mating flight seems to be influenced by the group of competitors. Singly approaching drones perform a chasing flight. They tend to fly almost straight to their target. In contrast, members of groups show complicated interactions, while competing for a better position in the drone cloud behind the queen. The shape, size and orientation of the cloud are fairly stable, but the internal drone constellation changes continuously. Drones are able to keep a certain minimal distance to each other. Nevertheless, occasional bumping can be observed too. Drones show a mating strategy which is split into two behavioural patterns, either chase or persistence. The described behavioural dichotomy reflects the rapid changes of mating situations under natural conditions. Reaching a freely flying queen requires a straight chasing flight. But while the queen is still engaged in copulation, a drone must keep his position for a next attempt.

14-052

REPRODUCTIVE ISOLATION AMONG SYMPATRIC ASIAN HONEYBEES

N. Koeniger, G. Koeniger, S. Tingek*

Institut für Bienenkunde (Polytechnische Gesellschaft),
Fachbereich Biologie, J.W. Goethe-Univ. Frankfurt a. M., Germany
*Agricultural Research Station, Tenom, Sabah, Malaysia

The genus *Apis* (A.) is a 'good' systematic unit and its synapomorphic characters concern many aspects of morphology, physiology and behaviour. Similarities in sex pheromones and mating behaviour cause deteriorating interactions which interfere with natural mating of the 'minority' species wherever the Western *A. mellifera* and the Eastern *A. cerana* are brought together. But in case of sympatric Asian honeybees naturally 3 or even 4 species are found closely together in many regions. Experiments and observation on reproductive isolation were undertaken in the area of Anuradhapura (North Central Province, Sri Lanka) with 3 sympatric species (*A. florea*, *A. dorsata*, *A. cerana*) and in Tenom (Sabah, Malaysia) with *A. dorsata*, *A. cerana*, *A. koschevnikovi* and *A. andreniformis*. In both locations the seasonal timing of mating was similar in all species: drone and queen production was synchronised and started parallel to a significant seasonal increase in availability of pollen and nectar. In Anuradhapura and Tenom times of daily mating flights were species specific, allowing each bee species its own, well separated time frame for mating. In *A. cerana* this time frame differed regionally and the median time for mating flights ranges from 12.00 (North Pakistan) to 16.30 (Sri Lanka). In *A. dorsata*, however, the mating time was similar in each place (on the basis of very few records only) and mating flights occur during a short period in the dusk of the evening. Differences in mating time form an effective 'pre-mating barrier' and are the main cause for reproductive isolation among sympatric *A.* species.

14-054

CURRENT STATUS AND EMERGING TECHNOLOGIES OF HONEY BEE REPRODUCTION

S.K. Narang

U.S. Department of Agriculture, ARS,
Beltsville, Maryland, USA

Molecular studies at the Beltsville Bee Research Laboratory (BBRL) have shown that there is significantly less genetic diversity in the U.S. commercial honey bee breeding population than in feral and old world populations. DNA-RFLP and PCR studies on sperms of individual drones are being used to determine the nature and extent of variability as well as to provide diagnostic markers for subspecies and populations.

DNA markers can be used for semen identification and certification. Artificial insemination of queens by using selected semen type would provide new ways of bee breeding. Commercial beekeepers could get into their stocks desirable genetic traits and genetic variability. However, suitable sperm cryopreservation methods are lacking.

The semen preservation methods are needed to establish bee sperm banks. The ongoing research at BBRL is focused on the development of bee germplasm preservation technology. This includes understanding the mechanism by which the sperm in the spermathecae remain viable for 3-4 years. Use of organ culture method for spermathecae is being looked into. In addition, methods for cryopreservation of eggs and early zygotes, as well as for DNA analysis on eggs, are being investigated. Results of these and other studies will be presented.

14-053

MALE REPRODUCTIVE ORGANS AND MODE OF MATING IN THE GENUS *APIS*

G. Koeniger, N. Koeniger,
Institut für Bienenkunde (Polytechnische Gesellschaft),
Fachbereich Biologie, J.W. Goethe-Univ. Frankfurt a. M., Germany

Mating in the genus *Apis*(A.) occurs in free flight and is further characterised by male monogamy and female multiple mating. Since the eversion of the huge endophallus leads to the paralysis of the drone, special mechanisms for coupling the partners are required to ensure sperm transfer.

In *A. mellifera* the coupling between the queen and the paralysed drone is achieved by the endophallus. In the stage of sperm transfer the endophallus is everted up to the cervix and the voluminous vestibulum contains the bulb with mating sign. After full eversion the drone falls to ground, leaving his sperm in the oviducts and the mating sign in the sting chamber of the flying queen. The mating sign is removed by the following drone prior to his own sperm transfer. After mating with about 10 drones the queen returns to the colony. About 5% of the spermatozoa collected in the oviducts will reach the spermatheca. Drones of the Asian cavity nesting honeybees (*A. cerana*, *A. koschevnikovi*) have an endophallus type similar to *A. mellifera* and these queens also collect a sperm number of at least about 10 drones in their oviducts during mating flight. In conclusion, mating and sperm transfer in all cavity nesting *A.* species seem to follow a similar pattern.

The drone's reproductive organs of the free nesting species are different. The dwarf honeybee drone does not produce mucus. The copulatory connection to the queen is attained by a special construction of the drone's hind leg. Queens returning from mating flight have no spermatozoa in their oviducts but only in the spermatheca. Thus sperm is apparently directly transferred into (the sperm duct of) the spermatheca by drones.

In *A. dorsata* microsatellite DNA analysis showed that queens are mated by an average of 30 drones. The sperm number per drone (2.5 mio) and the sperms in the spermatheca of queens (6 mio) seem to indicate sperm collection during mating in the oviducts. Further, the production of mucus may point to a type of sperm transfer in *A. dorsata* similar to the hive nesting bees. Nevertheless the *A. dorsata* endophallus with extremely long cornua and an elongated cervix has an unique morphology and its function during copulation is not yet understood.

14-055

REPRODUCTIVE COMPETITION IN THE CAPE HONEYBEE (*APIS MELLIFERA CAPENSIS*)

R.F.A. Moritz¹, P. Kryger¹, M. Allsopp²

¹ Inst. Ökologie, TU-Berlin, D-10587 Berlin, Fed. Rep. Germany

² Plant Protection Research Institute, Stellenbosch, 7599 Rep. South Africa

Reproductive dominance is usually linked to morphological caste in honeybees, *Apis mellifera*, with the queen as the reproductive and the workers as the infertile individuals. However, in queenless colonies of the Cape honeybee (*A. m. capensis*) workers can establish themselves as pseudoqueens expressing all features of reproductive physiology which are otherwise typical to the morphological queen caste. Within a few days after queen loss *A. m. capensis* workers can develop to a fully functional pseudoqueen producing female offspring through thelytokous parthenogenesis. Only very few workers produce offspring and the majority of the workers remains sterile. Since the queen is highly polyandrous and many subfamilies of supersisters coexist in the colony, there is a dramatic change in the genotypic composition of the colony after pseudoqueen take over. Most subfamilies disappear from the colony. The pseudoqueen determination appears to be under genetic control. Workers of the specific dominant subfamilies established themselves in independent trials as pseudoqueens, outcompeting workers of the other subfamilies. Strong intracolony genotype selection governs which workers are to become pseudoqueens and which remain sterile.

14-056

DRONE CONGREGATION AREAS AND MATING STATIONS FOR HONEY BEE QUEENS IN THE ALPINE MOUNTAINS

Pechhacker H., Austria

For a breeding program of honeybee queens in the Alpine areas good mating stations in the mountains are necessary for controlled mating. The site of the drone congregation areas around the mating station is important for the quality of this mating station.

Experiments were carried out in a steep mountain valley between Mariazell and Wildalpen in Austria. In the centre of the area Cordovan (cd) drones were kept, while black drones were flying only on the periphery. The virgin cd queens were placed for open mating in four directions at different distances (0, 2, 4, 6, and 8 km) from the centre. In all mated queens the worker offspring were controlled in order to find out the mating distance and the flight direction of the queens.

In Kärnten (near Möllbrücke) on a steep slope in an altitude of 1600 m cd drones were located. Up to 2000 m (3,3 km from the valley = 750 m altitude) and down to 1300 m altitude (2,7 km from the valley) 6 cd queens each at 100 m altitude were located for open mating. Dark drones were flying only at 900 m or lower.

The results show that the physiography seems to have a major influence on the queen's choice of a mating place. A close similarity between the orientation of drones (shown by F and H RUTTNER) and queens were demonstrated in these experiments. The mating distance was at maximum 6 km when the „view“ between queens and drones was open and lower than 2 km when there was a mountain or a narrow gorge („covered view“) between drones and queens. The difference in the altitude has no influence on the mating distance; cd-queens located for the mating flight at 2000 m altitude were also mated with dark drones like the queens at 1300 m.

14-058

COMPARISON OF NATURALLY AND INSTRUMENTALLY INSEMINATED QUEENS OF THE ITALIAN HONEYBEE (*APIS MELLIFERA LIGUSTICA*).

M. Lodesani¹, M. A. Vecchi², S. Tommasini³

Istituto Nazionale di Apicoltura, Bologna, Italy - 2 Istituto di Zooculture, Università degli Studi, Bologna, Italy - 3 Dipartimento di Biologia evoluzionistica sperimentale, Università degli Studi, Bologna, Italy.

This research project set out to examine a number of anatomic and physiological traits related to the type of mating (naturally mated = NM; instrumentally mated = II) in 57 2-year old queen honey bees of ligustica race.

Comparison between the number of ovarioles from the two ovaries (right and left) did not highlight any significant differences.

Both the weight of the queens (NM: $x=219\pm24$ mg; II: $x=222\pm30$ mg) and the number of ovarioles (NM: $x=345\pm38$; II: $x=351\pm42$) were not significantly different for the two groups. Despite this, the relationship between weight and the number of ovarioles was a differentiating element between queen bees with different mating method. There was no correlation between these two parameters for the NM queens ($r=-0.04$ $P=0.82$) but in II queens the correlation is positive and significant ($r=0.49$ $P<0.01$). There was no proportion between the size of the ovaries - divided into 3 categories, and the number of ovarioles. As regards ovary size, comparison of the two groups highlighted a different frequency distribution with a valuable higher proportion of II queens ovaries in the average category (II: 73.8%; NM: 57.6%). II queens also showed more uniform ovariole development. Our research suggests that a different ovariole functional status, growth cycles and functional rhythms are normal condition in every queen. The amount of sperm in the spermatheca was significantly higher for the NM queens (NM: $x=2.62\pm0.88$ millions.; II: $x=1.82\pm1.06$ millions).

14-057

DRONE CONGREGATION AREAS AND TIME OF MATING FLIGHT OF INDIGENOUS *APIS CERANA JAPONICA* AND IMPORTED *APIS MELLIFERA*

T. Yoshida

Honeybee Science Research Center, Tamagawa University, Machida, Tokyo, 194 Japan

The difference in the mating flight time of sympatric *Apis* species is thought to be a key factor in interspecific reproductive isolation. However, there is no detailed information about the interaction between indigenous *Apis cerana japonica* (Acj) and imported *A. mellifera* (Am). We compared the mating behavior of both queens and drones of the two species in the same biotope in Japan. Queens of Acj leave their hives between 13:15 and 17:00 while Am queens depart between 12:15 and 15:00. Queens with mating sign return as late as 14:45 to 16:35 for Acj, compared to 13:00 to 14:40 for Am. Drones fly from 13:15 to 16:30 for Acj, and from 11:30 to 15:00 for Am. In observations in Tokyo, both departure and mating flight times of Acj are 1.5 to 2 h later than those of Am. An Am drone congregation areas (DCA) was found 300 to 750 m south of our university apiaries. It is an open space surrounded by low trees. On the other hand, Acj DCA was found at 10 m above the canopy of *Quercus acutissima* trees.

Mating behavior was observed using a circling pole. Mounting behavior by Am drones on Acj queens was observed, and one drone even copulated. Therefore, Acj queens can mate with Am drones if they met. Am queens were inseminated with mixed semen of Am and Acj drones. The number of emerged Am workers corresponds well with the concentration ratio of Am spermatozoa. Interspecific copulation, if it ever occurs, has a deleterious effect because interspecifically-fertilized eggs do not hatch. When Am was first introduced into mainland Japan, however, it was suggested that both species had been separated chronologically due to the different allopatrically-developed mating timing. In addition to this, the reproductive isolation in the two species in Japan has been achieved also by spatial difference of mating place.

14-059

TEMPERATURE IN HONEY BEE BROOD CELLS AND ITS IMPACT UPON REPRODUCTION OF THE HONEYBEE PARASITE *VARROA JACOBSONI* OUDEMANS

B. Kraus

Universiteit Utrecht, Vakgroep Vergelijkende Fysiologie, Projectgroep Ethologie en Socio-oecologie, Utrecht, Netherlands

The parasitic mite *Varroa jacobsoni* Oudemans can only reproduce in capped brood cells of honey bees (*Apis*). Female mites lay up to 6 eggs, in intervals of about 24 h. Goal of the present study was to determine whether host and parasite have different temperature optima for developmental rate.

I. In field: The average temperature in brood cells during tests conducted from 8:00 p.m. to 8:00 a.m. ranged from 32.0°C to 35.4°C. In average temperature in brood cells located within the center of the brood nest was 1.8°C higher compared to temperature in cells located at the periphery of the brood nest. Besides position within the brood nest also ambient temperature, number of bees in the colony, the size of the brood nest and the number of bees per number of brood cells have a significant impact upon the temperature within the brood cell.

The results of measurements conducted with colonies of different honeybee races indicated, that differential race specific colony development causes differences in brood temperature during certain periods.

II. In incubator: Within the temperature range from 32°C to 35°C a temperature difference of 1°C during the capped brood phase results in a difference in development period of the bee brood of up to 33 h. If brood cells are kept at temperatures below 34°C, in some cases the increased development period of the bee brood is sufficient for even the 3rd-5th mite egg to reach adulthood. The percentage of mites producing offspring was not found to be dependent of temperature. In artificially infested brood cells kept at 33°C up to 4 daughter mites per mother mite reached adulthood whereas in brood cells kept at 35°C maximally 2 daughter mites per mother mite reached adulthood.

14-060

EXCHANGE OF *VARROA JACOBSONI* BETWEEN COLONIES OF *APIS MELLIFERA* AND *A. CERANA* SHOWS THAT NON-REPRODUCTION IN WORKER CELLS IS A TRAIT OF THE MITE. Willem J. Boot, Johan N.M. Calis, Joop Beetsma, Dong Minh Hai¹, Nguyen Kim Lan¹, Tran Van Toan¹, Le Quang Trung¹, Nguyen Hung Minh²
Department of Entomology, Wageningen Agricultural University, The Netherlands - 1 Bee Research and Development Centre, Hanoi, Vietnam - 2 University of Can Tho, Vietnam

In colonies of European *A. mellifera*, *V. jacobsoni* reproduces both in drone and in worker cells. In colonies of its original host *A. cerana*, the mites invade both drone and worker brood cells, but after invasion into worker cells they do not reproduce. This phenomenon of non-reproduction in worker cells is probably crucial for resistance of *A. cerana* to *V. jacobsoni*, because the population can only grow during periods in which drones are reared. To test if non-reproduction in worker brood of *A. cerana* is due to a trait of mite or a trait of the worker brood, mites from bees in *A. mellifera* colonies were artificially introduced into *A. cerana* worker brood and vice versa. About 80% of the mites from *A. mellifera* colonies reproduced, in naturally infested cells as well as when introduced into worker cells of *A. mellifera* and *A. cerana*. Conversely, only 10% of the mites from *A. cerana* colonies reproduced, both in naturally infested worker cells of *A. cerana* and when introduced into worker cells of *A. mellifera*. Hence, the phenomenon of non-reproduction in worker cells is due to a trait of the mites. Our results have large implications for selection programmes to breed less susceptible bee strains. They show that non-reproduction in worker cells may only appear if the mite population has evolved by natural selection, which may be the case in African and Africanized bees. In other cases, fitness of mites that reproduce in worker cells has to be measured to identify honey bee strains in which there is natural selection for non-reproduction in worker cells.

14-062

VOLATILE CUTICULAR COMPOUNDS OF EUROPEAN AND AFRICANIZED HONEY BEES WITH RESPECT TO THE ATTRACTIVITY TO THE PARASITIC MITE *VARROA JACOBSONI*
P. Aumeier & P. Rosenkranz
Landesanstalt für Bienenkunde, Universität Hohenheim, Stuttgart, Germany

Varroa mites are able to distinguish between several age classes of larval and adult honey bees. Reproductive *Varroa jacobsoni* females only invade brood cells containing bee larvae in the last instar shortly before capping. Also during their phoretic phase on adult bees, the mites show a clear preference behavior for nurse bees. Volatile chemical substances of the host cuticle are thought to be involved in this specific host recognition behavior. We compared the chemical composition and the *Varroa*-attractivity of cuticular extracts of larval and adult developmental stages. As there are reports that bees and larvae of the Africanized honey bee in South America are less attractive to the parasite, we also compared host stages of European and Africanized honey bees collected at the same site. Samples were taken from Africanized honey bees and *Apis mellifera carnica* bees in Ribeirao Preto, Brazil and from *Apis mellifera carnica* bees in Germany. Comparative chemical analysis of extracts were carried out by gaschromatographic methods. The preference behavior of single *Varroa* mites was tested in a laboratory bioassay where either living host stages were offered or extracts were presented on dummies. By this tests we could confirm the preference of *Varroa* females for certain host stages and for the corresponding extracts. The gaschromatographic analysis revealed differences in the chemical spectrum of extracts obtained from different larvae and adult bees. Quantity and composition of certain compounds within the unpolar fraction seem to be responsible for the specific chemo-orientation of the *Varroa* females. Although there are existing some odor differences between European and Africanized bees, we hardly could discover any race-specific preference behavior of the mites.

14-061

TRAPPING *VARROA JACOBSONI* IN DRONE BROOD COMBS OF *APIS MELLIFERA* AS A BIOTECHNICAL CONTROL METHOD
J.N.M. Calis, W.J. Boot, J. Beetsma, J.H.P.M. van den Eijnde¹, A. de Ruijter¹ & J.J.M. van der Steen¹
Department of Entomology, Wageningen Agricultural University, The Netherlands - 1 Research Centre for Insect Pollination and Beekeeping "Ambrosiushoeve", Hilvarenbeek, The Netherlands

Varroa mites invade drone brood cells 12 times more frequent than worker brood cells. Therefore, trapping mites in drone brood is a useful biotechnical control method. Currently, trapping of mites in drone brood is applied in normal colonies. Therefore, a substantial part of the mites will escape by invading brood cells on other combs than the trapping comb. Trapping mites in drone brood will be much more effective when it is applied during periods when no other brood is present in the colony. Under these conditions only 462 drone cells are needed to trap 95% of the mites in a colony of 1 kg bees^{1&2}. This knowledge was used to design a method to trap mites in pairs of colonies. One colony of the pair was made broodless. The brood was given to the other colony. This colony was split in a broodless part with the queen and a part in which a new queen was reared and that became broodless when all the old brood had emerged. This provided three times the optimal opportunity for trapping mites in drone brood: a broodless (part of a) colony. The effectiveness of the method was 93%. Thus, trapping mites in drone brood is an effective non-chemical alternative to control *Varroa* mites in honeybee colonies.

2. Calis J.N.M., W.J. Boot & J. Beetsma, 1994. Evaluation of *Varroa* control methods based on trapping mites in honey bee brood. In: A. Matheson (ed), *New perspectives on Varroa*. IBRA, Cardiff, UK, pp. 106-108.

14-063

CONSEQUENCES OF CHANGING HOSTS ON THE REPRODUCTIVE BIOLOGY OF THE PARASITIC HONEYBEE MITE *VARROA JACOBSONI*
Martin S. J.
Central Science Laboratory, National Bee Unit, ADAS Starcross, Staplake Mount, Starcross, Devon, England.
Difficulty in following individual mites throughout their life under natural conditions has meant that basic factors such as mite longevity and fecundity have often been estimated by indirect methods. This has resulted in a wide range of values without a cohesive picture emerging. This makes developing mite population dynamic models very difficult. Recent field work has demonstrated that the average number of reproductive cycles carried out by the mite may be double that of previous field studies. This increase may account for the rapid build up of mites sometimes observed in the field and offers some explanation for the wide range of values obtained in past studies. Further modelling of these mite populations has raised questions that may be answered by looking at the differences between the two bee hosts. The change of hosts has placed the mite in a new reproductive environment. This may have resulted in an imbalance between its reproductive and biological age. This may account for some of the abnormal reproductive behaviours observed in its new host.

14-064

COMMENTS ON THE ANTIQUITY OF HONEY BEE SUBSPECIES (HYMENOPTERA: APIDAE, *APIS MELLIFERA*)

Walter S. Sheppard, M. Cristina Arias

Department of Entomology, Washington State University
Pullman, Washington, 99164, USA

The *Apis cerana*-*Apis mellifera* cladogenesis is estimated to have occurred about one million years ago, based on comparative morphological, physiological and behavioral data. Other species within the genus are believed to have diverged much earlier. Analyses of mitochondrial and nuclear DNA sequences collected from a number of *Apis* species, lead us to postulate a much more ancient time of divergence for the *A. cerana*-*A. mellifera* clade. However, when calibrated to a *Drosophila* rate model of sequence divergence, mitochondrial sequence differences among *Apis mellifera* subspecies support comparatively recent origins for the subspecies groups. The implications of these seemingly incongruous conclusions to models of subspecies formation and phylogeography in *A. mellifera* are discussed.

14-065

POPULATION STRUCTURE AND PHENOLOGICAL ISOLATION IN HONEYBEES: THE AFRICAN PERSPECTIVE.

H.R. HEPBURN, S.E. RADLOFF

Departments of Zoology and Entomology and
Statistics, Rhodes University, Grahamstown, South
Africa.

The honeybees of Africa have been characterized morphometrically as eleven distinct subspecies at the continental macrolevel. Multivariate analyses of features of low (morphometrics) and high (pheromonal) heritability at the microlevel yield clusters of distinct populations within races throughout Africa.

The potential for gene flow among honeybee populations in Africa is largely structured by climate and the phenology of flowering. These drive the seasonal cycles of honeybee colonies including build-up, swarming and migration. The sum of the effects of the forces operating on honeybee colonies and their responses to them result in differing degrees of probability for the isolation of populations making them temporally allopatric. Whether these populations are in fact subspeciating is moot.

14-066

TESTING HYPOTHESES FOR THE EVOLUTION OF POLYANDRY IN THE HONEYBEE (*APIS MELLIFERA* L.) WITH SINGLE-LOCUS DNA-FINGERPRINTING

Peter Neumann, R.F.A. Moritz

TU Berlin, FB7, Institut für Biologie, Franklinstr. 28/29, 10587 Berlin, Germany

The honeybee queen mates with an extreme number of males, in some species exceeding 50 drones per queen. Here we use 40 *Apis mellifera* colonies, which were kept for performance evaluation, to test the different models for the evolution of polyandry (reviewed by Keller and Reeve 1994). The number of patrines of each colony was estimated with single-locus DNA-fingerprinting using four different loci. The number of effective matings per colony (ranging from 5 to 28.5) shows a positive correlation with the honey yield ($p < .05$). We found no evidence for a reduced susceptibility to parasites (tested organisms: *Varroa jacobsonii* and *Nosema apis*) as predicted by the theories of Hamilton (1987) and Schmidt-Hempel (1994). Moreover we found no increased variance for brood production in colonies with a lower number of patrines as predicted by Page (1980). Our results support the concept of increased colony fitness through genotypic variability capitalising on improved task specialization or greater homeotic capacity (Page and Robinson 1991, Crozier and Page 1985).

A NEW POLYMORPHIC AND DIFFERENTIATED ENZYME LOCUS: PEPTIDASE-2 IN EUROPEAN *APIS MELLIFERA*

P.Arduino, R.Prota¹, I.Floris², L.BulliniDipartimento di Genetica e Biologia Molecolare, Università di Roma
"La Sapienza", via Lancisi 29, I-00161 Roma, Italy - ¹ Istituto di
Ricerca sul Controllo Biologico dell'Ambiente, C.N.R., I-07100
Sassari - ² Istituto di Entomologia, Università di Sassari, via E. De
Nicola 1, I-07100 Sassari

Low levels of isozyme variation have been detected so far in European *Apis mellifera*. Three loci: malate dehydrogenase-1 (*Mdh-1*), esterase-3 (*Est-3*) and esterase-6 (*Est-6*) were successfully used in differentiating populations of different subspecies (Badino *et al.*, 1982, 1983, 1984, 1985; Bitondi and Mestriner, 1983; Marletto *et al.*, 1984; Sheppard & McPheron, 1986; Biasiolo & Comparini, 1990).

Data are presented here on peptidase-2 (leu-ala) locus. Its allele frequencies were compared among populations of *A. m. mellifera* (France and Corsica), *A. m. ligustica* (Piedmont, Latium, Calabria and Sardinia) and *A. m. sicula* (western and eastern Sicily). The *Pep-2¹⁰⁰* allele showed high frequencies (>0.90) in *A. m. ligustica* populations, whereas not reaching 0.30 in the *A. m. mellifera* samples, which showed a prevalence of *Pep-2¹¹⁰* (frequency 0.70-0.80). Population samples of *A. m. sicula* showed a distinct allele: *Pep-2¹⁰³*, at nearly equal frequencies with *Pep-2¹⁰⁰*. It is expected that this polymorphic and geographically differentiated locus will be useful, together with other molecular markers, to characterize different subspecies and populations of *A. mellifera* and to analyze hybridization and introgression phenomena.

MAPPING QUANTITATIVE TRAIT LOCI FOR HONEY BEE FORAGING BEHAVIOR

R. E. Page and M.K. Fondrk
Department of Entomology, University of California, Davis, CA, USA

Honey bees (*Apis mellifera* L.) forage for pollen and nectar and store surplus quantities in the nest. The amount of stored food materials is a result of behavioral decisions of workers to forage for pollen or nectar, the sizes of the loads they carry, the rates at which they forage, and the food consumption rate of the colony. We selected strains of bees for the amount of pollen they store. Within five generations, the high strain stored six times more pollen than the low strain. We then mapped two quantitative trait loci (QTL) that explained about 59% of the total phenotypic variance observed in a backcross population. These same two QTL were independently shown to have strong effects on the pollen and nectar load sizes of individual foragers.

14-070

THE IDENTIFICATION OF AFRICANIZED HONEY BEES: AN ASSESSMENT OF MORPHOLOGICAL, BIOCHEMICAL, AND MOLECULAR APPROACHES

T. Rinderer

US Department of Agriculture, Agricultural Research Service, Honey Bee Breeding, Genetics, and Physiology Laboratory, Baton Rouge Louisiana, USA

Africanized honey bees have spread through the Americas in the past 40 years. Desires to Monitor their progress, for survey and detection, regulation and research have lead to several identification approaches. Morphological procedures were developed in early studies of Africanized honey bees and have been improved to produce both rapid screening procedures for field use and laboratory procedures which are the officially authorized procedures of most countries and agencies throughout the world interested in identifying Africanized honey bees. Other approaches, especially biochemical and molecular ones, have use or promise as additional identification tools. Isozymes, mitochondrial DNA, RFLP, RAPID, microsatellite and minisatellite analyses of nuclear DNA, cuticular hydrocarbons, and non-specific proteins have all received experimental attention. Each approach has limitations in comparison to morphology although some have yet to be brought to their full potential.

14-069

POPULATION GENETIC STUDIES OF NATURAL HYBRIDIZATION AMONG AFRICAN HONEY BEES (HYMENOPTERA: APIDAE)

M.D. Meixner¹, W.S. Sheppard², N. Koeniger¹, F. Ruttner¹
¹ Institut für Bienenkunde (Polytechnische Gesellschaft), JW Goethe Universität, Frankfurt am Main, Germany - ² Department of Entomology, Washington State University, Pullman, Washington, USA

In mountainous and savanna regions of East Africa, a clear separation between honey bees inhabiting the mountain forests, *Apis mellifera monticola*, and bees of the savanna, *A. m. scutellata*, is found. This discrimination can be observed morphometrically and regarding the allozymes and the mitochondrial DNA of 43 samples studied. Samples classified as *A. m. monticola* have different mitochondrial haplotypes from *A. m. scutellata*. Also, *monticola* bees show a greater variability in their morphology and a higher degree of heterozygosity in their allozymes, compared to bees from the savanna. These results are discussed as consequences of a refugial situation of the mountain bee populations descending from a large pleistocene population. In two of the three areas studied, there seems to be some, but limited, gene flow between mountain and savanna bees. At Mt Elgon and Mt Kenya, only a few samples were found with the morphology and allozymes of one race, but the mtDNA of the other one. However, the situation in the third area is different. The morphological discrimination between mountain and savanna bees collected in the Ngong Hills is less distinct and the allozymes of all the bees collected here appear to be similar to *A. m. scutellata*. These findings are confirmed by the fact that in all the Ngong samples only the mtDNA haplotype of *A. m. scutellata* is present. The hybridization of the two races in Ngong is discussed as a consequence of environmental changes in the region, mainly by deforestation and agricultural activities of the local human population.

THE ORIENTAL ORCHID LURES THE JAPANESE HONEYBEE WITH NASONOV PHEROMONE MIMICS.

Hiromi Sasagawa¹, S. Matsuyama¹, R. Yamaoka², M. Sasaki³
Dept. of Physiol. and Behav., Natl. Inst. Seric. and Entomol. Sci., Tsukuba, Ibaraki, Japan, -1 Univ. of Tsukuba, Ibaraki, -2 Kyoto Inst. of Technol., Kyoto, Japan, -3 Tamagawa Univ., Tokyo, Japan.

Flowers of the oriental orchid (*Cymbidium pumilum* Rolfe: Cp) attract workers, drones, queen and swarming colonies of the Japanese honeybee (*Apis cerana japonica* Rad.: Acj), but not of the European honeybee (*Apis mellifera* L.: Am). In this study, a hypothesis that the flower scent mimics the Nasonov pheromone of Acj was tested.

The scent of Cp flowers was analyzed by GC and GC/MS and found to comprise acetone, acetophenone, 2-heptanone, 2-nonanone, benzaldehyde, n-heptanal, n-octanal, n-nonanal, linalool oxide (cis, trans) of both furanoid and pyranoid, (S)-(+)-linalool, benzoic acid, fatty acids. When bioassayed by a polyethylene bag method, a real flower attracted 97% of workers and drones, whereas 0.1 flower-equivalent extracts attracted 96% of Acj workers and drones. Neither a real flower nor the extracts was attractive to Am workers and drones. As the Acj workers gathered toward the Cp scent, they exposed their Nasonov glands. Acj Ng extract attracted 98% of Acj workers and drones. We conducted a chemical comparison between the Cp flower scent and the Ng extract. GC profiles of Ng extracts from Am and Acj were quite different. Linalool, furanoid and pyranoid type of linalool oxide (cis, trans), fatty acids were detected in both the flower scent and the Acj extracts. Authentic (S)-(+)-linalool and linalool oxide (furanoid and pyranoid type, cis:trans=1:1) attracted Acj workers and drones at the 5fg to 500ng level, however the standard fatty acids mixture did not attract Acj in the filed and bag test. On the other hand, linalool and linalool oxide did not attract Am workers or drones.

In conclusion, the oriental orchid was found to have the same components in its scent as Acj had in its Nasonov gland, that is, linalool and four types of linalool oxide.

14-072

OBSERVATIONS ON THE ACTIVATION AND PATHOLOGY OF ACUTE PARALYSIS VIRUS IN THE HONEY BEE *APIS MELLIFERA* L. (HYMENOPTERA: APIDAE)

C.H. Denholm, B.V. Ball, C.R. Bentley¹, P.J. Ham¹, H. Hurd¹, W.D.J. Kirk¹,

Department of Entomology & Nematology, IACR-Rothamsted, Harpenden, UK -1 Department of Biological Sciences, Keele University, Staffordshire, UK.

Acute Paralysis Virus (APV) commonly persists as a latent infection in honey bees and is only known to cause mortality in nature in colonies infested with the parasitic mite *Varroa jacobsoni* Oudemans.

In initial experiments APV was induced to replicate to lethal levels in latently infected adult hosts by the injection of foreign proteins (e.g. haemocyanin) into the haemolymph. Apyrase (a component of tick saliva) acts in a similar way, suggesting that secretions introduced into the host haemolymph during mite feeding interfere with the host immune mechanisms which normally suppress APV replication.

The injection of young adult bees with lethal doses of APV, together with foreign proteins (mimicking mite vectoring), changes the dynamics of virus replication, both quantitatively and temporally.

RESEARCHES ON THE TREATMENT OF SOME VIROSES AND MYCOSES OF HONEY BEE *APIS MELLIFERA* L.

S.V. Vernescu, S. Fendrihan

Research Institute for Plant Protection - Apidology and Useful Insects Laboratory -8, Blvd Ion Ionescu de la Brad Bucharest, ROMANIA

In the last ten years very dangerous diseases spreaded all over the world, damaging the honey bees colonies. The acute paralysis of bees is produced by a virus, identified and isolated in laboratory from infected bees and then inoculated as a low pathogenic strain in honey bees colonies. The authors obtained the immunisation of bees to "Wild" virus attack. The honey bees mycosis are produced by fungi from *Ascosphaera* and *Aspergillus* genera and they are treated now with chemicals and antibiotics which lead to a slow intoxication of bees and to pollution of bees products. The authors found by testing several antifungal products, a better treatment, nontoxic and easy to apply.

14-073

EFFECT OF PERORALLY GIVEN BIOLOGICALLY ACTIVE SUBSTANCE OF ANIMAL ORIGIN ON MICROSPORIDIOSIS INFECTED HONEY BEES (*APIS MELLIFERA*)

Tatiana M. Yefimenko

Petro Prokopovitch Apiculture Research Institute, Kyiv, 252627, Ukraine

Biologically active substances (BASs) isolated from different animal systems and organs possess stimulative effect permitting to use them in medicine and veterinary. In this report we present some data concerning a BAS preparation, RBS, isolated from cattle embryo tissues and its effect on healthy and Microsporidia-infected (MI) honey bees (HB), both insects infected in laboratory and naturally infected having been used. In our laboratory experiments HBs were twice fed with 0.1 % RBS containing 50 % sucrose syrup (immediately after infection and 10 days post MI); in field experiments HBs were fed with RBS three times with 14 days intervals. In laboratory tests insects of the same age were infected in July-August (10,000 spores/HB); our field experiments were made with HB families with natural infection occurred in May-June. We found that RBS had no therapeutic effect in laboratory experiments. Furthermore, some MI stimulation took place accompanied by higher mortality of RBS-treated infected HBs comparing to untreated infected ones, the latter having smaller spores according to morphometric data. These facts are well correlated with a conception of obligatory parasitism postulating that factors favourable for a host organism are also favourable for its parasites, the disbalance developed in host-parasite system killing one of this system members.

The use of RBS in natural HB families with low MI frequency stimulated rather host than parasite organism, the treated families became stronger comparing to control ones. So it is necessary to be careful when treating parasites-carrying insects with BASs. Such preparations are to be used in apiculture only for HBs slightly infected or treated previously with antinosemic drugs.

IDENTIFICATION OF A HONEY BEE BROOD PHEROMONE

Y. Le Conte¹, A. Mohammadi¹, L. Sreng², Jérôme Trouiller, A. Paris¹ and D. Crauser¹.

¹Station de Recherches de Zoologie et d'Apidologie, INRA, Site Agroparc, Domaine St Paul, F-84914 Avignon Cedex 9.

²Laboratoire de Neurobiologie - Communication Chimique. CNRS - LNB8., 31, Chemin J. Aiguier, F-13402 Marseille Cedex 09.

Apis mellifera workers perform many necessary complex parental behaviors according to the age, the caste and needs of the brood. There is evidence for a brood pheromone indicating presence and state of the larvae in the cells. Since a blend of ten fatty acid esters had been identified on honey bee larvae, four of them was characterized as a brood pheromone triggering the capping of the cells by the workers. The blend of esters vary in quantity and in proportion of each of the compounds as a function of the brood age and caste. Behavioral tests, performed in natural conditions using larval and pupal lures including the compounds released in an amount similar to the amount naturally found on the larval cuticle, showed that modulation in quantities and in proportions of each ester as a function of age represents a chemical signature of old or young larvae for the workers. These compounds are also present on the queen pupal cuticle, and three of them are involved in the recognition and acceptance, by the workers, of queen cells containing a pupa. Some of these esters can also modulate the feeding behavior of the workers to the larvae. More, they can also act, in experimental conditions, on the development of the hypopharyngeal glands of the workers and are involved in the inhibition of the queenless worker ovaries. Thus, the blend of esters is a releaser and a primer brood pheromone which can be considered as important components in the chemical ecology regulating honey bee society.

RADAR OBSERVATIONS AND REACTION TO QUEEN
PHEROMONE OF HONEY BEE DRONES (*APIS MELLIFERA* L.)
G.M. Loper, O.R. Taylor, Jr.¹, W.W. Wolf²
Honey Bee Research Laboratory Agricultural Research Service, U.S.
Department of Agriculture, 2000 E. Allen Rd., Tucson, AZ USA -
1 Department of Entomology, University of Kansas, Lawrence, KS
USA - 2 USDA-ARS, Rt. 5, Box 808, College Station, TX USA

Natural mating of honey bees occurs in the air, usually 10-25 m above ground sometimes at distances in excess of 3 km from the colony. Drones and queens both fly in the afternoon and drones in flight form flyways and drone congregation areas (DCA's). Our studies using a trailer-mounted X-band radar (9.4 gigahertz) documented the location of 18 km of flyways and 26 DCA's adjacent to a commercial apiary near Tucson, AZ.

The location of flyways was strongly influenced by local visual cues, especially tree-lines and roadways. The flyways were about 100 m wide (during maximum flight times) and were usually about 80 m to the side of tree-lines. The maximum height of drones in flyways was 21 m, whereas in DCA's they flew mainly from 30-50 m above ground (maximum height in a large DCA was 60 m). DCA location also appeared to be influenced by visual cues; abrupt changes in or termination of the visual cues seemed to induce the formation of DCA's. Some DCA's were consistently "bigger" either in area or numbers of drones than others.

Synthetic 9-ODA (queen substance) was used in the radar tests to confirm the presence of drones. In separate tests, other queen pheromone components (9-HDA, HOB, HVA) were tested at both 1 queen equivalent (Qeq) and at 10 Qeq and found to have no attractiveness to free-flying drones. However, drones responded positively when downwind 420 m from a mated queen and 800 m from a concentrated source of 9-ODA.

EFFECTS OF TWO PROTEINASE INHIBITORS ON DIGESTIVE
ENZYMES AND SURVIVAL OF HONEY BEES, *APIS MELLIFERA*
L.A. Malone, E.P.J. Burgess and J.T. Christeller
Horticulture and Food Research Institute of New Zealand Ltd,
Auckland and Palmerston North, New Zealand.

Proteinase inhibitors have been shown to be potent plant defense factors against insects and their effectiveness when incorporated into transgenic plants to confer pest resistance has been demonstrated. Proposals to use such plants as part of an integrated pest management plan must take into account their effects on pollinator insects such as the honey bee.

Two endopeptidase inhibitors, BPTI (bovine pancreatic trypsin inhibitor) and SBTI (Kunitz soybean trypsin inhibitor) were found to significantly reduce the longevity of adult honey bees (*Apis mellifera* L.) fed the inhibitors *ad lib* in sugar syrup at 1.0%, 0.5% or 0.1%, but not at 0.01% or 0.001% (w:v). Bees were taken from frames at emergence, kept in cages at 33°C, and provided with a pollen/protein diet, water and syrup. *In vivo* activity levels of three midgut endopeptidases (trypsin, chymotrypsin and elastase) and the exopeptidase leucine aminopeptidase (LAP) were determined in bees fed either BPTI or SBTI at 1.0%, 0.3% or 0.1% (w:v) at two time points: the 8th day after emergence and when 75% of bees had died. LAP activity levels increased significantly in bees fed with either inhibitor at all concentrations. At day 8, bees fed BPTI at all concentrations had significantly reduced levels of trypsin, chymotrypsin and elastase. At the time of 75% mortality, bees fed BPTI at each concentration had reduced trypsin levels, but only those fed the inhibitor at the highest dose level had reduced chymotrypsin or elastase activity. Bees fed SBTI at all concentrations had lowered trypsin, chymotrypsin and elastase activities at both time points.

14-078

FLATLY SPUN COCOONS: PRODUCTION METHOD, CHARACTERISTICS AND ITS USE FOR HUMAN WELFARE

S. Ishiko¹, M. Sumida²

Daioh-In Temple, Myoh-Shin-Ji Temples, Kyoto, Japan - Department of Applied Biology, Kyoto Institute of Technology, Kyoto, Japan

A special silkworm race named 'Mayu-gami-ko' in Japanese meaning 'a silkworm race to produce flatly spun cocoons' was bred by the first author by crossing several silkworm varieties. Subsequent inbreeding for approximately seventy generations using an artificial diet as a sole diet fixed the race and its diet taste. By combining a silkworm rearing system on an artificial diet and aseptic rearing techniques, a new method to produce flatly spun cocoons on a plant scale was established that is free from anxieties such as unstableness of diet supply due to inappropriate weather or occurrence of insect disease.

Flatly spun cocoons usually take a form of a sheet like papers in sizes and shapes needed for various purposes and are composed of multiple layers of long silk threads attached together with natural glue protein called sericin. Its transparency makes the written figures on it look like floating in the air.

Flatly spun cocoons, now named 'San-ken-shi' in Japanese meaning 'a paper made of flatly spun cocoons of silkworms', can be used for the human welfare just like a Japanese paper; materials for calligraphy, paintings, arts, ornament, clothes, artificial leather, athletic goods, architectural interior, and medical science.

FT-IR STUDIES ON FIBROIN SECONDARY STRUCTURES OF WILD SILKWORMS

M. Miyazawa¹ and M. Sonoyama²

Department of Insect Technology, National Institute of Sericultural and Entomological Science (NISES), Tsukuba Ibaraki, Japan - 1 Material Science Laboratories, Toray Research Center, Inc., Ohtsu Shiga, Japan - 2

The feasibility of silk fibroin for applications in high-performance fibers and biomaterial membranes depend largely on our knowledge of the structures of this natural product, which is critical for processing. FT-IR measurements of wild silkworm fibroin have been carried out to investigate fibroin structures. The curve-fitting analysis have been employed to estimate the secondary structure components with Fourier self-deconvolution procedures. These data showed that fibroin of *Samia cynthia ricini* have 45.5% helix, 17.0% sheet, 26.5% turn, and 11.0% disordered structures. Comparison of structures with other species will also be discussed.

14-079

THE MAIN TREND OF TUSSAH PRODUCTION OF LIAONING

Wang Wen-hang

(Department of Agriculture, Liaoning Province, Shenyang 110094, China)

Bu Ying

(Shenyang University, Shenyang 110094, China)

Tussah (*Antheraea pernyi*) is one of the peculiar biological resources of China, and is one of the economic insects which have great value in development. The tussah cocoon yield in Liaoning is 80% of that of China, and 70% of that of the world. It plays an important role in the tussah production of China and even of the whole world.

The main trend of tussah production in Liaoning will be: to pave a new way of comprehensive exploitation and multi-graded increment that means to develop silkworm farms fully and to process the tussah (including silkworm chrysalis, silk moths, silkworm eggs and larva) and silkworm excrement into biological products, such as insect made foodstuff, health products and biomedicines in order to increase benefits and serve the mankind; to pave a new way of intensive development with high-yield, high-quality and high-benefit that means to rise the labor productivity and the land output rate by improvement of tussah raising-tech, heighten of diseases prevention and curement ability, breeding a tussah of good strain; to pave a new way of ecological sericulture, that means to strengthen silkworm farms by improving its vegetation density and okra's canopy density in order to accomplish a better circle of ecological beneficial result on silkworm production.

STUDIES ON DOMESTICATION OF WILD TASAR SILKWORM
ANTHRAEA MYLITTA D - PERFORMANCE OF INDOOR REARED
YOUNG AGE SILKWORMS

S.K.Mathur, S.Radhakrishnan, C.M.Bajpeyi,
B.R.R.Pd.Sinha and S.S.Sinha

Central Tasar Research and Training Institute
Ranchi - 835303 (Bihar), India.

A B S T R A C T

In order to develop a method for indoor rearing of tropical tasar silkworm, *Antheraea mylitta* D., stagewise indoor rearing was conducted in wooden trays in room condition. Indoor rearing upto II stage followed by outdoor rearing on regular economic plantation of *Terminalia arjuna* has shown significant gain with regard to effective rate of rearing (13.43 - 18.16%) and absolute silk content per Dfl. (96-102.77%) over control (i.e., throughout outdoor rearing). The other economic characters of cocoons such as single cocoon weight, single shell weight and silk ratio were found to be at par with control. A decremental trend was observed in all the above parameters when rearing was conducted indoor for longer duration with minimum when reared upto cocooning.

The results indicate that indoor rearing may be conducted upto II stage and thereafter, larvae may be transferred to regular economic plantation to increase survivability and cocoon yield. Further studies with modifications are under progress to develop some appropriate technologies for domestication of tasar silkworm, *Antheraea mylitta* due its economic importance.

14-082

STUDIES ON ASSOCIATION BETWEEN COCOON WEIGHT AND SHELL WEIGHT OF MUGA SILKWORM (*ANTHRAEA ASSAMA* WESTWOOD) DURING DIFFERENT BROODS (LEPIDOPTERA : SATURNIIDAE)

G.S.Yadav¹, B.C.Goswami², S.S.Sinha¹

1. Central Tasar Research & Training Institute, Piska Nagari Ranchi (Bihar) India

2. Department of Botany, Gauhati University, Guwahati, Assam, India.

The extent of association between cocoon and shell of *A. assama* differed significantly during different seasons for both the sexes (male 'r'=+0.6035., female 'r'=+0.6887., df 48, both significant at 1 p. c level). The regression function of cocoon with shell was $Y = -0.02543 + 0.08212 X$ for male and $Y = -0.07756 + 0.07488 X$ for female during different broods. Both the variables of Jethua (May-June), Katiya (Oct-Nov) and Aherua (June-July) crops showed close and uniform affinity with the regression line and deviation recorded was maximum during Jarua (Dec-Feb). The factorial analysis of variance adduced the fact that association (A) of cocoons and shells was significant in both the sexes in all the broods. The interaction was significant at 0.1 p.c. level only in the case of female cocoons.

14-084

INSECT SPECIES WHICH ACCOMPLISH CROSS POLLINATION IN *RUBUS ULMIFOLIUS* SHOTT, 1818 (ROSACEAE)

F.G. González, C. Ornos, M.D. Martínez

Departamento de Biología Animal I (Entomología), Facultad de Biología, Universidad Complutense, Madrid, Spain

The reproductive strategies of *Rubus ulmifolius* Schott, 1818, which lead to allogamy, are based on a great range of factors which attract insects and lead to cross pollination. The morphological and structural of traits of the flowers are added to the offer of nectar and pollen allowing these rewards, to be available for a variety of insects.

The *Rubus ulmifolius* flowers received 1028 visitors (excluding *Apis mellifera* Linnaeus, 1758). They were selectively collected by an entomological net, during the years 1994 and 1995, in the flowering period of the plant. The localities are in Madrid (Spain): Casa de Campo (Madrid City) and Torremocha del Jarama (Northeast Madrid Province).

71 per cent of the collected insects are pollinators of this plant, and they belong to several families of the orders Hymenoptera, Coleoptera, Diptera and Lepidoptera.

The main pollinators of *Rubus ulmifolius* are bees (Hymenoptera, Apoidea), a 78 per cent of the total of the pollinators found, more than 45 species.

Wild bees are the most important group implied in the cross pollination of this plant, due to their special structural pollen-gathering features and their elevated rhythm of activity. This, besides their diversity and abundance.

14-083

Lac Z GENE EXPRESSION IN *BOMBYX MORI* EMBRYONIC TISSUES USING A DENSONUCLEOVIRUS.

J.-L. Thomas, B. Mauchamp, V. Tournadre, and G. Chavancy. (UNS/INRA 25 Quai J.J. Rousseau 69350 La Mulatière, France).

In an attempt to obtain germinal transgenesis in *B. mori* we examined integrative potentiality of Densonucleovirus of *Jujonia coenia* as a vector. The viral genome was cloned in pBR322 and the construct named pBRJ (1). A recombinant viral genome was obtained by inserting *lac Z* reporter gene in EcoRV unique site, under viral promoter control. This construct named pBRJlac Z allows easier expression studies (2).

We inoculated this vector in eggs 3 to 5 hours after laying near the micropyle and examined LacZ gene expression at different stages of embryonic development.

Expression of the reporter gene was observed in vitellophages for each experiment and in some time in tissues of two, four and ten day old embryos. For two day old embryos the nature of expressing tissues was not determined, but we observed, both in four and ten day old embryos expression in epidermal cells and in ten day old embryos expression in silk gland for one of them and in trachea for some of the others. However it was difficult to reproduce these results and in positive embryos the somatic expression frequency remained very low (<1%) and if it correlates the presence of viral genome, we can assume that it was too low for obtaining the statistical transgenesis of germinal cells. Currently we are studying the presence of viral sequences in genomic DNA of inoculated reared larvae by Southern blot.

POLLINATION OF GREENHOUSE TOMATOES (*LYCOPERSICON ESCULENTUM* MILL.) (SOLANACEAE) WITH THE SOLITARY BEE *OSMIA CORNUTA* LATR. (HYMENOPTERA, MEGACHILIDAE).

A. Felicioli, A. Rossi, M. Pinzauti

Dipartimento di Coltivazione e Difesa delle Specie Legnose, Sezione di Entomologia Agraria, Università degli Studi di Pisa, Pisa, Italy.

The possibilities of using the solitary bee *Osmia cornuta* Latr. as a pollinator of tomatoes (*Lycopersicon esculentum* Mill.) under confined environmental conditions was investigated.

The effect of the osmia-pollination was compared with natural self-pollination. The effectiveness of pollination was determined by measuring the percent of fruit-set on the first two trusses of the plants.

Fruit-set in osmia-pollinated plants resulted significantly higher (90,98%) than in the natural self-pollinated ones (50,6%). The *Osmia cornuta* did not increase its population but readily accepted to feed on artificial flowers filled with syrup and then visited the tomato flowers and pollinated them successfully. The analysis of the pollen provisions collected from the osmias artificial nests confirmed that the bees visit the tomato flowers and gather pollen from them.

These preliminary observations make the Megachilid bee *Osmia cornuta* an interesting alternative pronubial insect for pollination of tomato plants cultivated in confined environments.

14-086

WHEN FOREIGNERS MEET: BEHAVIOURAL INTERACTIONS BETWEEN AN ENDEMIC HOVER FLY (DIPTERA: SYRPHIDAE) AND INTRODUCED POLLINATORS (HYMENOPTERA) IN NEW ZEALAND
G.L. Lövei, J.M. Hickman¹
HortResearch, Palmerston North, New Zealand - ¹ Department of Biology, University of Southampton, Southampton, United Kingdom

Hover fly larvae can be important natural enemies of insect pests in many crops; the role of bees as pollinators is also of vital importance. In New Zealand, the most common hover fly is the native *Melanostoma fasciatum*; the native pollinator fauna is poor and honey and bumble bees have been introduced for this purpose. Both groups feed on pollen and nectar and interference may occur between them. It is important to devise management techniques that maximise the potential of both groups of organisms. The flowers of *Phacelia tanacetifolia* (Hydrophyllaceae) attract both groups. In this experiment, interactions between bees and hover flies on *Phacelia*, using both individual plants in pots and small plots, were studied. Techniques used included censusing of bees and hoverflies to obtain data on number of visits, visiting times, and flower choice; observations of the behaviour of individual insects, and comparisons of hoverfly behaviour in bee exclusion zones and control areas. Preliminary results suggest that although there may be some disturbance of feeding hoverflies by bees, weather conditions, especially temperature, and different diurnal activity patterns, are also of importance in dictating the peak foraging periods of each species. The implications of the results for management of field margins and flowering strips are discussed.

SEMIOCHEMICALS IN THE JAPANESE HONEYBEE, *Apis cerana japonica* Rad.
S. Matsuyama, T. Suzuki, Hiromi Sasagawa¹
Institute of Applied Biochemistry, University of Tsukuba, Tsukuba, Ibaraki, Japan - ¹ Department of Physiology and Behavior, National Institute of Sericultural and Entomological Science, Tsukuba, Ibaraki, Japan.

In marked contrast to the European honeybee, *Apis mellifera* L. (Am), our knowledge on the chemical ecology of the Japanese honeybee, *Apis cerana japonica* Rad. (Acj) is limited. Therefore, comparative studies have done on the Nasonov gland, sting gland and head extract of Am and Acj by GC, GC/MS and by behavioral assays. In the Nasonov gland extract of Am, the presence of seven previously identified Nasonov pheromone was confirmed. On the other hand, Acj extract gave none of these compounds. Instead, linalool and linalool oxide (*cis* and *trans* of both furanoid and pyranoid) were identified. In a laboratory bioassay, Acj workers were attracted (52-94%) to authentic linalool oxide (5-500ng). Sting gland extract of both species gave isopentyl acetate and (Z)-11-eicosen-1-ol as major components. The absolute amounts of these two compounds found in Acj sting gland were lower than those in Am extract. Isopentyl acetate elicited alerting behavior in both species. 2-Heptanone was identified in head extract from both species. This compound is known to exist in mandibular gland of Am worker and is regarded as one of the alarm pheromone. The survey on the biological function(s) and the origin of 2-heptanone in Acj is now underway.

INFLUENCE OF GRASSLAND MANAGEMENT ON POLLINATING HYMENOPTERA.
M. Hirsch, V. Wolters, G. Bauschmann
Institute of Zoology, Department of Animal Ecology, Justus-Liebig-University of Giessen, Germany.

The effect of management practices on pollinating insects of grasslands (Wetzlar, Germany) was investigated by means of yellow, white and blue water traps. The sampling areas form a small scale pattern of differently managed orchards and meadows (sheep-pasture, moving-pasture, one-, two- and multiple-moving-meadow). The results of the ANOVA show that bees (Apoidea) and other aculeate apocritans reached highest density on sheep-pasture. For parasitic and gall-forming Hymenoptera, in contrast, no significant effect of management practices could be established. Significant taxon specific differences in the preference for colors could be demonstrated. Bees and other aculeate apocritans significantly preferred white traps. Bees were additionally strong attracted by blue traps. Parasitic and gall-forming Hymenoptera, in contrast, preferred yellow traps. This suggests that the exclusive use of yellow traps in many field studies on pollinating insects may be inadequate. In conclusion, our data show that Hymenoptera significantly respond to differences in management practices on a very small scale. This opens up new perspectives for the conservation of insect communities of grasslands.

14-089

THE HONEY BEE (*APIS MELLIFERA* L.) AS PESTICIDE BIOINDICATOR. EVALUATION OF THE DEGREE OF POLLUTION BY MEANS OF ENVIRONMENTAL HAZARD INDEXES
C. Porcini, V. Colombo¹, G. Celli
Istituto di Entomologia "Guido Grandi", Università degli Studi di Bologna, Bologna, Italy - ¹ Dipartimento di Matematica, C.I.R.A.M., Università degli Studi di Bologna, Bologna, Italy

The use of the honey bee as a biological indicator of pesticide pollution is mainly based upon its particular sensibility to most of the active ingredients used in agriculture. In fact, these insects react to the presence of pesticides in the environment showing various levels of mortality or bodily residues or a contamination of the hive products. The intensity of these effects depends upon the type of active ingredient used, the type of crops sprayed, the spraying time of day, the weather conditions during and after spraying and so on. A suitable innovative processing of the collected data can enable the drawing of detailed maps showing the degree of endangering of a certain environment, following similar assessed methods used in processing data coming from other bioindicators. In this frame we propose a data processing procedure that uses both toxicity informations for the pesticides detected on dead bees by means of chemical analysis and bee mortality values collected in the monitoring network stations, each one consisting of two hives equipped with cages for the collection of dead insects.

	no pesticide traces*	BEE MORTALITY CLASSES			
		0-100 D*	100-400 C*	400-800 B*	> 800 A*
LOW	0 - .25	D	D	C	C
MEDIUM LOW	.25 - .5	D	C	C	B
MEDIUM HIGH	.5 - .75	C	B	B	A
HIGH	.75 - 1.	B	B	A	A

The Table shows values of the Index of Environmental Hazard (IEH): A maximum hazard; B high hazard; C medium hazard; D low hazard. Results of IEH classes marked with * refer to situations where no pesticide traces have been detected in dead bees. Mortality classes have been set relying on the analysis of nearly 5000 weekly samplings carried out in Italy in recent years. The Index of Pesticide Toxicity (IPT) can be evaluated using the formula:

(IPT)_{month} = f_{corr} ∑_{c=1}^N (c̄t)_c (f̄p)_c / N

where (IPT)_{month} is the Index of Pesticide Toxicity over the month, (c̄t)_c defines the class of toxicity for sampling c normalized to the maximum expected value, (f̄p)_c is the persistency factor for sampling c normalized to the maximum expected value, f_{corr} is an (IPT) corrective factor over the monthly samplings and N is the total number of monthly samplings. The value of IPT is calculated using pesticide data available in literature. Crossing values of IPT and of averaged bee mortality leads to the obtainment of values for IEH, describing the level of pesticide pollution when referring to the sensibility towards it of the honey bees monitoring a certain environment.

14-090

LABORATORY AND OPEN FIELD INVESTIGATION OF *HERIADES TRUNCORUM* L. (HYMENOPTERA MEGACHILIDAE) DIET.

G. Ricciardelli D'Albore, M. Pinzauti, A. Felicioli
Dipartimento di Coltivazione e Difesa delle Specie Legnose, Sezione di Entomologia Agraria, Università degli Studi di Pisa, Pisa, Italy.
A palinological investigation was carried out in central Italy, in the framework of bio-ethological studies on *Heriades truncorum* L., in order to study the favourite diet of these insects in the state environment, with the aim of tracing the pollen sources visited. Microscopical analysis of pollen gathered and stored in cells of artificial nests showed that although *Heriades truncorum* L. prefers flower of compositae; in the environment under examination the above insect can extend their diet to other species of other botanical families.

14-092

BACILLUS LARVAE PROTEINASE INTERFERES WITH ANTIBACTERIAL RESPONSE PEPTIDES OF THE HONEYBEE

J. Jarosz, P. Jabłoński
Department of Insect Pathology, Marie Curie-Skłodowska University, Lublin, Poland
Insect has only a limited number of ways reacting to a considerable variety of bacterial pathogens. The honeybee defends itself against a wide range of bacterial invaders by an inducible immune system. Two classes of antibacterial immune proteins, the apidaecins (Casteels P. et al., EMBO J. 8, 2387-91; 1989) and abaecin (Casteels P. et al., Eur. J. Biochem. 187, 381-86; 1990) are well biochemically characterized inducible molecules in *Apis mellifera*. Some insect bacterial pathogens (Sidén I. et al., J. Gen. Microbiol. 114, 45-52; 1979) including *Bacillus larvae* (Jarosz J. & Gliński Z., J. Invert. Pathol. 56, 143-49; 1990), a causative agent of American foulbrood (AFB), produce exoproteases during parasitism that degrade inducible antibacterial immune proteins in holometabolous insects. As a result of depression of insect's non-self immune response, the pathogen develops in the haemolymph, and insect death occurs. The proteinases acting as immune inhibitors of the type A (InA) (Edlund T. et al., Infect. Immun. 14, 934-41; 1976), by degrading proteolytically the cecropin-like antibacterial proteins (Dalhammar G. & Steiner H., Eur. J. Biochem. 139, 247-52; 1984), could explain partly the mode of pathogenesis of insect bacterial infections. During parasitism in the honeybee, *B. larvae* excretes an extracellular proteinase of a character of immune inhibitor that suppresses selectively the inducible immune peptides in the bee haemolymph. Apidaecins and abaecin exposed to the action of *B. larvae* proteinase lost entirely antibacterial activity directed against *Escherichia coli*. Similar to other immune inhibitors released by insect bacterial parasites, the proteinase of *B. larvae* destroys specifically an antibacterial activity of cecropins from *Galleria mellonella*, *Celerio euphorbiae*, and activity of synthetic cecropin B (Serva) of *Hyalophora cecropia*. The AFB scales collected from various apiaries differ significantly in their proteolytic activity that coincides with the ability to inhibit antibacterial response proteins in insect immune haemolymphs. Preliminary identification indicates the similarities of the *B. larvae* exoproteinase to an immune inhibitor of the type A (InA) from *Bacillus thuringiensis* (Sidén I. et al., J. Gen. Microbiol. 114, 45-52; 1979). Evidence presented in this note seems promising in understanding way by which *B. larvae* could disturb non-self response system in the honeybee. By inhibiting the antibacterial response peptides, the multiplication of *B. larvae* in bee brood coelomic cavity is made easier.

14-091

A COMPARATIVE STUDY OF HYGIENIC BEHAVIOR IN SEVERAL HONEY BEE RACES

K. P. Gramacho, L. S. Gonçalves
Departamento de Biologia - Faculdade de Filosofia, Ciências e Letras de Ribeirão Preto - USP - Ribeirão Preto, SP, Brasil.
Hygienic behavior was studied in four types of honey bees: Italians (*Apis mellifera ligustica*), Carniolans (*Apis mellifera carnica*), Africanized bees (wild type bees in Brazil, predominantly *Apis mellifera scutellata*), and hybrid Italian/Africanized bees (virgin Italian queens open mated with Africanized drones). The tests were done in Ribeirão Preto, in the state of São Paulo, Brazil. Each type of bee was represented by five four-frame nucleus colonies, with standard deep Langstroth frames, except for the "hybrid" bees, which included only three nuclei. Each group of colonies was tested five times, at intervals of 10 days. Hygienic behavior was induced by perforating the cell cappings of sealed worker brood with a needle, to a depth that would also pierce the enclosed pupa. The Africanized bees were the most efficient (P < 0.05, Tukey test). The Carniolan bees were the least hygienic among the four types of bees.

THE INFLUENCE OF DIET ON VITELLOGENIN AND TOTAL PROTEIN TITRES IN THE HEMOLYMPH OF CONFINED ADULT HONEY BEES (*APIS MELLIFERA*).

T.M. Cremonez¹; M. M. G. Bitondi¹; D. De Jong²; Z.L. Paulino Simões¹
1 Dep. Biologia, Fac. Fil. Ciências Let.; 2 Dep. Genética, Fac. Medicina, Universidade de São Paulo, Ribeirão Preto, Brasil
A laboratory-based test of diet supplements for honey bees was made. It consisted of evaluating total protein and vitellogenin (Vg) in the hemolymph of bees confined in small cages in groups of 120, kept since emergence, at 34°C and 80% RH, and fed with 1) 1:1 beebread (pollen stored in the comb) and candy (honey mixed with sucrose), 2) 1:1 frozen pollen, previously collected from honey bee colonies and candy, 3) 40% soy meal, 10% sugar cane yeast (from an alcohol distillation plant), and 50% sucrose, 4) 1:1 fine corn meal and sugar, or 5) 50% sucrose syrup. Water was added to the powdered ingredients of diets 3 and 4 to form a thick paste. Additionally water was supplied *ad libitum*. At 0, 2, 4 and 6 days, total protein in the hemolymph was determined in 10 bees from each group, using a protein-binding dye assay. Vg was estimated, using rocket immunoelectrophoresis, in three pools of hemolymph, each prepared from four 6-day old bees. Two-day-old workers fed on beebread had a statistically greater amount of total protein than did those fed on frozen pollen, corn meal or sugar syrup. By the fourth day, workers maintained on frozen pollen diet demonstrated a recuperation of total protein titre, comparable to those fed on beebread. On day six, only the bees fed on frozen pollen had non-specific protein levels comparable to that seen in bees fed on beebread. The soybean - yeast diet was significantly better than corn meal or sugar alone, both for total protein and Vg. However this artificial diet, along with frozen pollen was inferior in terms of Vg, to the beebread. There was no Vg production with corn meal or syrup alone. Though soybean meal and yeast have a protein level similar to pollen, this diet does not promote normal protein secretion levels in honey bees. The laboratory tests proved to be useful for discriminating the utility of the diets tested. Research supported by CAPES.

INHIBITION OF FAT BODY PROTEIN SYNTHESIS BY JUVENILE HORMONE ANALOGUE (PYRIPROXYFEN) IN AFRICANIZED BEES

L.P. Zuanazi¹, M.M.G. Bitondi², Z.L. Paulino Simões²
¹ Depto Genética, Fac. de Medicina; ² Depto Biologia, Fac. Filosofia Ciências e Letras, Universidade de São Paulo, Ribeirão Preto, Brasil.

Several studies have shown that juvenile hormones (JH) or their analogs can promote fat body protein synthesis in insects. Little is known, however, about the control of protein synthesis and secretion, particularly vitellogenin (Vg), during the adult life of honey bees. The aim of this study was to assess the action of a JH analog, Pyriproxyfen (PPN), on fat body protein synthesis in *Apis mellifera* workers.

Five groups of 120 newly emerged workers were topically applied with 0 (controls), 0.01, 1, 5 or 10 µg PPN in 1 µl acetone. These bees were kept confined at 34°C, 80% R.H. for 6 days and were fed on a diet (40% beebread, 10% honey and 50% sucrose) that permits normal synthesis of protein and Vg. Water was supplied *ad libitum*. Fat body and hemolymph from 20 workers, aged 0 to 6 days, randomly collected from each confined group, were pooled for protein-binding assay, SDS-PAGE and rocket immunoelectrophoresis. The quantitative data (four repetitions) were analyzed by Kruskal-Wallis test. Ultrastructure of fat body cells from treated workers and controls were compared by transmission electron microscopy.

Normal Vg accumulation in hemolymph during the first week of adult life does not occur in workers treated with 10 µg PPN. Low Vg ($p=0.02$) and protein ($p\leq 0.05$) titres were observed in 5 and 6-day-old treated workers. This result was confirmed by the faint Vg band in hemolymph on SDS-PAGE. Fat body of treated groups showed no alteration in the protein pattern, but a decrease in number and volume of protein granules was observed in 10 µg PPN-treated workers, demonstrating the inhibitory effect of the higher PPN dose on protein synthesis. The lower doses did not change fat body ultrastructure and did not cause any detectable effect on protein and particularly on Vg titres. In conclusion, the JH action in bees is related to inhibition and not activation of protein synthesis and secretion by fat body cells.

CUTICULAR MELANIZATION AND PROPHENOLOXYDASE ACTIVITY INDUCED BY A JUVENILE HORMONE ANALOG IN *APIS MELLIFERA*

I.M. Mora, M.M.G. Bitondi, Z.L. Paulino Simões

Depto. Biologia, Faculdade Filosofia, Ciências e Letras, Universidade de São Paulo, Ribeirão Preto, Brasil.

In *Apis mellifera* a precocious and altered pigmented cuticle results from juvenile hormone analog (Pyriproxyfen - PPN) treatment. This hormonal control of melanization, described in some insects, was studied in worker pupae treated with 1 µg PPN, by measuring prophenoxydase (PO) activity.

Activity of the PO system, a key enzyme involved in pigmentation, was determined by homogenizing 15, 16 or 17 day-old pupae previously treated with PPN on day 11 or 12, in 400 µl of 0.01M sodium cacodylate buffer, pH 7.0 and 5mM calcium chloride. After centrifuging at 0-4°C and 10,000 x g for 15 min, the supernatant was poured through glass wool to remove floating fat particles, and used for the PO-activating assay. Filtered supernatant (50 µl) was incubated with 200 µl L-dihydroxyphenylalanine (saturated solution in water) and 450 µl cacodylate buffer. A few crystals of phenylthiourea (PTU) were added to some reaction mixtures. After 15 min at room temperature the absorbance at 490nm was measured in a spectrophotometer. All quantifications were made within the range in which reaction rates were proportional to enzyme concentration.

PO activity was higher in treated than in untreated pupae. Activity was strongly inhibited by PTU. The alteration of timing of cuticular melanization onset by the JH analog used, and the increased PO activity detected in PPN-treated bees demonstrated an effect of JH on the metabolic pathway leading to melanin synthesis in *Apis mellifera*.

HEAT-SHOCK INDUCED PROTEINS IN FAT BODY CELLS OF *APIS MELLIFERA* CULTURED *IN VITRO*.

V.M.L. Chacon-Almeida¹, Z.L. Paulino Simões², M.M.G. Bitondi²
¹ Depto de Genética, Fac. Medicina; ² Depto de Biologia, Fac. Fil. Ciências Let., Universidade de São Paulo, Ribeirão Preto, Brasil.

Effects of heat shock in insects have been studied and special attention was given to protein synthesis after expositions to high temperatures. To obtain evidence concerning to temperature-induced proteins in worker bee, fat bodies from 5th instar larvae (feeding and spinning phases) were cultured *in vitro*. After rinsing in insect Ringer solution and incubation for 15-40 min in complete medium, the fat bodies were placed in 1 ml of incorporation medium containing 12.5 µCi [³H] leucine (167 Ci/mmol) for 2 h, with rotary shaking, at 34.5°C (controls) or 42°C. The medium was assayed for secreted radioactive proteins. Fat bodies were homogenized in 10% sorbitol for qualitative and quantitative studies of radioactive unsecreted proteins. Secreted and unsecreted proteins were concentrated by acid precipitation and counted by liquid scintillation. SDS-PAGE and fluorography were performed on precipitated samples of fat bodies and culture media. There was synthesis of temperature-induced proteins in fat bodies cultured at 42°C. Three bands corresponding to 29, 70 and 80 kDa polypeptides were detected in the fat bodies submitted to heat-shock. In fat body controls, maintained at 34.5°C these polypeptides were not detected. The temperature-induced proteins were only detected in the fat body cells, they were not secreted into the culture medium, and possibly were synthesized to protect cells against the harmful effects caused by high temperature. A possible analogy between temperature-induced *A. mellifera* 70 kDa protein and *Drosophila* 70 hsp is under investigation.

IMPACTS ON HONEY BEES OF PROTEASE INHIBITORS *IN VITRO* AND IN TRANSGENIC OILSEED RAPE PLANTS.

L.A. Malone¹, E.P.J. Burgess¹, A.L. Picard-Nizou², C. Girard², L. Jouanin³ and M.H. Pham-Delègue²
¹ Horticulture and Food Research Institute of N.Z. Ltd, Auckland, New Zealand - ² Laboratoire de Neurobiologie Comparée des Invertébrés, INRA-CNRS, Bures-sur-Yvette, France - ³ Laboratoire de Biologie Cellulaire, INRA, Versailles, France

Protease inhibitor (PI) genes incorporated into transgenic plants may effectively protect against pest attack. However, their safety to honey bees must be established before field release. Serine protease activities predominate in the guts of larval and adult bees. *In vitro* tests in which caged adult bees were fed *ad lib* with 3 serine PIs in sugar syrup, BPTI (bovine pancreatic trypsin inhibitor), SBTI (Kunitz soybean trypsin inhibitor) and SBBI (Bowman-Birk soybean trypsin inhibitor), and a cysteine PI from rice, OCI (oryzacystatin I), showed that high concentrations (1-10 mg/ml) of BPTI and SBTI reduced the activities of gut serine proteases and also significantly reduced bee longevity. Longevity was not reduced among bees fed lower concentrations (10-1000 µg/ml) of BPTI and SBTI, or those fed SBBI and OCI at 26 µg/ml. SBBI and OCI did not alter serine protease activity levels in bees fed PI at 26 µg/ml for 15 days. Bees fed 11 µg of SBBI or cystatin (cysteine PI from egg white) over 24h consumed food at a normal rate and showed less than 10% mortality 1-3 days after dosing. Addition of SBBI or OCI (1, 5, 10 µg/ml) to the reward offered to bees in a conditioned proboscis extension assay showed that the PIs did not affect short-term learning ability in 15-day-old bees. Continuous feeding with these PIs (26 µg/ml) for 15 days did not affect their olfactory learning ability. Nectar analysis of 2 lines of OCI-transgenic oilseed rape plants showed that plants from the higher expressing line secreted a greater volume of nectar with a higher sugar content than the controls. However, bees did not show any preference for these plants when foraging behaviour patterns were observed.

NON-ADDITIVE EFFECTS ON HONEY BEE (*A. MELLIFERA*) COLONY PERFORMANCE BY ARTIFICIAL INSEMINATION OF QUEENS WITH MIXED SEMEN FROM DRONES OF SEVERAL BEE LINES (APIDAE: HYMENOPTERA)

S. Fuchs, R. Büchler¹, S. Hoffmann², K. Bienefeld³

Institut für Bienenkunde (Polytechnische Gesellschaft) Oberursel, FRG - Hessische Landesanstalt für Tierzucht, Abteilung für Bienenzucht, Kirchhain, FRG, - Institut für Landwirtschaftliche Zoologie und Bienenkunde der Universität Bonn, FRG, - Länderinstitut für Bienenkunde Hohen Neuendorf, FRG

The performance of the bee colony as a whole is determined by the cooperation of thousands of individual workers. Due to the multiple mating of the honeybee queen, workers may differ in characteristics relating to the genetic properties of their respective fathers. The result of a cooperation between these workers might be specific to the particular combination and might deviate from what would be expected from a mere summation of the performance of the genetic types between themselves.

It was investigated whether synergistic effects would occur in colonies headed by queens which were inseminated with drones from several breeder lines. Sperm was mixed using either drones from the same line or using equal numbers of drones from all of the 3 or 4 breeder lines. In most of the the measured colony parameters there was no clear difference between the performance of the combined group and the mean calculated from the single groups. There was, however, a consistend trend towards lower performance in traits relating to disease control, as hygienic behavior or defending against the parasite *V. jacobsoni*.

14-100

THE INSECT GROWTH REGULATOR FENOXYCARB AFFECTS LARVAL GROWTH RATE, LARVAL DEVELOPMENT AND K⁺-DEPENDENT MIDGUT AMINO ACID ABSORPTION IN THE SILKWORM *BOMBYX MORI*

M.G. Leonardi, S. Cappellozza², P. Ianne³, P. Parenti¹, L. Cappellozza², B. Giordana.

Dip. Biologia e 1 Dip. Fisiologia Biochimica Generali, Università di Milano - 2 Istituto Sperimentale per la Zoologia Agraria, Sezione Specializzata Bachicoltura, Padova - 3 ENEA-Ratti Laboratorio di Ricerca, Guanzate, Como - Italia

Fenoxycarb is a potent non-neurotoxic insect growth regulator (IGR) which induces a non-spinning syndrome in the silkworm *Bombyx mori*. Larvae are particularly sensitive when exposed during the last instar. Fifth instar larvae were force-fed or topically treated with different amounts of the IGR (from 10⁻¹⁵ to 10⁻⁶ g/larva). Prolongation of feeding period, reduction of growth rate, dose-dependent increase in number of dauer larvae was observed with doses higher than 10⁻¹² in both treatments. Instead, a dose-dependent frass reduction was seen only in topically treated insects, while a significative and constant inhibitory effect was obtained from an ingested dose of 10⁻¹⁵.

Midguts, divided in their anterior-middle (AM) and posterior (P) regions, were removed from treated larvae at day 6 and brush border membrane vesicles (BBMV) prepared. Labelled leucine uptake with time was measured in the presence of K⁺-gradient, that provides the driving force for intravesicular amino acid accumulation. Despite some differences with the two treatments, the main results indicate an increase of leucine uptake and accumulation, especially in AM-BBMV, with an IGR dose of 10⁻¹⁵, suggesting a hormone-like effect. Conversely, a dose of 10⁻⁶ causes a reduction of both parameters, possibly an aspecific toxic effect of the carbamate, involving the transport protein or the characteristics of the membrane lipid bilayer.

14-099

REPRODUCTIVE SUCCESS OF *APIS MELLIFERA SCUTELLATA* IN THE AMERICAS

T. Rinderer

US Department of Agriculture, Agricultural Research Service, Honey Bee Breeding, Genetics, and Physiology Laboratory, Baton Rouge Louisiana, USA

Africanized honey bees, the progeny of *Apis mellifera scutellata* in the Americas, has spread from central Argentina in South America to the southern United States in North America in less than 40 years. This remarkable range expansion has been the subject of numerous research efforts to determine the underlying ecological, behavioural and genetic processes. The antecedents of the range expansion can be found in the natural history of *Apis mellifera scutellata*. The African honey bee traits of high swarming rates, nomadic behavior, intensive absconding, and a "k-selected" demography all combined with the highly favorable tropical environment of South America to produce the remarkable population explosion of Africanized honey bees. Differences in ecologically based population cycle regulators allowed Africanized honey bees to expand populations where European honey bees could not survive. The genetic processes have been less easy to discover but persistent efforts now indicate that hybridization, differential fitness, and selection have all played a role.

14-101

METABOLIC FATE OF ECDYSONE INJECTED INTO DIAPAUSE EGGS AND NON-DIAPAUSE EGGS OF THE SILKWORM, *BOMBYX MORI*

Haruyuki Sonobe, Hideki Tokushige and Toshihiro Makka
Department of Biology, Faculty of Science, Konan University,
Okamoto 8-9-1, Higashinada-ku, Kobe, Japan

It has been demonstrated that silkworm eggs contain various ecdysteroids and that the amounts of ecdysteroids differ between diapause eggs and non-diapause eggs. In the present study, in order to compare the metabolism of ecdysone between diapause eggs and non-diapause eggs, we injected [3H]ecdysone into two types of eggs at various stages of embryonic development. The resultant radioactive metabolites were analyzed by reverse-phase HPLC.

A significant difference in ecdysone metabolism between diapause eggs and non-diapause eggs was detected from the late stage of gastrulation (48-hr embryo), at which stage the embryos enter into diapause. In the diapause eggs, most of the radioactivity was detected in the conjugated ecdysteroid fraction (mainly 3-epiecdysone 22-phosphate). By contrast, in non-diapause eggs, scarcely any radioactivity was detected in the conjugated ecdysteroid fraction, and most of the [3H]ecdysone was efficiently converted to 3-epi-20,26-dihydroxyecdysone. These results suggest that phosphorylation of ecdysteroids is major pathway in diapause eggs, while, hydroxylation at C-20 and C-26 of ecdysteroids is the dominant metabolic pathway in non-diapause eggs. Although the causal relationship between the initiation of embryonic diapause and phosphorylation of ecdysteroids is obscure at present, our present results suggest the possibility that a marked increase in phosphorylation of ecdysteroids causes the embryos to enter into the embryonic diapause.

14-102

THE CHANGE OF SORBITOL CONTENT IN *BOMBYX MORI* EGGS DURING CONTINUOUSLY INCUBATION AT 25°C (LEPIDOPTERA: BOMBICIDAE)

T. Kikawada, K. Shimizu, E. Kosegawa, and T. Okajima

Department of Genetics and Breeding, National Institute of Sericultural and Entomological Science, Yamanashi, Japan

Diapause of silkworm, *Bombyx mori*, eggs is initiated by exposure at 25°C for several days after oviposition, but the longer period of 25°C incubation cause the fewer number of hatchable eggs. To understand why long term incubation at 25°C causes a decline of the hatchability of *B. mori*, we investigated a change of the content of sorbitol, as an index of embryonic diapause, in some strains of the eggs during continuously incubation at 25°C.

As a result, the sorbitol content was decreased in all strains of the eggs during 25°C incubation. However, the curves of the degradation were categorized into 2 types.

We will discuss a relationship between the degradation of sorbitol content in *B. mori* eggs during continuously 25°C incubation and their hatchability.

14-103

EVALUATION OF ENZYMATIC ACTIVITY IN HONEY PRODUCED BY *APIS MELLIFERA* L.

L. Persano Oddo, P. Pulcini, M.G. Piazza

Istituto Sperimentale per la Zoologia Agraria, Sezione di Apicoltura, Roma, Italy

The honey enzymes diastase and invertase are generally considered as being of animal origin. However a number of researches on the characterization of Italian unifloral honeys showed that the enzyme content is stricly depending on the honey botanical origin.

In this study diastase and invertase content were determined on a large sampling of unifloral honeys from the following botanical sources: *Arbutus*, *Carduus*, *Castanea*, *Citrus*, *Erica*, *Eucalyptus*, *Hedysarum*, *Helianthus*, *Rhododendron*, *Robinia*, *Rosmarinus*, *Taraxacum*, *Thymus*, *Tilia*, fir honeydew and honeydew produced by *Metcalfa pruinosa*.

The honey types studied showed a considerable difference in their enzyme content. In particular, *Arbutus*, *Robinia*, *Erica*, *Citrus* and *Rosmarinus* honeys are characterized by the lowest values; *Thymus*, *Eucalyptus*, *Castanea* and the two honeydew honeys by the highest values.

The observed variability may be probably due to a series of different intrinsic and extrinsic factors as, for example, the period of nectar flow in relation to the biologic cycle of the honey bee family.

This high variability among the different honey types must be taken into account when these parameters are used to establish honey freshness.

PUTTING THE PIECES TOGETHER: FINE-SCALE MOVEMENTS AND LARGE-SCALE DISTRIBUTION OF A FOREST DAMSELFLY IN AGRICULTURAL LANDSCAPES.

P. D. Taylor
Atlantic Cooperative Wildlife Ecology Research Network,
Department of Biology, Acadia University, Wolfville, NS,
Canada

The forest damselfly *Calopteryx maculata* has two focal resource patches - streams for mating and oviposition and forested areas for foraging. Animals fly between these patches, linking the resources within the landscape. In pre-dominately agricultural landscapes, animals must move farther to access the same set of resources. I experimentally manipulated damselflies in forested and agricultural landscapes to measure connectivity as a function of landscape type. Simulation models were then used to predict medium- and large-scale patterns of distribution from fine-scale movements and predictions were tested against empirical data from Ontario and Nova Scotia. Landscape structure alters patterns of movement at fine- and medium- spatial scales, however, these patterns are not necessarily manifested in altered distributions at larger spatial scales.

15-001

THE EFFECTS OF FEEDING PROTEASE AND α -AMYLASE INHIBITORS, SINGLY AND IN COMBINATIONS TO THREE SPECIES OF LEAFROLLERS (LEPIDOPTERA: TORTRICIDAE)

N.P. Markwick¹, W.A. Laing¹, J.T. Christeller², J.Z. Maxwell³ & M.R. Newton¹

The Horticultural and Food Research Institute of New Zealand Ltd, Auckland¹ and Palmerston North², New Zealand
Australian National University³.

The larvae of three leafroller species - *Epiphyas postvittana* (Walker), *Planotortrix octo* (Dugdale) and *Ctenopseustis obliquana* (Walker) - were chronically fed six digestive enzyme inhibitors in artificial diets over a two-week period from hatching, and their growth rate and digestive enzyme activities were measured. The inhibitors were fed singly and in combinations set to target most of the digestive enzyme groups present in these leafrollers. Of the four protease inhibitors (PIs), three were extracted from potatoes (POT1, 2, and 4) and the fourth was bovine pancreatic trypsin inhibitor (BPTI). The two α -amylase inhibitors (α AI) were extracted from wheat, the dimer (WD) and tetramer (WT). Previous trials had shown these inhibitors to be the most effective from a range of 21PIs and 6 α AI.

POT1 significantly affected the growth rate of all three leafrollers and BPTI was effective against *E. postvittana* and *P. octo*. Most combinations of inhibitors did not reduce the growth rate further than the single most effective constituent, i.e. inhibitors presented singly in the diet were generally more effective in reducing the growth rate. One exception to this was a combination of POT1, BPTI and WT against *P. octo*.

All digestive enzyme activity was affected by the presence of the inhibitors in the diets. α AI increased α -amylase activity between 1.5 and 10 times. BPTI, either singly or in combination, dramatically reduced trypsin activity (10 times) and raised elastase activity (about 1.5 to 3 times) in all species. Since larval growth rate was so little affected whilst all enzyme activities were greatly altered, the question of compensation of one digestive enzyme for another, is discussed.

15-003

EFFECTS OF HABITAT FRAGMENTATION ON PLANT-INSECT COMMUNITIES

A. Kruess, T. Tscharntke

FG Agrarökologie, Georg-August-Universität, Göttingen, Germany.

The fragmentation of habitats is a major threat to near-natural ecosystems in the agricultural landscape, resulting in both decreasing area and increasing isolation of the remaining fragments.

Investigations were conducted using the leguminous plant species *Trifolium pratense* and *Vicia sepium* and the associated insect-communities consisting of endophagous herbivores and their parasitoids.

Effects of fragmentation were analyzed on near-natural meadows of different size and isolation near Karlsruhe, southwestern Germany. Insect diversity on both *T. pratense* and *V. sepium* was positively correlated with habitat size. On small meadows loss in both diversity of insect species and number of specimens was higher for parasitoids than for endophagous herbivores. Local extinction was more severe for rare species than for abundant ones. Furthermore, species with small populations showed a higher variability in their abundances between populations than species with large populations.

The effect of isolation on colonization-success of insects was analyzed experimentally on manually created plant islands. The experiments showed a decrease in insect diversity with increasing isolation of the plant islands. Abundant species colonized more islands than rare ones. Colonization-failure was higher for parasitoids than for herbivores. Thus, isolation of the plant-islands led to a significant reduction in parasitism of the endophagous herbivores and to imbalance of herbivore-parasitoid interactions.

15-004

THE IMPACT OF UNCULTIVATED CORRIDORS ON ARTHROPOD POPULATIONS WITHIN SIMULATED AGROLANDSCAPES

G. W. Barrett

Institute of Ecology, University of Georgia, Athens, Ga USA

We learned during the 1980s that biotic diversity cannot be conserved by a single-species approach; we hopefully will learn during the 1990s that we cannot sustain agricultural productivity by a single-field (agroecosystem) approach. Rather, as agrolandscape approach must be adopted in which landscape elements (e.g., patches and corridors) are patterned to optimize for a set of parameters such as insect pest control, nutrient retention, habitat fragmentation, net energy, trophic diversity, and crop productivity. An experimental approach is necessary to evaluate these factors in an replicated (simulated landscape) research design.

Results from several investigations indicate that uncultivated grassy corridors within soybean agroecosystems reduced the densities and affected distribution of adult potato leafhoppers (*Empoasca fabae*), and increased the rate of infestation of the green cloverworm (*Plathypena scabra*) by the frugal pathogen (*Nomvraea aileyi*). Uncultivated successional corridors, however, failed to "funnel" predators into the soybean crop.

Cultivated corridors planted in either tall or short sorghum (*Sorghum bicolor*) significantly reduced densities and the rate of dispersal of the Japanese beetle (*Popillia japonica*) in intercropped soybean agroecosystems. Patch architecture and corridor "associational resistance" functioned as mechanisms to regulate populations of insects pests. Findings from these studies suggest that integrated pest management should be investigated and implemented at the agrolandscape temporal-spatial scale.

15-006

THE ROLE OF NATURAL WATER CATCHMENTS ON THE PRODUCTION OF VECTORS OF PLANT VIRUSES IN THE ARAVA VALLEY, ISRAEL

M. E. Irwin¹, Benny Raccach²

¹Department of Natural Resources and Environmental Sciences, University of Illinois, Urbana, Illinois 61801 USA; ²Volcani Center, Bet Dagan, Israel.

The timing and quantity of insect pests invading intensive agriculture is important to understand, and predicting these events is critical to developing successful control strategies. Leafhoppers, aphids, thrips and whiteflies, taxa known to contain plant virus vectors, were studied over a two-month period (March-April 1995) in natural, xeric habitats near intensive agricultural settings of the Arava Valley, Israel. The study was carried out to determine if the timing and quantity of emigrants were differentially influenced by the moisture regimes of three habitats, separated by less than 1 km. These habitats were monitored for target taxa using a variety of collecting devices: yellow pans; malaise traps; small, battery-powered suction traps; and emergence traps. Yellow pans proved useful for capturing aphids and thrips; malaise traps collected large quantities of leafhoppers and aphids; the small suction traps, operated only occasionally, were excellent for monitoring thrips abundance just above ground level; and emergence traps captured target taxa erratically and proved to be of limited value during this study. Whiteflies were scarce during the two-month study, but the other 3 taxa were abundant. Several thousand specimens within the target insect families were collected and are being curated and identified to species. The composition of taxa captured in the three habitats was different. The possible reasons for these difference is discussed.

15-005

INTERCHANGES OF A COMMON PEST GUILD BETWEEN ORCHARDS AND THE SURROUNDING ECOSYSTEMS: A MULTIVARIATE ANALYSIS OF LANDSCAPE INFLUENCE

Ph. Jeanneret

Swiss Federal Research Station for Agroecology and Agriculture, Reckenholz/Zürich, Switzerland.

Landscape quality and structure should be an important factor to explain insects distribution and activity, at a regional or local scale. The measurement of faunal exchanges occurring between an agroecosystem and its surrounding habitats is relevant to test landscape influence. But in cultivated landscape, management practices may be an important factor influencing the exchanges between ecosystems. The activity of tortricids (Lep. Tortricidae), flying between apple orchards and their surrounding habitats were used to test this hypothesis in the region of Nyon - La Côte (Switzerland). A Malaise trap was placed on each of the North, East, South and West margins of six apple orchards of two types (three IPM and three abandonned). Two collectors were placed on top of the traps to separate emigrant from immigrant individuals. From the beginning of June to October 1992 and 1993, 48 samples were collected on 14 successive weeks.

There were a high similarity (Mantel test for multivariate data) between emigrant and immigrant tortricid captures, if they were caught by the same Malaise trap. We conclude that there were neither emigration nor immigration but an activity of tortricids at the interface of habitats.

The hypothesis of the landscape influence on tortricids activity at the interface was tested at two scales. The first concerned the proximate surroundings of the orchard and the second the distant surroundings (300m.). Proximate and distant surroundings were assigned to 6 categories including woodland, vineyard, cereal crop, orchard, garden and meadow. At both scales, multivariate analysis (Correspondence Analysis, Canonical Correspondence Analysis) and associated statistics (multiple regression and canonical coefficients, Monte Carlo permutations test), showed that landscape explained a significant part of the variation of tortricids caught at the interface between both types of apple orchards.

15-007

EFFECT OF HABITAT HETEROGENITY ON DIVERSITY AND DENSITY OF POLLINATING INSECTS (HYMENOPTERA, APOIDEA)

J. Banaszak

Department of Biology and Environment Protection, The Pedagogical University, Bydgoszcz, Poland

Diversity and density of wild bees *Apoidea* were studied in different landscape ecosystems, i.e. in bee refuges (forests, shelterbelts, natural swards and field margins) and on selected plantations (red clover, alfalfa, sunflower, winter rape, yellow lupine, buckwheat, flax). Special analysis was carried out for several forest islands of various sizes which indicated that they are inhabited by bee communities consisting of many species. Densities of these insects were higher than anywhere else.

Diversity and density of wild bees in two types of agricultural landscape with complex and simplified structure in Poland and Romania were compared. It was found that in the complex landscape the density of wild bees is 3-4 times higher. Also the diversity of wild bees in this landscape is higher.

The rules of occurrence in landscape were studied. It was indicated that one of the factors compensating for reducing effect of economy on wild bees populations is mosaic structure of landscape.

15-008

AGRICULTURAL TRANSFORMATION AND ANT DIVERSITY: THE CASE OF COFFEE IN THE NEOTROPICS

I. Perfecto

School of Natural Resources and Environment, University of Michigan, Ann Arbor, MI 48109-1115, USA
Traditionally, coffee has been produced in a diverse agroforestry system that includes a diverse canopy of shade trees in addition to fruit trees and other crops. Over the last 50 years many coffee plantations in the neotropics have been converted to plantations with a low density and diversity of shade trees, or to coffee monocultures. Ants (Hymenoptera: Formicidae) were used as an indicator group to examine the effect of changes in vegetational complexity associated with the transformation of the coffee agroecosystem in Costa Rica. Both within and between-habitat diversity were examined to gain insights about the consequence of the transformation at the local and landscape levels. Ant diversity is significantly reduced as the agroecosystem is simplified, and patterns of species similarity suggest that the loss of species diversity at the landscape level could be even more dramatic. Mechanisms responsible for the diversity decline include direct ones, such as changes in microclimatic conditions and loss of nesting sites, and indirect ones, such as changes in species interactions among the ground-foraging ant community.

15-010

MOVEMENT BETWEEN AGROECOSYSTEMS AND SURROUNDING HABITATS: A DETERMINANT FACTOR IN THE POTENTIAL MANIPULATION OF NATURALLY OCCURRING PARASITIDS

J. N. McNeill¹, J. Brodeur²

Départements de biologie¹ et de phytologie², Université Laval, Ste-Foy, Canada

Naturally occurring parasitoids are frequently unable to maintain pest species at densities below the economic threshold. One possible explanation for this poor performance is the asynchrony of agroecosystem colonization by herbivores and their primary parasitoids and we will discuss the results of two different studies addressing this subject: one in tobacco the other in potato. In both cases there is clear evidence that spring emergence of the parasitoids occurs significantly earlier than their appearance in the agroecosystems. Furthermore, in the tobacco study there is appreciable asynchrony between emergence dates of the parasitoid and the pest herbivore. Therefore, a few generations must be completed in habitats surrounding the agroecosystems by exploiting an alternate host and/or the same host but on other plant species. The feasibility of various management practices proposed to increase the efficacy of these naturally occurring control agents will be discussed in the context of between habitat movement at the beginning and the end of the season.

15-009

PREDATOR MOVEMENT PATTERNS AND THEIR RELATION TO HABITAT STRUCTURE

R. Bommarco, B. Ekbom

Swedish University of Agricultural Sciences, Department of Entomology, Box 7044, S-750 07 Uppsala, Sweden

We have found large variation in the size and fecundity of individual *Pterostichus cupreus* L. from different field populations located within a small geographical area. Some populations are larger and more fecund than others. By using comparisons with laboratory experiments on food limitation we conclude that field variation is partially due to different resource levels.

We are interested in testing hypotheses as to the causes of this variation. Differences in the surroundings, for example field edges and field size, of the different populations and how they may affect movement are considered. We are using individual based movement models in order to estimate correspondence between the distribution of resources and the dispersal of the beetles. Comparisons of diffusion rates into and out of areas with different levels of resources are considered.

15-011

PARASITOID COMMUNITY STRUCTURE: IMPLICATIONS FOR BIOLOGICAL CONTROL IN AGRICULTURAL LANDSCAPES

D. A. Landis and P. C. Marino¹

Department of Entomology and Pesticide Research Center, Michigan State University, E. Lansing, MI USA - ¹Department of Biology, College of Charleston, Charleston, SC USA

The community of parasitic Hymenoptera attacking each of 45 Lepidopterous pests of corn, soybean, wheat and maize in the North Central Region of the US was determined. The impact of herbivore host range, host plant type, feeding niche and host plant chemical defense on the species richness and relative proportion of generalist versus specialist parasitoids was examined.

Results indicate that exposed-feeding, polyphagous herbivores predominate in these crops and that generalist parasitoids make up the largest proportion of the parasitoid community (42%). Parasitoid richness is greatest on polyphages with generalist parasitoids equally common (ca. 50%) regardless of herbivore feeding breadth. Exposed feeders have the most parasitoids, while concealed feeders have relatively more specialists. Herbivores of monocots have the fewest parasitoids with a higher proportion of specialists and host plant chemical defense did not significantly affect parasitoid species richness. Because of the predominance of generalist parasitoids, the host habitat of their alternate hosts was determined. Over 60% of these species utilize alternate hosts that feed on mid or late successional plants. This indicates the potential importance of maintaining these non-crop habitats in the conservation of parasitoid communities in agricultural landscapes.

15-012

THE USE OF INVERTEBRATES IN EVALUATING RURAL SUSTAINABILITY

M. G. Paoletti

Department of Biology, Padova University, Padova, Italy

Evaluate rural landscape sustainability is a main topic of western countries. The use of species abundance, diversity and distribution appears an useful tool to evaluate and compare different farming systems and different rural landscapes. Basic resources of diversity (invertebrate diversity) are allocated and supported by field margins, including hedgerows and uncultivated borders. Evaluate these reservoirs and develop an appropriate research method is crucial.

Some sampling methods, including broad or narrow taxonomical categories are discussed. Some key groups will be discussed as well. Comparison and evaluation of different peach orchards and apple orchards under decreasing pesticide input are analysed. Biological orchards compared with integrated and conventional ones support higher number of invertebrates species.

15-014

WHEN THE INFLUENCE OF LANDSCAPE PATTERNING SHOULD MAKE THE GREATEST DIFFERENCE

J. E. Banks

Department of Zoology, University of Washington., Seattle, Washington, USA

While it is widely recognized that patchiness or heterogeneity of habitat can dramatically influence insect population dynamics, few field experiments or theoretical explorations have yielded practical guidelines for use in applications. I performed a field experiment in which plots of broccoli (*Brassica oleraceae*) were mixed with natural vegetation (an assortment of weeds) in long strips which varied in (1) proportion consisting of crop, and (2) absolute size of crop/weed patches. This design allowed me to examine the effects that both the pattern and the scale of landscape heterogeneity have on insect populations in an agroecosystem. Response variables were densities of herbivores -- cabbage aphids (*Brevicoryne brassicae*), flea beetles (*Phyllotreta cruciferae*) and cabbage butterfly larvae (*Pieris rapae*) -- sampled from broccoli plants in each of the different strips/treatments. While cabbage aphids showed a response strictly to proportion of strip consisting of crop, flea beetles were impervious to differences in crop proportion, but were strongly affected by scale, exhibiting further a sensitivity to an interaction between the two main effects. These results demonstrate that heterogeneity means different things to different insects, something which bears further examination. A model linking dispersal of the different insects to the spatially distinct treatments will be discussed as a way of predicting when pattern or scale of heterogeneity might be effective in influencing pest densities. This leads the way to developing a protocol for future predictive efforts based on measuring important behavioral insect characteristics such as dispersal.

15-013

THE IMPACT OF FIELD BOUNDARY HABITATS ON THE DIVERSITY AND ABUNDANCE OF NATURAL ENEMIES IN CEREALS

P. Dennis¹, G. L. A. Fry² and A. Andersen³¹ Macaulay Land Use Research Institute, Craigiebuckler, Aberdeen AB9 2QJ Scotland, UK.² Norwegian Institute for Nature and Cultural Research, Urbygningen, Norwegian Agricultural University, 1432-Ås, Norway.³ Norwegian Crop Research Institute, Fellesbygget, 1432-Ås, Norway.

The winter assemblage of predatory Coleoptera and Araneae was investigated in soil and vegetation samples in field boundaries around cereal fields. The assemblage was compared with the spring distribution of predatory arthropods in the field-margin zone and further into cereal fields.

The diversity and abundance of predatory species in cereal fields was greater within 10 m of the field boundary in spring and summer but not all the species were detected overwintering in the field boundary during the previous winter. The reasons for the apparent discrepancies in species composition are discussed in relation to the pattern of arthropod distribution, measurements of crop development and microclimate gradients out from field boundaries. The profile of predatory pressure of the arthropods was measured out to 50 m from field boundaries.

These results are used to interpret the relative merits of field management promoting a wider diversity of predators versus measures resulting in greater abundance of fewer species of more effective predators of aphids.

15-015

MOLECULAR BASIS OF CUCUMOVIRUS TRANSMISSION BY APHIDS

K. L. Perry

Department of Botany and Plant Pathology, Purdue University, West Lafayette, IN, USA.

Cucumber mosaic virus (CMV) and other members of the cucumoviruses are transmitted by aphids in a nonpersistent manner. Viral genomic RNAs 1, 2 and 3 are encapsidated in separate icosahedral particles. A successful transmission event requires the delivery of at least three virus particles to the same cell. Genetic analyses have shown that the primary determinant of aphid transmission maps to CMV RNA 3, and specifically to the encoded coat protein gene. Further analyses were made using infectious viral RNAs transcribed from a set of cDNA clones. Mutations were introduced in the coat protein gene in order to identify specific amino acids which play a role in aphid transmission. The transmission of a transmission-defective mutant by the aphid *Aphis gossypii* was restored by two nucleotide substitutions affecting encoded amino acid changes in two regions of the coat protein gene. Surprisingly, these same changes did not restore efficient transmission by a second aphid, *Myzus persicae*. Additional changes in the coat protein gene were required to restore efficient transmission by this aphid. Structural and immunological studies are underway to establish if the critical amino acids are present on the surface of virions, or if they influence transmission indirectly by altering secondary structure or physical properties of virions. Monoclonal antibodies are being used to differentiate mutants with single amino acid changes in the coat protein.

15-016

MOLECULAR BASIS OF POTYVIRUS TRANSMISSION BY APHIDS

T.P. Pirone, R.Y. Wang, J.J. Lopez-Moya and E.D. Ammar
Department of Plant Pathology, University of Kentucky,
Lexington, KY USA

Transmissibility of potyviruses by their aphid vectors is dependent upon the presence of appropriate amino acids in a domain near the N-terminus of the capsid protein (CP) as well as a functional helper component (HC) protein. Mutational analyses with tobacco vein mottling virus (TVMV) confirmed the importance of an asp-ala-gly (DAG) sequence near the CP N-terminus, but further studies with TVMV and tobacco etch virus (TEV) have shown that alteration of the context within which the DAG lies also affects virion transmissibility.

The HC protein is thought to function by binding to aphid mouthparts and to virions, allowing the retention required for subsequent virion egestion and inoculation. The effect of mutations, in either the CP or HC, on the fate of virions in *Myzus persicae* was studied by immunogold and radioisotope labeling. Mutations, in either the CP or HC, which abolished aphid transmissibility also resulted in lack of virion retention in the food canal of the stylets. Our interpretation of these results is that the defective HC mutants either fail to bind to the aphid, fail to bind to virions, or bind to neither. The transmission-defective CP mutants fail to bind to HC. Either process leads to lack of virion retention in the food canal and hence lack of transmission. The results of *in vitro* and *in vivo* experiments to obtain direct evidence of a double binding role for HC will be presented.

15-018

MORPHOLOGICAL AND CELLULAR BASES OF VIRUS TRANSMISSION BY WHITEFLIES

K.F. Harris¹, Z. Pesic-Van Esbroeck¹, J.E. Duffus²
¹ Department of Entomology, Texas A&M University, College Station, TX USA - ² USDA-ARS, Salinas, CA USA

Preparation of Whiteflies for Microscopy and Immunocytochemistry. A protocol was established for embedding whole insects in LR White at a sufficiently moderate temperature to preserve viral antigenicity. The four-step protocol includes infusing the resin with N₂ gas, evacuating or degassing the N₂-infused resin, covering embedding molds with Aclar®, and polymerizing the resin in a N₂ atmosphere at 55°C.

Whitefly Morphology and Noncirculative Virus Transmission. The combined afferent duct, cupula, piston, efferent duct and maxillary saliva canal of *Bemisia* can be likened to a hypodermic syringe in both form and function. Saliva exiting the pump, via the efferent duct, enters the salivary canal where food from the maxillary food canal enters the antecibarium. The roof of the latter is formed by the epicibarium (inner wall or sclerite of the clypeus) and its floor by the hypocibarium (inner wall or sclerite of the hypopharynx). The postcibarium (cibarial or "sucking" pump) of the feeding apparatus functions as a reversible bellows, allowing for egestion as well as ingestion. The latter morphology suggests that noncirculative whitefly-borne viruses are "cuticula-borne": acquired by ingestion, carried at specific sites on the cuticula lining of the feeding apparatus (maxillary food canal, precibarium, cibarial valve and postcibarium) and inoculated to plants via egestion.

Localization of Geminiviruses in Plants and Whiteflies. The aforementioned N₂-infusion embedding technique and elucidation of the internal morphology of *Bemisia* enabled us to localize SLCV geminivirus in plants by light microscopy and silver-enhanced immunogold staining and in whiteflies by electron microscopy and immunogold labeling. Geminiviruses are circulative and presumably inoculated to plants in watery saliva excreted into the phloem during "declogging" activity to clear the lumina of the feeding apparatus.

15-017

MOLECULAR BASIS OF CAULIMOVIRUS TRANSMISSION BY APHIDS

S. Blanc, I Schmidt, M. Cerutti and C. Louis
Station de pathologie comparee, INRA-CNRS, Saint Christol-les-Ales, France.

Semi-persistent aphid transmission of cauliflower mosaic virus (CaMV) is dependent on the presence of a virus-encoded 18 kDa polypeptide (P18), designated aphid transmission factor. CaMV gene II, which encodes P18, was expressed in Sf9 insect cells using a recombinant baculovirus. Aphid transmission factor activity was recovered from these cells. Native P18 accumulates in Sf9 cells as characteristic paracrystals which are also found in CaMV infected plants. The active form of P18 can be solubilized from paracrystals and the equilibrium between the two states is influenced by calcium concentration. Therefore, it is suggested that paracrystals act as reservoirs for the solubilized active aphid transmission factor.

A current hypothesis is that aphid transmission factors act as molecules bridging between virions and vectors, *via* two distinct domains. The C-terminal P18 domain (31 amino acids) was consistently demonstrated to mediate a specific binding to virus particles. Since P18-virion binding alone is not sufficient to explain transmission, the putative involvement of additional P18 properties (such as microtubule-binding) in the molecular mechanisms of CaMV aphid-transmission will be discussed.

15-019

MOLECULAR BIOLOGY OF WHITEFLY-BORNE CLOSTEROVIRUSES

B. W. Falk, V. A. Klaassen, T. Tian, J. Soong, Z. Bao
Department of Plant Pathology, University of California, Davis, CA 95616, USA

A number of RNA plant viruses are transmitted by whiteflies. Of these, lettuce infectious yellows closterovirus (LIYV), transmitted by *Bemisia tabaci*, the sweet potato whitefly, is the best studied and well characterized. The LIYV genome is composed of two single-stranded RNAs of 8,118 (RNA 1) and 7,193 (RNA 2) nucleotides. Computer-assisted sequence analyses suggest that LIYV RNA 1 encodes for the principal replicative proteins, while RNA 2 contains 7 ORFs and includes the hallmark closterovirus gene array. Despite being bipartite, the LIYV genome size and overall organization are very similar to the monopartite genomes of the aphid-transmitted beet yellows closterovirus and citrus tristeza closterovirus, and some of the encoded proteins show significant levels of similarity. Full-length cDNA clones representing LIYV RNAs 1 and 2 have been constructed and transcripts have been generated *in vitro* and used to successfully infect tobacco mesophyll protoplasts. Interestingly, LIYV RNA 1 is capable of replication in the absence of RNA 2. Although LIYV replicates to high levels in protoplasts, we have so far been unsuccessful in transferring LIYV from protoplast extracts back to plants by using *B. tabaci*. A RT-PCR assay was developed based on predicted, conserved nucleotide sequences for LIYV and other closteroviruses and used to detect other whitefly-transmitted closteroviruses. LIYV appears to be representative of a group of emerging whitefly-borne closteroviruses.

15-020

MOLECULAR BASES OF LUTEOVIRUS TRANSMISSION BY APHIDS

K. E. Richards, A. Bruyère¹, V. Brault, V. Ziegler-Graff, E. Herrbach¹, J. F. J. M. van den Heuvel², G. Jonard, H. Guilley
Institut de Biologie Moléculaire des Plantes du CNRS, Strasbourg, France - 1 Station de Recherches 'Grandes Cultures', INRA, Colmar, France - 2 DLO Research Institute for Plant Protection, Wageningen, the Netherlands

Beet western yellows luteovirus (BWYV) is transmitted in a circulative, non-propagative manner by aphids. Virions contain a minor protein, P74, produced by translation extension of the coat protein (CP) cistron into the neighboring readthrough domain (RTD). We have previously shown that the RTD contains determinants essential for BWYV acquisition/transmission by *Myzus persicae*. Subdomains within the RTD are being functionally characterized by site-directed mutagenesis followed by aphid transmission assays. Inoculum was delivered to aphids as purified virus, leaves of agro-infected plants or extracts of transcript-infected protoplasts. In-frame deletions in the C-terminal, variable half of the RTD generally did not abolish acquisition/transmission but greatly reduced its efficiency. By contrast, the N-terminal, conserved half of the RTD appears to be largely essential for acquisition/transmission. Deletion of the proline hinge between the CP and the RTD abolished incorporation of P74 into virions and no acquisition/transmission was observed. The effects of RTD mutations on accumulation of virus in agro-infected plants and tests for a potential role of other viral non-structural proteins in the acquisition/transmission process will also be discussed.

15-021

APHID AND VIRAL FACTORS REGULATING THE CIRCULATIVE TRANSMISSION OF SUBGROUP 1 LUTEOVIRUSES

S. M. Gray, F. E. Gildow, W. A. Miller & M. J. Young. USDA,ARS, Pennsylvania State Univ., Iowa State Univ., and Montana State Univ.

The barley yellow dwarf luteoviruses (BYDV) are obligately transmitted by aphids in a circulative, nonpropagative manner and efficient transmission is often limited to one or two specific aphid species. The transmission process requires that virions traverse the aphid hindgut epithelial cells into the hemocoel and then traverse accessory salivary gland (ASG) cells into the salivary canal. Virus exits the aphid along with salivary secretions during feeding. Ultrastructural studies suggest that the passage of BYDV virus particles across the plasmalemma of hindgut and ASG cells occurs by receptor mediated endocytosis. In addition, virus must bind to, and move across, the basement membrane surrounding the ASG; the mechanisms of which are unknown. The membrane that serves as a barrier to transmission in non-vector aphids differs for various virus isolate-aphid species combinations suggesting that different virus capsid protein domains interact with putative receptors on the three aphid membranes.

The BYDV capsid is composed of two proteins; a 22-kDa coat protein (CP) and a minor readthrough protein, (RTP). The RTP contains the CP sequence fused to a 50-kDa C-terminal extension, encoded by ORF5 and expressed by translational readthrough of the CP gene termination codon. Preparations of luteoviruses purified from plants contain a truncated form of the RTP which lacks the C-terminal portion of the 50-kDa domain. Various genetic modifications in the RTP coding sequence indicated that the RTP is not required for assembly of luteovirus particles or for plant infection. The C-terminal portion is not required for transmission, but may influence virus movement in plants. The N-terminal portion is not required for virus movement through the hindgut, but is required for virus to move through the ASG associated membranes.

15-022

MOLECULAR BASIS OF TOSPOVIRUS TRANSMISSION BY THRIPS

R.W. Goldbach, I. Wijkamp, F. van de Wetering & D. Peters
Department of Virology, Wageningen Agricultural University, Binnenhaven 11, 6709 PD Wageningen, The Netherlands.

Among plant viruses, tospoviruses take a special position with respect to morphology, taxonomic position and transmission. The success of tomato spotted wilt virus (TSWV), the type species of the tospoviruses, is based on its property to be persistently transmitted by thrips and by its broad host range (which seems to be defined by the feeding preference of the vector, rather than other (host plant) determinants). The current (re-)emergence of TSWV is caused by the worldwide spread of its most potent vector, the western flower thrips *Frankliniella occidentalis*. For proper and environmentally safe control, knowledge about the virus-vector interactions is needed. Therefore we started to study the molecular determinants, both of the virus and the vector, which are essentially involved in transmission. Immuno-localizing of the NSs protein of TSWV in midgut muscle and salivary cells shows that TSWV replicates in its vector. It has no pathological effect on the vector and is not transovarially transmitted. Acquisition studies using various developmental stages revealed that only L1 larvae are able to retain the virus. Ingestion of virus by L2 or later stages did not result in virus replication. This finding suggests the existence of a receptor in the midgut of L1 larvae solely. By serial passage of TSWV on plants, mutants were obtained which were defective in transmission but still able to infect plants at wildtype rate. These mutants do not anymore produce the two envelope glycoproteins (G1 and G2), suggesting their crucial involvement in acquisition by the thrips. Inspection of the sequences of tospoviral glycoproteins reveals the presence of a conserved RGD ("cell attachment") motif in the exposed N terminus of G2 and this motif may represent the receptor binding site of these viruses.

15-023

LOCAL AND GLOBAL EPIDEMIOLOGY: INTERACTIONS OF VECTORS, PLANTS AND CLIMATE WITH THE PATHOGEN XYLELLA FASTIDIOSA

A. H. Purcell

Division of Insect Biology, University of California, Berkeley, CA USA

Xylem-sap-feeding hemipterans transmit the bacterial pathogen, *Xylella fastidiosa*, to numerous species of plants, causing disease in numerous perennials such as grape, lucerne (alfalfa), *Prunus* species, oak, elm, and citrus. These diseases are limited to the Americas but with recently reported detections in Europe and Taiwan. Can we predict future expansions of the range of *X. fastidiosa* or to new crops? Because of the very broad range of competent vectors, a lack of potential vectors should not restrict the potential geographic range of the bacterium. Winter climate appears to limit the geographic range of *X. fastidiosa*, based on its reported distribution, experimental cold therapy, and the geographic distributions of disease resistance of indigenous plant species. It is proposed that climate governs rates of plant recovery from acute infections. Regionally and locally, vector distribution and behavior and the persistence and systemic movement of *X. fastidiosa* in reservoir plant hosts are the critical determinants of infection rates and thus disease intensity. Implications for strategies for local control, prevention, exclusion and the rapid evolution of new diseases of diseases caused by *X. fastidiosa* will be discussed.

15-024

THE ROLE OF APHIDS AS VECTORS IN THE EPIDEMIOLOGY OF A STONE FRUIT VIRUS: PLUM POX VIRUS (PPV).

G. Labonne
Institut National de la Recherche Agronomique, 34060 Montpellier, France

PPV is a nonpersistent aphid-borne virus. It is the only virus transmitted by this way which causes serious economic problems in fruit tree crops. Since it was first seen in Bulgaria (1915), it progressively extends its geographical area. Presently, it has been recorded from nearly all the European countries and from several countries of the Mediterranean area.

Until the end of the eighties, only a low number of aphid species were identified as PPV vectors. The species identified as vectors were mainly those able to colonize fruit crops hosts of the virus. However, a number of common aphid species were never tested. We carried out transmission tests with 40 species commonly found in our orchard area. 14 of them transmitted PPV in our conditions. Thus, PPV does not seem to differ from other nonpersistently transmitted viruses by its in range of aphid vectors.

The percentage of infectious alatae aphids was monitored within a highly infected orchard. An estimate of 1 infected aphid out of 1000 was obtained. This value was 10 times less than that was estimated with other nonpersistently transmitted viruses in annual crops. PPV transmission rates by *Myzus persicae* were measured under controlled conditions. They were also about 10 times less than those obtained with other nonpersistently transmitted viruses, in agreement with the field data.

The number of aphids alighting on a tree (50,000 to 250,000 on a medium tree) compensates for the low transmission efficiency of PPV. Thus, it seems that PPV differs from other nonpersistently transmitted viruses by its transmission efficiency but not by its range of vectors.

As an applied result, it appears that the elimination of aphids colonizing trees will not be sufficient to decrease the speed of PPV epidemics. On an evolutionary point of view, it seems that an increase of the PPV transmission efficiency is still possible. The virus spread in new areas and its increasing prevalence are favouring factors for such an evolution.

BIOLOGY OF *CICADULINA* LEAFHOPPERS AND EPIDEMIOLOGY OF MAIZE STREAK VIRUS

N.A. Bosque-Pérez¹ and F.M. Kimmins²
¹International Institute of Tropical Agriculture, Ibadan, Nigeria
²Natural Resources Institute, Kent, United Kingdom

Maize streak geminivirus (MSV) is indigenous in African grasses and is transmitted by *Cicadulina* leafhoppers in a persistent manner. MSV causes sporadic but severe disease outbreaks in maize in sub-Saharan Africa with yield losses approaching 100% on epidemic years. MSV disease epidemics have been attributed to different interacting factors but consensus exists that epidemics are associated closely with the biology of leafhopper vectors. In order to clarify these factors studies have been conducted on the ecology and behavior of *Cicadulina* spp., the incidence and severity of MSV in relation to maize varietal susceptibility, and the role of indigenous grasses as reservoirs of the virus and its vectors. Results of recent studies are presented and the significance of these factors in relation to MSV epidemiology is discussed.

15-025

IMPACT OF BROWN CITRUS APHID (HOMOPTERA: APHIDIDAE) ON DIVERSITY AND DISEASE DYNAMICS OF CITRUS TRISTEZA VIRUS IN FLORIDA

R. K. Yokomi, USDA-ARS, U.S. Horticultural Research Laboratory, Orlando, FL USA

Establishment of brown citrus aphid (BrCA), *Toxoptera citricida* (Kirkaldy), and severe strains of citrus tristeza virus (CTV) has caused rapid death of millions of citrus trees on sour orange rootstock in South American CTV disease epidemics from the 1930's to the 1970's. In 1993, the aphid became established in Puerto Rico and periodic surveys of CTV incidence there was conducted by serology to determine impact of BrCA on CTV epidemiology and diversity. This is relevant to Florida because in November 1995 the aphid was discovered on dooryard citrus in two counties in south Florida and was declared established in the state.

In 1993, CTV incidence in Puerto Rico was 5% and only 1.4% reacted with MCA13, a severe-strain discriminating monoclonal antibody. By 1995, CTV incidence had increased to 58% and the proportion MCA13 positive reached 26%. Single BrCA transmission rates for two different CTV isolates were 70% and 44%. Although BrCA was caught in low levels (1%) in yellow traps compared to the spirea aphid (56%) and the melon aphid (26%), aphid counts on trees indicated that BrCA was one of the principal colonizers. These data indicated that CTV has increased rapidly after the aphid's establishment in Puerto Rico and that at least two strains of CTV are being spread. A similar increase in CTV spread is now expected in Florida when the aphid becomes established in commercial groves. Because of a high reservoir of CTV decline strains in existing citrus on tolerant rootstock which at present are being spread slowly by indigenous aphid vectors in Florida, a rapid increase in CTV decline is expected as well as an increase in stem pitting CTV. Significant economic damage may result since Florida has 18 to 20 million citrus trees on CTV-sensitive sour orange rootstock and approximately 10.5 million grapefruit trees at risk to stem pitting CTV regardless of rootstock.

AN EPIDEMIOLOGICAL APPROACH TO MANAGEMENT OF WHITEFLY-BORNE TOMATO INFECTIOUS CHLOROSIS VIRUS

T.M. Perring, C.A. Farrar, T.B. Pinkard
Department of Entomology, University of California, Riverside, CA USA

Tomato production in southern California was threatened in 1993 by tremendous population densities of greenhouse whitefly (GHWF) *Trialeurodes vaporariorum* (Westwood). Additionally, plants in many fields exhibited virus-like symptoms (interveinal chlorosis on the leaves near the base of the plant, subsequently leading to necrosis on the oldest foliage). This new virus tentatively has been named tomato infectious chlorosis virus (TICV).

Epidemiological studies have shown that many plant species in the area contribute to GHWF populations levels, however there is seasonal and temporal variation in the relative contributions of the different species. The majority of GHWF population growth was attributed to crop host species, including strawberry, cucurbits, and tomato. Data suggest that GHWF in this geographic region does not have a tendency for long-distance migration and that infestations of TICV are locally driven. This has a profound impact on the epidemiology of TICV from areas of high incidence to those of low incidence. It also provides an avenue for disease management through vector management.

15-028

WHITEFLIES AND WHITEFLY-BORNE VIRUS EPIDEMICS

J.E. Duffus

U.S. Department of Agriculture, Agricultural Research Service, Salinas, CA USA

Whitefly-transmitted viruses are a rapidly increasing threat to world agriculture. The years since the mid-1970's until the present have seen the threat of these viruses greatly intensify. The magnitude of the problem with increases in whitefly population densities and the occurrence of whitefly-borne viruses in the tropics and in wide areas of the subtropics, including areas of intensive agricultural production such as the Mediterranean region and southern United States, is largely unexplained. The intensified losses have been attributed to the widespread use of synthetic organic insecticides, resistance to pesticides, enhancement by pesticides, changing climatic conditions, intensified agricultural practices and the international transport of plant material with contaminant populations of whiteflies. Even though some of the diseases induced by these viruses have been known since the early 1900's, and the number of diseases has been estimated at over 100, only relatively few have been characterized, understood, and controlled. Intensified studies on the biological factors and mechanisms of virus distribution including host range, vector transmission, and vector biotypes, are crucial to devising strategies for their control.

VIRUS/VECTOR/PLANT RELATIONS IN THE EPIDEMIOLOGY OF TOSPOVIRUSES

D. Peters, I. Wijkamp, F. van de Wetering, & R. Goldbach.

Department of Virology, Wageningen Agricultural University, Binnenhaven 11, 6709 PD, Wageningen, the Netherlands.

A emergence of tospoviruses have been experienced almost worldwide in the last ten or fifteen years. This was accompanied with a revival of research on these viruses in several countries. Much progress have been made on the virus-vector relationships. It has been known for years that the larvae were able to acquire the virus, whereas the transmission was the privilege of adults.

Using antisera to structural and nonstructural proteins viral and nonviral proteins, it could unequivocally be established that the virus replicates in the vector. Transmission studies showed that the virus can be acquired and transmitted in periods as short as 15 min, whereas the AAP₅₀ and IAP₅₀ range between one and two hours depending on the host. In between acquisition and transmission a latent period occurs which, depending on the temperature, ranges between 90 and 180 hours. Second instar larvae proved to be efficient transmitters, when newly born larvae were allowed to feed on infected plants. Approximately, 70 percent of the thrips becoming transmitters does so as larvae. Analyses of the acquisition of virus has showed that only L1 larvae has the unique capacity to acquire virus.

These virus/vector relations, especially the short period required to transmit will determine the dynamics of virus spread in the field. In addition, the random distribution of infected plants, the absence of any effect of the control of thrips on the progress of the disease and a stimulation of the spread by application of repellents shows that a continuous immigration of viruliferous thrips into crops is another factor of importance in the spread of these viruses.

15-029

UV-ABSORBING PLASTIC SHEETS IMPAIR THE EPIDEMICS OF INSECTS VECTORED VIRUS DISEASES

Y. Antignus, M. Lapidot¹, N. Mor², R. Ben-Josaph¹, S. Cohen¹

Department of Virology, ARO, The Volcani Center, P.O.Box 6, Bet Dagan 50250, Israel - ¹ Department of Virology, ARO, The Volcani Center, P.O.Box 6, Bet Dagan 50250, Israel - ² Extension Service, Hadera 38342.

Field experiments confirmed that crops grown in "walk in" tunnels covered with UV-absorbing plastic sheets were highly protected from infestation with whiteflies, *Bemisia tabaci*, thrips, *Frankliniella occidentalis* and aphids, *Aphis gossypii*. Protection against *B. tabaci*, was associated with a dramatic reduction in the spread of the whitefly-borne geminivirus tomato yellow leaf curl (TYLCV) and with a pronounced delay in plant infection and disease severity. Two month after transplantation, the average TYLCV disease incidence under three different UV-absorbing plastic sheets was 50, 30, and 20% compared with 93% under UV-nonabsorbing polyethylene sheets. In additional experiments, it was shown that the UV-absorbing sheets were also highly effective in the protection of cucumbers against *F. occidentalis* and *A. gossypii*. The association of these phenomena with the "UV vision" of insects will be discussed.

ANALYSIS OF THE DYNAMICS OF VIRUS TRANSMISSION BY VECTORS

M.J. Jeger, F. van den Bosch¹, J. Holt² and L.V. Madden³.

Department of Phytopathology, Agricultural University, Wageningen, The Netherlands - ¹ Department of Mathematics, Agricultural University, Wageningen, The Netherlands - ² Pest Biology Department, Natural Resources Institute, Chatham, U.K. - ³ Plant Pathology Department, Ohio State University, Wooster, U.S.A.

Plant virus diseases have generally been classified according to transmission characteristics and the behaviour of the virus in the vector. For insect, mainly Homopteran, vectors four categories have usually been recognised: non-persistent, semi-persistent, persistent-circulative; and persistent-propagative. Only in the last category does the virus multiply in the vector and in some cases there can be transovarial transmission to offspring.

A general epidemiological model has been developed which can deal with the four categories of virus transmission by vectors. Additionally host mortality due to disease, and vector birth, death and migration rates can be included. In cases where there is a constant population size, then a full qualitative analysis of the dynamics is obtained. A basic reproductive number is derived which describes both plant-to-vector and vector-to-plant transmission.

Vector activity and turn-over rate are important factors determining whether the disease will persist in the host and vector populations. It is also possible to deal with both immigration and emigration explicitly but interpretation of the qualitative results is difficult except using graphical techniques. The analysis is used to compare the effectiveness of vector control, eg. by insecticides or vegetation management, with sanitation measures involving the removal and destruction of diseased plants.

BIOTYPIC VARIATION IN WESTERN FLOWER THIRPS IN RELATION TO DURABILITY OF HOST PLANT RESISTANCE IN CUCUMBER

W.J. de Kogel, M. van der Hoek & C. Mollema
Centre for Plant Breeding and Reproduction Research (CPRO-DLO), Wageningen, The Netherlands

Western flower thrips, *Frankliniella occidentalis* (Pergande), is a serious pest on many ornamental and vegetable crops. Development of resistant cultivars is one of the strategies to control this insect. Biotypes of insect pests, however, may overcome the protective properties of such cultivars. The study of biotypic variation is therefore of prime importance. Variation in performance in a worldwide collection of western flower thrips was studied on susceptible and partial resistant cucumber genotypes. Leaf disc assays indicated that some strains from New Zealand and USA were less aggressive than the reference strain from The Netherlands. None of the strains tested was more aggressive than the reference strain. Selection experiments are performed in order to study the possibility of adaptation of thrips to partial resistant cucumber plants. First results indicate a slightly higher reproduction and lower mortality of a selection line of thrips on partial resistant cucumber after a few generations. Results are discussed in relation to durability of host plant resistance to western flower thrips.

15-034

TOSPOVIRUS TRANSMISSION BY WESTERN FLOWER THIRPS FROM DIFFERENT GEOGRAPHIC REGIONS

F. van de Wetering, M. van der Hoek, R. Goldbach, D. Peters & C. Mollema¹
Department of Virology, Agricultural University Wageningen, Binnenhaven 11, 6709 PD Wageningen, the Netherlands - 1 Centre for Plant Breeding and Reproduction Research, PO Box 16, 6700 AA Wageningen, the Netherlands.

The tospovirus/western flower thrips (WFT) complex is of worldwide concern to the greenhouse industry as well as to crops in the open field. In view of the worldwide spread of WFT, its ability to infest many plant species and its occurrence in different biological niches, diversity at different levels may exist between various populations. A number of WFT populations sampled in Italy (bean), France (cucumber), Israel (mango, strawberry), USA (chrysanthemum 2x, lemon), New Zealand (egg plant), and the Netherlands (chrysanthemum, cucumber, bean) were compared for the frequency with which they transmitted two tospoviruses, tomato spotted wilt virus (TSWV) and *Impatiens* necrotic spot virus (INSV), using the petunia leaf disk assay. All populations were able to transmit these tospoviruses, although differences in efficiencies were found. Thrips originating from France, Israel (strawberry), New Zealand and the Netherlands transmitted twice more frequently than populations from USA, but twice less frequently than the thrips from Israel (mango) and Italy (bean). These results provide more insight in the evolution of the various tospovirus species and WFT thrips populations.

SYMBIOTIC BACTERIA IN WESTERN FLOWER THIRPS AND VARIATION BETWEEN DIFFERENT THIRPS STRAINS

Egbert J. de Vries¹, Gerrit Jacobs¹, Johannes A.J. Breeuwer¹ and Chris Mollema².

¹Institute of Systematics and Population Biology, University of Amsterdam, Kruislaan 320, 1098 SM Amsterdam.

²DLO-Centre for Plant Breeding and Reproduction Research (CPRO-DLO), PO Box 16, 6700 AA Wageningen.

Symbiotic microorganisms are a widespread in phytophagous insect species. They are often associated with the digestive system. These symbionts are important in the ecology of the insect host: e.g. they supply essential nutrients or degrade toxic plant compounds. We study the role of bacterial symbionts in host plant adaptation in Western Flower Thrips.

Western Flower Thrips (*Frankliniella occidentalis*) is a world wide insect pest on a large number of greenhouse crops. We investigated the composition of gut bacteria in thrips populations from different host plants. Symbiotic bacteria isolated from the insects were cultured outside the thrips. Analysis of the 16S rDNA sequences made clear that these bacteria belong to the family Enterobacteriaceae, closely related to *Escherichia coli*. Detailed screening with RAPD markers showed that these bacteria were associated with the thrips strains over generations and that each thrips strain contained one type of symbionts. Genetic variation in and between thrips strains was analysed using RAPD markers, RFLP markers and sequencing of the ITS 1 region of rRNA genes.

15-036

HOW AND WHY DO THRIPS TRANSMIT TOSPOVIRUSES: A CELLULAR APPROACH TO UNDERSTANDING

Diane E. Ullman¹, Murali D. Bandla², Leslie R. Campbell¹ and John L. Sherwood²¹Department of Entomology, University of California, Davis, California; ²Department of Plant Pathology, Oklahoma State University, Stillwater, Oklahoma.

The tospoviruses are important emerging phytopathogens causing severe epidemics worldwide. Among the 5,000 or so known thrips species, only seven transmit tospoviruses. The thrips/tospovirus relationship is unusual in that transmission occurs only when first instar larvae acquire the virus. There is also apparent specificity between tospovirus species and their thrips vectors. The known vector species represent two of the largest genera of the Thripidae. Although the species involved do not form closely related groups phylogenetically, they do share important ecological characteristics. Recently, the status of several vector species has apparently changed dramatically, i.e. *Thrips tabaci*, once the most important vector species worldwide apparently no longer transmits contemporary isolates and *Thrips palmi*, formerly thought to be a nonvector, transmits at least three important tospoviruses. Close scrutiny of thrips/virus interactions suggests that evolution of tospoviruses and/or selection pressures on both the viruses and vectors contributes to changing vector specificities. On a cellular level evidence from electron microscope studies indicate that acquisition of tomato spotted wilt tospovirus (TSWV) is receptor mediated. The location of the viral glycoproteins (gps) in the virion envelope, presence of a RGD-motif in the gp2 and the absence of this motif in nontransmissible TSWV deletion mutants support the hypothesis that TSWV gps serve as viral attachment proteins. Analyses to identify the counterpart cellular receptor site in thrips, reveal an approximately 50 kD thrips protein that binds both TSWV gps, but not TSWV nucleocapsid protein or the nonstructural protein encoded by the TSWV S RNA. Similar preparations from leafhoppers, aphids and non-vector thrips species did not bind any TSWV proteins. Furthermore, anti-idiotypic antibodies that mimic TSWV gps detected the 50 kD thrips protein. These data suggest the 50 kD thrips protein is a component of the cellular receptor site for TSWV attachment proteins and may play a critical role in virus acquisition. The relevance of these findings to possible mechanisms underlying emergence of tospovirus/thrips relationships and vector specificity will be discussed.

15-038

THE RELATION BETWEEN SAPROPHAGY AND PHYTOPHAGY IN THRIPS

R. Marullo

Dipartimento di Biologia, Difesa e Biotecnologie Agro-Forestali, Università della Basilicata, Potenza, Italy

Some Thysanoptera species in the families Phlaeothripidae and Thripidae, living in leaf litter and vegetative parts of forest plants, were studied relating to their feeding activity. Differences in both the feeding apparatus and gut structure are reported and discussed. Biological data related to field populations are also provided.

15-037

THRIPS' (THYSANOPTERA) RESPONSES TO VARIABLE ABIOTIC FACTORS

Henrik F. Brodsgaard

Department of Plant Pathology and Pest Management, Danish Institute of Plant and Soil Science, Lottenborgvej 2, DK-2800 Lyngby, Denmark

Thrips are widespread throughout the world. The majority of species are tropical, many are temperate, and only a few species extend into Arctic regions. Many species of tropical and subtropical origin have become widely established in glasshouses in temperate regions where they may cause considerable economic damage. For the past two decades, especially the subtropical *Frankliniella occidentalis* and the tropical *Thrips palmi* have expanded their distribution area by infesting glasshouse crops in colder regions.

The interest in obtaining a thorough knowledge on the biology of economical important thrips species has increased as control of these species with pesticides has become difficult or undesired. Detailed knowledge on thrips' biology under different environmental conditions is essential to, e.g., pest risk assessments, timing of control measures, or utilisation of alternative control measures.

Knowledge on tolerance to unfavourable abiotic conditions in thrips infesting glasshouses is essential to illustrate the species' ability to overwinter under ambient conditions. Such knowledge may also reveal possibilities for manipulating glasshouse environments to increase mortalities or to slow down developmental rates to such an extent that integrated control will be more successful.

The present presentation gives a mini-review on thrips' responses to selected variable abiotic factors with emphasis on economical important species.

PROBLEMS AND PROSPECTS OF MANAGING *BEMISIA* IN PAKISTAN

Mustaq Ahmad Central Cotton Research Institute, PO Box 572, Multan, Pakistan

The cotton whitefly, *Bemisia tabaci*, is now posing a serious threat to cotton in Pakistan due to both its direct damage and acting as a vector of leaf curl virus. In 1992, 1993 and 1995, it was the major cause of yield reductions in cotton. Its outbreaks during the nineties were characterised by poor control by many recommended insecticides. Monitoring of whitefly populations from 1992 through 1995 reveal that a high level of resistance has developed to organophosphates like dimethoate, methamidophos and monocrotophos, and pyrethroids like cypermethrin and deltamethrin. In this situation, control practices for whitefly and other cotton pests need to be modified with special emphasis on the proper application techniques and non-chemical control methods to reduce whitefly populations and conserve natural enemies. A rotation of still effective insecticides including new chemicals having different modes of action, along with other IPM tactics, is recommended to combat whitefly

15-042

LABORATORY AND GREEN-HOUSE STUDIES OF INSECTICIDE RESISTANCE IN *BEMISIA TABACI* GENNADIUS (HOMOPTERA: ALEYRODIDAE)

Matt Cahill, Ian Denholm, Frank Byrne, Kevin Gorman, Wayne Jarvis and Sara Day
Department of Biological & Ecological Chemistry, IACR-Rothamsted, Harpenden, Herts, AL5 2JQ, UK.

Many populations of *B. tabaci* found in glass and plastic greenhouses in Europe have been exposed to heavy selection pressure from a range of insecticides, including the established compounds such as organophosphates and pyrethroids as well as the newer insecticides such as buprofezin and imidacloprid. Examples of populations resistant and susceptible to these insecticides were examined in the laboratory and in the field, and experiments conducted to demonstrate the impact of the levels and frequencies of the resistance genes on the field performance of the insecticides. In some populations buprofezin resistance was unstable, although re-selection was rapid. This instability was correlated with increased development times compared to susceptible strains. *In situ* selection for resistance plus passive transport of resistance genes to other regions highlights the difficulties of controlling this pest and suggest that insecticide resistance management strategies for *B. tabaci* need to be considered within an international perspective.

15-041

LOCALIZED MIGRATION BY *BEMISIA*

Laboratory populations of the sweet potato whitefly, *Bemisia tabaci*, have been shown to consist of both migratory and trivial flying morphs. The behavior of these forms to be examined under field conditions. Insects were marked in a field of cantaloupes using fluorescent dust. During the first growing season, passive traps, used to collect living whiteflies, were placed along 16 transects radiating out from the field to a distance of up to 1.0 km. Wind out of the northeast consistently carried migrating whiteflies to traps along placed along transects in the southwestern quadrant because cold air drainages dictate wind. For this reason, during the second season traps were laid out in a grid extending 2.7 km to the southwest of the marked field. If dispersal was solely was entirely passive or wind directed, patterns could be described using a diffusion model. Statistical examination of the data, however, demonstrate that the distribution on all days was patchy. Traps in the immediate vicinity of the marked field caught more whiteflies than the daily median. Large numbers were also collected from around the periphery of the grid. Whiteflies were far less prevalent in the center. As a result, the distribution of captured whiteflies can be described as bimodal. These patterns confirm behavior observed in the laboratory, i.e., a portion of the population are trivial fliers that do not engage in migration and are consequently captured in traps near the field, and a portion initially ignore vegetative cues and fly for a period of time before landing in distant traps so that they comprise the second peak in the model. During both years movement out of the field had an exaggerated directional component as evidenced by highly significant chi-square values produced on 13 of 14 days.

15-043

BEMISIA RESISTANCE MONITORING AND PREVENTION IN THE FIELD

T.J. Dennehy

Extension Arthropod Resistance Management Laboratory, Department of Entomology, University of Arizona, Tucson, Arizona, USA

Whiteflies threaten the economic viability of crop production in many areas of the world. They are inherently difficult to control with pesticides and have rapidly developed resistance to virtually all chemicals used for their control. Whitefly resistance problems have constituted the classical resistance treadmill in which pest resistance has caused increased rates and numbers of applications of insecticides and this in-turn has resulted in more rapid loss of effectiveness of the remaining chemical controls. Overcoming this resistance treadmill in whiteflies constitutes the objectives of collaborative research programs based in England, Israel, California and Arizona. With examples from the aforementioned programs, I will overview current efforts to: 1) reduce overall insecticide use through implementation of alternatives to conventional pesticides, 2) identify and obtain registration of 'softer' insecticides, such as insect growth regulators, 3) formulate, implement on an area-wide basis and evaluate provisional resistance management strategies, and 4) establish and maintain resistance monitoring programs that continually evaluate and improve resistance management strategies targeting whiteflies.

15-044

THE IMPACT OF PREDATORS ON *BEMISIA* POPULATIONS.D. Gerling¹, S. Naranjo², and Moshe Guershon¹¹Department of Zoology, the George S. Wise Faculty of Life Sciences, Tel Aviv University, Israel - ²Western Cotton Research Laboratory, USDA, ARS, USA.

Numerous predatory arthropods are able to prey on *Bemisia*. The most prominent species belong to the Heteroptera, Neuroptera and Coleoptera. However, it is difficult to assess the impact of the predators on *Bemisia* populations for a number of reasons. Many are general predators that may prefer other prey, and are not well adapted to feed on *Bemisia* either nutritionally or behaviorally. The predators are mobile, and often they and evidence of their activity are hard to find.

Several techniques have been used to determine which predators have the largest impact on the whitefly populations. These include nutritional studies, whole plant samplings, *in situ* field observations, and immunoanalysis using monoclonal antibodies. So far these studies have shown that some species of Coleoptera, and Heteroptera appear to have the greatest impact on *Bemisia* populations.

15-046

THE GEMINIVIRUS CAPSID PROTEIN: EVIDENCE FOR A DIRECT ROLE IN WHITEFLY-MEDIATED VIRUS TRANSMISSION
J. K. Brown

Department of Plant Sciences, University of Arizona, Tucson, AZ 85721, USA

Whitefly-transmitted geminiviruses, or subgroup III Geminiviridae, are important viral pathogens of crops cultivated in dry subtropical/tropical locales, worldwide. A single species of whitefly, *Bemisia tabaci* (Genn.), is the universal vector of the subgroup III geminiviruses, based on its ability to experimentally transmit viruses indigenous to the Eastern and Western Hemispheres (Bedford et al., 1994). This indicates highly specific virus-vector interactions, and implicates a conserved viral gene in the transmission process. The capsid protein (CP) gene is the most highly conserved gene of the subgroup III geminiviruses. Alignment of the predicted CP amino acid sequences of representative subgroup III viruses reveals 80-96% sequence identity (Rosell & Brown, 1993). In this model, the viral CP, assembled into nucleoprotein particles, interact directly with sites in the whitefly vector during the uptake, acquisition, and/or transmission processes. PCR-based monitoring of squash leaf curl virus ingested by the whitefly vector, *B. tabaci* and a non-vector whitefly, *Trialeurodes vaporariorum* (West.) indicates the presence of virus in insect extracts and honeydew of both whitefly species, and virus is detectable in saliva excreted by the whitefly vector, but not in saliva from the non-vector whitefly; this is the first direct evidence of transmissible virus in whitefly vector salivary excretions (Rosell & Brown, 1996). Further, replacement of the CP of African cassava mosaic virus (ACMV) by the analogous gene of the leafhopper-transmitted beet curly top virus (BCTV) (subgroup II) yields ACMV DNA encapsidated in BCTV coat protein, and rendered the hybrid virus leafhopper-transmissible (Briddon et al., 1990). CP mutants that do not make coat protein are not vector transmissible (Azzam et al., 1994; Brown et al., 1996). Exchange of the CP of the whitefly-transmissible SqLCV with that of the non whitefly-transmissible abutilon mosaic virus (AbMV) abolishes vector-transmissibility, and replacement of AbMV CP with SqLCV AR1 gene yields a vector-transmissible hybrid (Brown, Hartitz, Rosell & Bisaro, 1996). Collectively, these results demonstrate a direct role for geminiviral capsid protein in whitefly-mediated geminivirus transmission.

15-045

THE IMPACT OF PARASITOIDS ON *BEMISIA* POPULATIONS.

M. S. Hunter

Department of Entomology, Texas A&M University, College Station, TX USA

Biological control programs against whitefly have been very successful relative to programs against other groups of insect pests, and parasitoids have been the natural enemies credited with this success. However, biological control programs directed against *Bemisia* face some unique challenges. Unlike whitefly pests of orchard systems, *Bemisia* has a very wide host range and is generally a pest of annual crops, in which habitat disruption and pesticide use are frequent occurrences. In the large agricultural valleys in the southern U.S. where *Bemisia* is a pest, populations migrate from crop to crop, building up in size as the year progresses.

The following questions will be addressed. What is the potential for parasitoids to control *Bemisia* in a multiple cropping system? Can the use of parasitoids be integrated with current chemical control practices? What is the relative role of native and exotic parasitoids in biological control of *Bemisia*? What are the likely effects of the unusual autoparasitoid life history on biological control of *Bemisia*? Lastly, the current evidence for the reduction of *Bemisia* populations as a result of parasitoid attack will be reviewed.

15-047

BEMISIA TABACI (GENNADIUS) (HEMIPTERA:HOMOPTERA:ALEYRODIDAE), BIOTYPE/HOST/VIRUS INTERACTIONS

Ian D Bedford, S. Haider, M. Soko, Peter G Markham.
John Innes Centre, Colney Lane, Norwich, United Kingdom.
NR4 7UH.

Bemisia tabaci, the tobacco whitefly, has usually been associated with tropical and subtropical crops. It can transmit plant viruses in six different groups including approximately 60 geminiviruses. *B. tabaci* populations from locations worldwide have been characterised by DNA and esterase analysis, size, mating behaviour and in rare cases by larval morphology. Most populations could transmit most geminiviruses from any location. Many populations of *B. tabaci* prefer a narrow range of host plants; some populations are oligo or monophagous although most may eventually adapt to a wider host range. This narrow host range of most populations (non-B biotypes) may restrain the spread of whitefly-transmitted viruses.

The most polyphagous strain of *B. tabaci*, (the "B" biotype or "Silverleaf whitefly"), has evolved and been spread around the world through the movement of ornamental plants, produce and cut flowers. Its wide host range has increased the potential for whitefly-transmitted viruses to infect new host plants and crop species. Its increased fecundity and ability to induce phytotoxic damage increased its pest status.

Transmission of geminiviruses is a complex of interactions including those between the virion, virus replication, viral movement proteins and the feeding behaviour of the vector. Clones and mutants of insect transmissible and non-transmissible isolates of African cassava mosaic virus (ACMV), show that both cell to cell movement proteins and coat proteins play a key role in acquisition and transmission processes respectively.

WHITEFLY PROBLEMS AND RESEARCH IN LATIN AMERICA

C.A. Serra

'Proyecto 'Mosca Blanca', Instituto Superior de Agricultura (ISA), Santiago de los Caballeros, Dominican Republic

Endemic and introduced whitefly species have widely colonized tropical to temperated regions of the subcontinent. With few local exceptions, only the 'greenhouse whitefly' (*Trialeurodes vaporariorum*), adapted to (sub-)tropical highland conditions, and specially the *Bemisia tabaci* complex have produced consistently severe yield losses in several economic relevant crops, the latter mainly in arid lowlands. Besides through causing direct damage by sucking, indirect effects like honeydew production, phytotoxic disorders and/or the transmission of whitefly-specific geminiviruses (WFTG) have been limiting an increasing amount of crops in numerous regions.

WFTGs have been appearing in many regions and distinct crops like beans, peppers, cotton and cucurbits causing periodically (1970-90) economic losses in Brazil, Argentina, Central America and the Caribbean, being responsible with regional differences endemic *B. tabaci* biotypes (e.g. the 'A' biotype). Sudden outbreaks (1987/88) and severe attacks to formerly not reported hosts (e.g. tomatoes, pepper, cucurbits and cabbage) in countries of the Caribbean basin pointed to a recent introduction of the Old World 'B-biotype'. Linked to this so called 'silverleaf whitefly' (syn. *B. argentifolii*), new phytotoxic disorders appeared, e.g. the silvering of cucurbit leaves and uneven ripening of tomato fruits. Heavy WFTG infestations produced dramatic yield losses in tomato and fields being involved New World WFTGs in South and Central America besides to the recently introduced 'tomato yellow leaf curl virus' (TYLCV-Is) in some Caribbean islands. The continuous spread of the 'B-biotype' all over the subcontinent has recently been reported causing problems in Ecuador, Peru and other countries. Due to severe economic losses and an important reduction of crop areas, national research and extension activities have been increased under international co-operation in most of the countries. Research efforts have been focused on an IPM approach including monitoring, improved chemical control (incl. resistance management, selective compounds), application techniques, testing tolerant genetic materials, new (cultural) strategies for 'small farmers' incl. seedbed protection (e.g. covers, living barreers, sticky traps), natural and classical biocontrol (incl. parasitoids, predators and entomopathogens). During the last two seasons tomato growers of different regions have been able to reduce yield loss substantially due to improved extension activities, legal measures, chemical and fitogenetic control practices as well as climatic factors.

15-050

GENETIC COMPATIBILITY AMONG DIAPAUSING RED, NON-DIAPAUSING RED AND DIAPAUSING GREEN FORMS IN *TETRANYCHUS URTICAE*

T. Gotoh, T. Tokioka

Laboratory of Applied Entomology and Zoology, Faculty of Agriculture, Ibaraki University, Aml, Ibaraki, Japan

The occurrence of diapause and reproductive compatibility were studied among three different forms of the two-spotted spider mite, *Tetranychus urticae* (Acari: Tetranychidae), found in Japan. The three forms were the diapausing red (DR) form (first described here), the non-diapausing red (NDR) form (formerly called *T. cinnabarinus*) and the green (G) form. Almost all DR and G females entered diapause, whereas females from NDR completely lacked diapause.

In intra-population crosses, all populations produced both female and male progeny. Inter-population crosses within the same forms also resulted in the production of both sexes, suggesting that these populations were compatible. However, no fertile F₁ females were produced in crosses between DR and either NDR or G, indicating that the former was reproductively incompatible with the latter two. On the other hand, NDR mites produced a smaller number of fertile F₁ and F₂ females when mated with G mites, showing that gene exchange between them is possible. Thus, it seems that NDR and G are conspecific, although they show severe genetic incompatibility.

15-049

RECENT ADVANCES IN AGRICULTURAL ACAROLOGY

V. Vacante, J. Gutierrez¹

Dipartimento di Protezione delle Piante, Universita degli Studi della Tuscia, Viterbo, Italy - ¹ ORSTOM, Montpellier, France

Much work was performed on agricultural acarology after the Second World War and until the mid-1980s. Most publications were devoted to systematics and field research by agronomists to provide a rapid solution to the problems raised by outbreaks of phytophagous mites on crops. Research in this field has necessarily become increasingly academic and calls on all the disciplines developed in recent years:

-the proposal of mathematical models thanks to progress in data processing; such models are used both for the analysis of population dynamics and the drawing up of spraying schedules;

-analyses of the various aspects of the behaviour of the pests and that of predators;

-studies of population genetics first using classic methods, then based on isoenzyme variability and finally involving a range of molecular biology techniques. The aims are the search for genome markers, better definition of biological entities, the determination of phylogenetic relations, analysis of exchange between populations and attempts at genetic transformation to increase the potential of predators.

15-051

USEFULNESS OF DNA SEQUENCE INFORMATION IN THE ANALYSIS OF TETRANYCHID INTRASPECIFIC VARIABILITY

M. Navajas, J. Gutierrez¹

INRA, Montpellier, France - ¹ ORSTOM, Montpellier, France

Ribosomal and mitochondrial DNA variation were used to study intraspecific divergence in three tetranychid species. Mites originating from 29 localities distributed world-wide (19 for *Tetranychus urticae* Koch, 4 for *Mononychellus progresivus* Doreste and 6 for *Amphitetranynchus viennensis* (Zacher)) were analyzed by polymerase chain reaction amplification and direct sequencing of both the internal spacer ITS2 and part of the cytochrome oxydase I gene (COI).

Mitochondrial COI variations were detected between localities in the three spider mites. ITS2 sequences were virtually identical among *T. urticae* samples whereas there were appreciable differences in the two other species. Ecological features such as feeding specificity and geographic distribution may explain the contrasted patterns of molecular divergence. The relevance of nucleotide sequences in assessing intraspecific variability in spider mites is discussed.

15-052

PERSPECTIVE ON ERIOPHYOID MITE RESEARCH

G. Nuzzaci, E. de Lillo

Istituto di Entomologia agraria, Bari, Italy

This lecture deals briefly with the current status of the knowledge on Eriophyoidea (Acari Prostigmata), which are obligatory phytophagous Mites. Some points need attention for developing guidelines in a future progress regarding mainly a faunistic and systematic point of view, morphology, anatomy, biology, reproductive strategies, direct and indirect injuries, tritrophic inter-relationship, natural enemies, biological weed control, etc.

A few aspects, for instance, that could be promoted, are:

- 1) to organize a useful instrument for the researchers consisting in a database (i.e. on CD) containing information on the original description and illustration, biogeography, habit, hosts, references, etc., that may be easily and quickly looked up;
- 2) to more deeply investigate some anatomical aspects for which there are scarce information such as the nervous system, sensory organs, gonads, differences between deutogyne and protogyne, male and female, immature stages and adult.
- 3) to individuate and improve rearing techniques for studying reproduction, development, behaviour and life-history strategies;
- 4) to ascertain the salivary compounds involved in biochemical mechanisms inducing galls, rusting, edge-rolling, deformations, and other alterations on plants;
- 5) to look into the relationship between eriophyoids and plant pathogens (virus and mycoplasma) for carrying out the transmission mechanisms;
- 6) to continue in verifying the role and the importance that Eriophyoid populations play in the alimentary chains.
- 7) to establish appropriate criteria for identifying and selecting promising candidates in weed control and estimating their potential effectiveness.

15-054

THE FEEDING EXPERIENCE OF POLYPHAGOUS SPIDER MITE (*TETRANYCHUS URTICAE* KOCH) THAT ALTERS THE ACCEPTABILITY OF UNEXPERIENCED HOST PLANTS

S. Yano, M. Wakabayashi, J. Takabayashi, A. Takafuji

Laboratory of Ecological Information, Graduate school of Agriculture, Kyoto University, Kyoto, Japan

Adult females of the phytophagous mite, *T. urticae*, escape from unfavorable plant resources. We experimentally introduced the mites onto leaf disks of their potential hosts. Host qualities were ranked in terms of the fecundity the mites exhibited on them. The mites tended to escape from any hosts when they had previously experienced hosts of higher rank, whereas they tended to accept any hosts when they had experienced hosts of lower rank. The result suggested that the mites accurately evaluated unexperienced plant resources on the basis of their earlier feeding experiences. The characteristics of host acceptability of the mites will be discussed with respect to their host range in the field.

15-053

DISTRIBUTION, BIOLOGY, PEST STATUS AND CONTROL STRATEGIES OF THE MOST IMPORTANT PHYTOPHAGOUS MITES OF TEMPERATE FRUITS IN ITALY

C. Duso

Istituto di Entomologia agraria, Università di Padova, Italy

The economic importance of phytophagous mites in Italy has greatly increased after the second world war corresponding with dramatic changes in agricultural practices. Mite outbreaks appeared to be more frequent in orchards, vineyards and protected crops and chemical control represented the main response to this problem until the late 70's. Mite resistance to broad-spectrum pesticides was initially contrasted by a rapid succession of acaricides. Failures of chemical control and the occurrence of secondary pests, due to the side-effects of pesticides, allowed for the spread of the IPM approach in several areas.

The most serious pests of temperate fruits in Italy belong, in particular, to the families Tetranychidae and Eriophyidae while the importance of other groups (e.g. Tenuipalpidae and Tarsonemidae) is lower. Among the Tetranychidae, some species are widespread and economically important in orchards and vineyards (e.g. *Panonychus ulmi* and *Tetranychus urticae*), others (e.g. *Eotetranychus carpini*) are distributed more locally or occur in neglected or unsprayed orchards (e.g. *Bryobia rubrioculus*, *T. viennensis*). The Eriophyidae can be injurious especially on apple (e.g. *Aculus schlechtendali*), pear (e.g. *Epirimerus pyri*), peach (e.g. *Aculus fockeui*) and grapevine (e.g. *Calepitrimerus vitis*).

Some notes on the biology, behaviour and economic importance of the most serious pests of temperate fruits in Italy are briefly reported with a summary of recent progress in biological and integrated control strategies on apple, pear, peach and grapevine.

15-055

TRANSMISSION BIOLOGY OF *ERIOPHYES INSIDIOSUS*-VECTORED PEACH MOSAIC VIRUS

C. Gisbert, T.M. Perring, G.N. Oldfield & R. Creamer^{1,2}

¹ Department of Entomology, ² Department of Plant Pathology, University of California, Riverside, USA

Peach mosaic is an infectious disease that impacts peach production in California and Mexico. Our studies have shown that the causal agent is a closterovirus-like particle. Experiments to elucidate the transmission biology have shown that transmission efficiency varies with the specific buds from which inoculative mites are taken. In two sets of experiments we found that transmission efficiency of single mites was 15.4% whereas transmission by 5 and 10 mites was 2.7%. We also have determined the minimum inoculation access period to be as low as 6 hr. Experiments to test the minimum acquisition access period and latent period are in progress. Information gained through these experiments not only will further our understanding of mite-vector pathogens but may prove useful in designing management strategies.

15-056

A CASE OF SIBLING SPECIES IN *TYPHLODROMALUS* (ACARI: PHYTOSEIIDAE)

G.J. de Moraes, M.S. Zacarias¹

Laboratório de Quarentena, CNPMA/EMBRAPA, 13820-000 Jaguariuna-SP, Brazil - ¹ EMBRAPA/IITA/IFAD Agreement, CNPMA/EMBRAPA, 13820-000 Jaguariuna-SP, Brazil

Phytoseiid mites identified as *Typhlodromalus aripo* DeLeon have been commonly reported in South America on cassava plants (*Manihot esculenta* Crantz) and several kinds of weeds. The fact that on the former plants those phytoseiids are found almost exclusively in the growing tips whereas on the latter they are found on fully grown leaves prompted the investigation of a possible case of sibling species. Laboratory crossing studies were conducted with specimens collected from cassava and from *Baccharis* sp.. They indicated that matings occurred between individuals of the same or different substrates. Oviposition was only observed when females were mated, and almost all females oviposited when mated with males from the same substrate, producing more than 85% of viable eggs. No eggs were produced by females from cassava crossed with males from *Baccharis*. Most females from *Baccharis* oviposited when crossed with males from cassava; however, resulting F1 females did not oviposit when crossed with males from either substrate or F1 males. Morphological evaluation of mites used in the crossing studies failed to show any reliable differences. Populations of this mite group collected from cassava in Brazil have been mass produced for releases in cassava fields in Africa for the control of the cassava green mite, *Mononychellus tanajoa* (Bondar). A re-evaluation of the correct identity of those populations is warranted in light of present knowledge.

15-058

PHYLOGENETIC AFFILIATIONS OF FULGOROMORPHA (HEMIPTERA: ARCHAEORRHYNCHA) INFERRED FROM 18S rDNA NUCLEOTIDE SEQUENCES

Bruce C. Campbell¹, Thierry Bourgoin², Jody D. Steffen-Campbell¹, John T. Sorensen³, Raymond J. Gill³ Western Regional Research Center, United States Department of Agriculture, Albany, CA, USA. - ² Muséum national d'Histoire naturelle, Laboratoire d'Entomologie, Paris, France - ³ Plant Pest Diagnostics Center, California Department of Food and Agriculture, Sacramento, CA USA

Evolutionary affiliations of major groups of insects in the order Hemiptera (*sensu lato*) have been debated for more than a century. Based on various morphological features of wings, mouthparts, head, antennae, genitalia and alimentary canal, a number of conflicting phylogenetic scenarios have been proposed. Shared characters of aristate antennae and tymbals have been used to place fulgoromorphans and cicadomorphans in the traditional suborder, Auchenorrhyncha. A thorough examination of both fossil and extant hemipteran taxa reveal that these "auchenorrhynchan synapomorphies" could likely be the result of convergence. Alternatively, tree topologies of major hemipteran lineages based upon homologous nucleotide sites of the gene encoding 18S rRNA (18S rDNA) suggest: 1) there are at least four main monophyletic lineages in extant Hemiptera (sternorrhynchans, cicadomorphans, fulgoromorphans and coleorrhynchans), 2) Sternorrhyncha is sister to all other Hemiptera (*i.e.*, Euhemiptera *sensu* Zrzavy), 3) there is little or no support for a monophyletic Auchenorrhyncha, and 4) radiation of these four major lineages occurred rapidly from a common ancestor. A renaming of hemipteran suborders to better reflect natural, evolutionary affiliations has been proposed by Sorensen *et al.* The best supported topology based on molecular data indicates that fulgoromorphans are sister to a clade consisting of true bugs and peloridiids. This monophyletic clade has been named Neohemiptera.

18S rDNA nucleotide sequences also provide possible insights into family-level evolutionary affiliations among fulgoromorphans. A molecular based phylogeny supports a basal elade of cixiids and delphacids. However, the enigmatic tettigometrids appear to occupy a distal clade with that of tropiduchids and flatids.

15-057

VOLATILE PLANT COMPOUNDS AS ANTIFEEDANTS FOR A PHYTOPHAGOUS MITE

Y. Jiang¹, T.J. Ridsdill-Smith², Gaull, K.R.² and E.L. Ghisalberti¹

Cooperative Research Centre for Legumes in Mediterranean Agriculture, Perth, Western Australia, Australia - ¹Department of Chemistry, University of Western Australia, Perth, Western Australia - ²CSIRO Division of Entomology, Perth, Western Australia

In the plant/mite interaction *Halotydeus destructor* (Tucker) - *Trifolium subterraneum* (L.), numbers of mites are lower and they feed less on cotyledons of resistant varieties, than of susceptible varieties, during a three hour test period. Artificially damaged cotyledons release several volatile metabolites, including 1-octen-3-one, arising from lipid peroxidation. The levels of 1-octen-3-one in different *T. subterraneum* varieties are negatively correlated with levels of feeding damage to the varieties. In a bioassay using *H. destructor*, the EC₅₀ for 1-octen-3-one deterrent activity is 50ppm, while at 1000 ppm all mites are repelled from feeding. The 1-octen-3-one is produced in a time-dependent manner from artificially damaged cotyledons. The wound induced C₈ compound, 1-octen-3-one, is considered to play a role in the deterrence of cotyledons of some resistant subclover varieties.

When foraging, *H. destructor* are very restless, running, palpating (tapping the surface), probing (pausing to apply mouthparts to the plant surface), and feeding (stationary, with legs braced on the plant surface). A hole is made in the epidermal surface, through which the cell contents are sucked when feeding. Mite feeding elicits production of the volatile compounds from peroxidised lipids in damaged cells. On non-preferred hosts, the mites palpate and probe, but seldom settle down to feed. We suggest that mites face the highest concentrations of the antifeedant volatiles, in either liquid or vapour form, at the plant surface after probing, and are deterred from further feeding. Identification of resistance mechanisms is helping in a program to select and breed annual pasture legumes with resistance to *H. destructor* feeding.

15-059

INFERENCE OF PHYLOGENETIC AFFILIATIONS OF FULGOROMORPHA (HEMIPTERA, ARCHAEORRHYNCHA) BASED UPON MORPHOLOGY

T. Bourgoin (1) and B. C. Campbell (2).

1. Laboratoire d'Entomologie et EP 90 du CNRS, Muséum national d'Histoire naturelle, Paris, France - 2. Western Regional Research Center, United States Department of Agriculture, Albany, CA, USA.

Hypotheses in phylogenetic relationships of Tettigometridae within Fulgoromorpha families have never reached a full agreement. Most authors regard the Tettigometridae as the sister-group of all other fulgoromorph taxa (Asche, 1988; Emljanov, 1990; Wilson *et al.*, 1994) and this hypothesis has been used in studying evolutionary patterns (Denno & Perfect, 1994, and contributors in it). Accuracy of these studies is directly related to the quality of phylogenetic assumptions employed. However, there are at least two other phylogenetic hypotheses based on morphological data.

The possibility that Tettigometridae represents a relatively distal lineage of Fulgoromorpha was proposed by Bourgoin (1985) based on a cladistic assessment. In this study the Tettigometridae were grouped in a lineage with the Flatidae and the Tropiduchidae but their relationships were not specified. Since then, Bourgoin has firmly established the monophyly of the tettigometrids (1987) and reinforced his contention in several papers dealing with new characters (1986, 1993, Bourgoin & Deiss, 1994), and with biogeographical arguments (1988, in press) Yang & Fang (1993), based on a phenetic assessment, regarded the Fulgoromorpha as a paraphyletic taxon in that the Tettigometridae were more closely related to the Cicadellidae than to other families of fulgoromorphs.

These varying phylogenetic hypotheses raise two basic questions: 1) Are the Fulgoromorpha a monophyletic taxon ? and, 2) What is the sister group to the Tettigometridae ?

This contribution presents a new cladistic analysis based on morphological characters and concludes in favor of the monophyly of the Fulgoromorpha and the non basal position of the Tettigometridae. This phylogeny is compared to that based on DNA and the position of Fulgoromorpha within Hemiptera is also discussed.

15-060

THE PHYLOGENETIC RELATIONSHIPS OF FULGOROMORPHA BY DNA SEQUENCE ANALYSES

Wen-Bin Yeh, C.T. Yang, Cho-Fat Hui¹

Department of Entomology, National Chung-Hsing Univ., Taichung, Taiwan, R.O.C. - ¹ Institute of Zoology, Academia Sinica, Taipei, Taiwan 115, R.O.C.

Phylogenetic reconstruction of the family relationships within Fulgoromorpha based on sequence information was conducted using DNA sequences of two genes. The sequence comparisons of 420 bases of the 3' end of the 16s rRNA sequences from 15 taxa of 11 families and those of 414 bases of the 5' end of the cytochrome b genes from 10 taxa of 7 families reveal general congruence. Both genes suggested that Meenoplidae is a basal lineage among those taxa sampled and that Issidae is a non-monophyletic group. The results of 16s rRNA sequence did not group Dictyopharidae with Fulgoridae, as suggested by morphological characters, but was closer to Derbidae.

15-061

THE NYMPHAL ANTENNAE OF AUCHENORRHYNCHA (HOMOPTERA): A PHYLOGENETIC TEST

Hsieh, Wen-chi, Shan-jen Fang and Chung-tu Yang

Department of Entomology, National Chung-Hsing Univ., Taichung, Taiwan, R.O.C.

The antenna of first to fifth instar nymphs of Peloridiomorpha and Auchenorrhyncha (Archaeorrhyncha + Clypeorrhyncha *sensu* Sorensen) were examined. The developmental arrests at the widest part of the basiflagellum in the Membracoidea and Fulgoroidea were observed and treated as a synapomorph of the two superfamilies. The polymerized antennae of Cercopoidea and Fulgoroidea are homoplasious. Mapping the character of number of nymphal antennal segments upon four given phylogenetic trees of Hemiptera using the program MacClade ver. 3.01 indicates that 3-segmented antennae of fifth instar nymph is the synapomorph of Euhemiptera and was derived from the 7-segmented antennae, which is the most primitive state within Hemiptera. While 3-segmented antennae is the primitive state of Auchenorrhyncha, the 9-segmented antennae in fifth instar nymph is a synapomorph for the (Cicadoidea + Cercopoidea). The hypothesized ground plan of the fifth instar nymphal antenna of Auchenorrhyncha *sensu* Zrzavy is 3 segments, and without developmental arrests. Auchenorrhyncha is reconsidered as a monophyletic group according to this specific feature.

15-062

THE REPRODUCTIVE APPARATUS IN CIXIDIA (HOMOPTERA, AUCHENORRHYNCHA, ACHILIDAE)

V. D'Urso, A. Guglielmino¹

Dipartimento di Biologia Animale, Università degli Studi di Catania, Catania, Italy - ¹ Dipartimento di Protezione delle Piante, Università della Tuscia, Viterbo, Italy

Male and female reproductive apparatus of *Cixidia sikaniae* were investigated.

In male, each testis consists of 6 follicles; in living specimens, both vas deferens and seminal vesicles appear orange-coloured; the ejaculatory duct is very long and receives a pair of long and convoluted accessory glands.

In female, each ovary consists of 6 ovarioles with long pedicels; both lateral and median oviducts are short; the latter widens to form a broad chamber; the spermatheca is long and complicated; the bursa copulatrix is broad and bears a sclerified plate.

15-063

EVOLUTIONARY PATTERNS OF HOST PLANT USE BY PLANTHOPPERS (HEMIPTERA: FULGOROIDEA)

S. W. Wilson

Department of Biology, Central Missouri State University, Warrensburg, MO USA

Planthopper host plant associations were surveyed for 17 of the 19 families to determine if there was evidence for parallel diversification of planthoppers and their host plants. Parallel evolution between planthoppers and host plant taxa was not found, however, there was evidence for phylogenetic patterns in feeding location. In one family, the Delphacidae, weak evidence for parallel diversification with monocot taxa was found as well as a strong tendency toward monophagy. Departures from this pattern suggest that host shifts may be influenced by habitat fidelity as exemplified by the host associations of Pacific Island faunas.

15-064

THE ROLE OF TAXONOMY AND BIOLOGY IN PATTERNS OF PEST AND VECTOR DISTRIBUTION WITHIN THE FULGOROMORPHA (HEMIPTERA)

M.R. Wilson

Department of Zoology, National Museums & Galleries of Wales, Cardiff, CF1 3NP, UK

The distribution of pest species and the vectors of plant disease is not evenly spread within the planthopper families (Hemiptera; Fulgoromorpha). For instance, the Delphacidae contains the majority of pest and vector species, while some large, species-rich families contain no known pest species.

Pest species distribution within and between families are analysed. Reasons for the observed patterns of pest and vector species, related to both taxonomy and host preferences are discussed. In the majority of cases, if not all cases, the interaction of human agricultural use of plant species and insect host preferences are the main determinants.

15-066

BIODIVERSITY OF FULGOROMORPHA (HEMIPTERA) : HOW MANY SPECIES ARE THEY ?

E. Guilbert and T. Bourgoïn

Laboratoire d'Entomologie et EP 90 du CNRS, Muséum national d'Histoire naturelle, Paris, France.

Managing intelligently biodiversity studies will not be the same with 10 or 100 millions of species. However, insect species number ranges from 8 to 100 millions (Groombridge, 1992). In such a frame, the question of specific richness appears as one of the first to answer.

Attempting to know the number of living species, scientists have developed different methods. Two main kinds of approaches have been tried : the number of species versus area and the number of species versus time (number of described species per year). It is clear that both approaches cannot provide a correct estimate because human constraints are strongly linked with the data available. However some land marks or tests may help to control the accuracy of the resulting estimates.

In order to illustrate this approach the Hemiptera Fulgoromorpha have been taken as a model.

Hemiptera Fulgoromorpha are an old lineage probably originating from Archaeoscytinoidea around the end of the early Permian ; modern fulgoromorpha groups (Cixiidae, Achilidae) do not appear until the Cretaceous (Scherbakov, 1988). Twenty families, mostly tropical, are currently recognized within the Fulgoromorpha. The whole of described species has increase from 7093 (given in Metcalf's catalogues published between 1932 and 1958), to 9200 (Woodward et al, 1970) and more than 10000 in the last edition of Insect of Australia (Carver et al., 1991). It amounts 10571 at the end of 1993.

Most of the trend curves of the number of species described each year by family show a sigmoidal form. From all the models tested by previous authors and from those available in mathematical literature, the logistic and the Gompertz models fit the best with the observed data. Nevertheless both do not provide the same range of number of species by family. More complex models using inflexion point estimation are thus proposed.

15-065

THE DISPERSAL OF FULGOROIDEA (HOMOPTERA) TO OCEANIC ISLANDS.

Lois B. O'Brien

Department of Entomology, Florida A& M University, Tallahassee, USA.

Fulgoroidea are disproportionally common on oceanic islands compared to other Auchenorrhyncha. However, their occurrence by family does not reflect their relative species abundance or population abundance on continents. The presence of Delphacidae, with the greatest number of species on islands, is expected because they represent 97.8 % of the aerial plankton collected over oceans by Gressett et al., with Cixiidae 0.1% and Derbidae 2.1%.

Five of the most commonly found families other than delphacids, Cixiidae, Derbidae, Achilidae, and the Kinnaridae-Meenoplidae pair, may have a competitive advantage for rafting because nymphs are found under bark or in holes in logs or in soil. Five other families found on islands (Tropiduchidae, Issidae, Flatidae, Nogodinidae and Ricaniidae) do in some genera oviposit within plant tissue.

The family Fulgoridae has no representatives on small oceanic islands, nor do five other small families. Eurybrachidae and Dictyopharidae have one and two species respectively.

At least 2/3 of the species are endemic to their island. There is no correlation between the percent of polyphagous species in a family and its success in colonizing islands.

15-067

INSECT PEST CONTROL BY CAMBODIAN RICE FARMERS

G.C. Jahn, S. Pheng, B. Kiev, C. Pol

Cambodia-International Rice Research Institute - Australia Project, Phnom Penh, Cambodia

Over 1000 lowland rice farmers, 400 upland rice farmers, and 400 deep water rice farmers were interviewed throughout Cambodia to determine farmers' pest control practices. Over 100 farmers were interviewed per province. Data was analyzed by province as well as nationally. In the province of Kampong Cham, 12 to 13 times as many farmers grow lowland rice in the wet season as in the dry season. Less than 20% of these farmers use insecticides during the wet season, while over 80% use insecticides during the dry season. There are currently no laws regulating the import, sale, or use of pesticides in Cambodia. Most of the pesticides used in Cambodia are WHO Class I insecticides, which are usually banned or restricted in other countries. Farmers employ a combination of biological control, cultural control, home-made botanicals, and insecticides to manage rice pests. This paper will describe each of these methods in relation to sociodemographic factors, with particular emphasis on those pest control techniques unique to Cambodia. In addition, there will be a discussion of the sources of insecticides, the types of insecticides available, and the quality of insecticides in Cambodia.

15-068

SOYBEAN CULTIVATION. INSECT PEST MANAGEMENT. & BENEFIT /COST RATIOS IN JAPAN

O. MOCHIDA . A. KIKUCHI

National Agriculture Research Centre, Ibaraki-ken, Tukuba-si, Japan

Soybean was cultivated in 68600ha with a production of 98500 metric ton(mt) and an avg of 1.81 mt/ha in 1995. About 271 invertebrates(245 insect, 12 nematode, 7 Stylopomatophoran, 5 mite, and 2 Isopod species), 9 birds, and 13 mammals are recorded as pests. In the south-western, insect pests are very serious: Lepidopterous defoliators (*Spodoptera litura*, *Plusia* sp. [Noctuidae], Dipterous podfeeder (*Asphodylia* sp. [Cecidomyiidae]), Lepidopterous podborers (*Etiella zinckenella* [Pyralidae], *Matsumuraesia* spp. [Tortricidae]), Heteropterous podsuckers [Pentatomidae and Alydidae], etc. occur. In Ibaraki, central part Japan, yield loss due to insect pests was assessed using 3 applications of Parmathion 40 (fenitrothion 30 + fenvalerate 10%) WP in treated plots in 1995. Under non-tillage for seeding, yields were 1.6 (relative value of 100) and 0.4t/ha(25) in treated & untreated plots, respectively. Under a common method or tillage for seeding, those were 2.0(100) and 1.2 t/ha (58), respectively. Thus, yield losses due to insect pests were estimated at least 75 & 42%, respectively. Benefit/cost ratios were 5.6 & 17.0 in non-tillage and tillage seeding fields, respectively.

15-070

THE SOYBEAN PESTS IN SOUTHWEST OF IRAN.

Kocheili, F. & A.A. Komeili

Department of plant protection, College of Agriculture, Shahid Chamran University, Ahwaz, Iran.

In three years survey, the Soybean pests were studied in khuzestan province, southwest of Iran. Two different experimental fields were selected at Ahwaz Agricultural College field station. By different methods of sampling such as light trap and leaf sampling, the Soybean pests were collected and identified as follow:

- 1- *Bemisia tabaci* Gennad (Homop., Aleyrodidae).
- 2- *Tetranychus tukrestani* Ugarov and Nikolski (Acarina, Tetranychidae)
- 3- *Nezara viridula* L. (Hemip., pentatomidae).
- 4- *Aphis craccivora* Koch (Homop., Aphididae).
- 5- *Spodoptera exigua* Hubner (Lepidop., Noctuidae).
- 6- *Prodenia litura* Fabricious. (Lepidop., Noctuidae).
- 7- *Heliothis armigera* L. (Lepidop., Noctuidae).
- 8- *Thrips tabaci* Lin. (Thysanop., Thripidae).
- 9- *Agriotes* SP. (coleop., Elateridae).
- 10- *Anacridium aegyptium* L. (Orthop., Acrididae).
- 11- *Epilachn chrysomelina* F. (coleop., coccinellidae).

Moreover, the populations of *B. tabaci* and *T. turkestan* two important of Soybean pests were estimated.

15-069

FORECASTING OF POPULATION DENSITY AND OUTBREAKS IN *AELIA* AND *EURYGASTER* SPECIES (HEMIPTERA: HETEROPTERA: PENTATOMOIDEA).

M. Javahery

Lyman Entomological Museum & Research Laboratory, Campus Macdonald of McGill University, Quebec H9X 3V9 Canada

Fluctuations in population density from one year to another in the cereal pest species, *Aelia acuminata* L., *A. furcula* Fieb., *A. melanota* Fieb., *A. rostrata* Boh., *A. virgata* Klug., *Eurygaster integriceps* Put., and *E. maura* L. is related to the physiological condition of the individuals and ecological factors of biotic and abiotic nature. It is possible, from a study of the physiological condition of the internal organs of these species, to forecast the degree of their abundance during forthcoming invasions of wheat and barley fields.

Survival of individuals depends on the quantity and quality of food reserves (size of fat-body), from the time of migration to resting site (summer, autumn, winter) until they return to the fields during the spring of the following year.

A long term study of population density of *Eurygaster integriceps*, in two localities with different ecological conditions during 1960-1995 support the above hypothesis.

15-071

AN INVESTIGATION ON THE DISTRIBUTION OF *DOCIOSTAUROS* FIEB. SPECIES (ORTHOPTERA: ACRIDIDAE) IN WESTERN IRAN (ILAM)

By: P. Azmayesh Fard

Entomology Department

College of Agriculture Tehran University
Karaj-IRAN

An investigation carried out on the distribution of *Doclostaurus* species in five districts of province revealed that at least five species and subspecies: *D. maroccanus* (Thunb.), *D. hauensteini hauensteini* (I. Bol.), *D. hauensteini elbursianus* uv., *D. anatolicus* (Kr.) and *D. jagoi* n. sp. with various populations are distributed in these regions, distributional map for these regions is prepared. According to these findings Mehran district in Ilam province is permanent breeding area of Moroccan locust, in outbreak area there will be more than one thousand nymphs in a square meters, it spends 8-9 months of the year as eggs in the soil, it takes 58-85 days from first instar to the end of oviposition Period.

As far as economic importance is concerned, *D. maroccanus* caused economic damage to many agricultural and forage crops and due to rather high population density applied methods of control is necessary to reduce its damage.

15-072

MONITORING THE FIRST FLIGHT ACTIVITIES OF CEREAL APHIDS USING SUCTION TRAPS AND COLOURED WATER TRAPS

W. Meyer zu Brickwedde¹, H.-M. Pochling²

¹ Institute of Plant Pathology and Plant Protection, Department of Entomology, University of Göttingen, Germany, - ² Institute of Plant Diseases and Plant Protection, University of Hannover, Germany

The primary colonization of cereals by aphids in autumn and spring is a critical event concerning the risk of BYDV infection. Prediction of population trends (i.e. settling, spread) is essential for risk evaluation. Basic data needed are time and intensity of the first immigration of the three species *Rhopalosiphum padi* (L.), *Sitobion avenae* (F.) and *Metopolophium dirhodum* (W.). However, visual controls and D-vac sampling are very time consuming since high numbers of replicates are needed due to the spatial distribution pattern during the immigration period. Therefore the suitability of stationary traps for monitoring was tested from 1993 to 1995.

During spring and summer 1995 yellow and green water traps were used to monitor the flight activity of cereal aphids in addition to three suction trap types (high-level: 12 m, low-level: 1.7 m, variable low-level: 0.5-1.5 m). In the 12-metre trap the first alatae of all three species were recorded at May 7th and 8th, in the lower suction traps 5-7 days later. The first cereal aphids were caught in coloured water traps a few days up to three weeks later. The first flight activity of *S. avenae* corresponded well in both types of colour traps in contrast to that of *M. dirhodum*. *S. avenae* was dominant within the crop which was reflected by the suction traps. *R. padi* however was much more dominant in the 12-m trap compared to the real abundance in the crop. Only in the green water traps the distribution of the species corresponded well with observations in the field. The data show that suction traps and coloured water traps can be used to measure time and intensity of immigration. Similar trends were previously observed for suction traps.

15-074

EFFECT OF DIFFERENTLY STRUCTURED FIELD MARGINS ON THE ABUNDANCE AND DISPERSAL OF CARABID BEETLES (COLEOPTERA: CARABIDAE)

A.M. Kopp*, H.M. Poehling**

*Research Centre Agriculture and the Environment, University of Göttingen, Germany
** Institute of Plant Diseases and Plant Protection, University of Hannover, Germany

Long-term studies indicate drastic reductions in epigeic predatory arthropod densities due to intensification of farming practices, including fertilisation and pesticide use, and the reduction of diversely structured field boundaries. These results stress the importance of non-cultivated habitats as possible sources of restoration of field-dwelling beneficial arthropod fauna. The aim of this study was to estimate the importance of differently structured field margins on the abundance and migration of carabid beetles in and between agricultural and surrounding landscapes.

The study sites were situated on two winter wheat fields in Northern Germany. The fields were bordered by three different types of field margins (permanent succession, annual succession, sown wildflower mixture). All these boundary strips had a width of 3m and a length of at least 30m, with 4 replications on each study site. Estimates of absolute densities of carabid beetles were obtained by means of quadrat samples, taken both in the field margins and in the winter wheat. The activity density was recorded using pitfall traps. The dispersal of carabid beetles between crop and adjacent field margins was measured by directional pitfall trapping (gutter traps) and mark-recapture techniques.

The species composition and the abundance of carabid beetles differed between the crop free strips and the arable land. An exchange of carabids during the vegetation periods could only be recorded for some species. The mark-recapture estimates reveal the species-dependent permeability of field boundaries.

15-073

DOES STRAW MULCH PROTECT LUPIN CROPS FROM INCOMING APHIDS (HOMOPTERA: APHIDIDAE)?

E. A. Berlandier, L.M Cartwright

Entomology Section, Plant Protection Branch, Agriculture Western Australia, South Perth, WA, Australia

Studies of aphid landing show that in some species, fewer aphids land on plants where there is more ground cover. Trials were conducted to investigate the effect of ground cover (straw mulch) on aphid landing behaviour in lupin crops, with the intention of controlling aphid infestations and the spread of aphid-borne plant viruses.

Plots were sown with lupins and half the plots were covered with straw mulch (to simulate stubble retention), the other half had bare earth. Alighting aphids were collected from water traps positioned over the plots.

Significantly more aphids (up to three times as many) were caught in traps positioned in the bare earth plots than those with mulch, particularly early in the season when there were large gaps between plants. Aphids were less attracted to plots where lupin plants were interspaced with straw mulch. Differences in aphid landing rates between bare earth and stubble treatments decreased as the canopy cover increased.

Stubble will offer some protection to the crop from aphid attack, especially when aphids arrive early and the open canopy makes the crop more vulnerable. How does stubble alter aphid landing behaviour? Aphids respond to visual signals (wavelengths) emitted from the ground, in particular light reflectance. Some species of aphids were repelled by the higher proportion of light reflected by straw mulch than that reflected by bare earth.

15-075

DIVERSITY, ABUNDANCE AND PHENOLOGY OF PHYTOSEIID MITES (ACARI: PHYTOSEIIDAE) IN VINEYARDS AND ON THE SURROUNDING VEGETATION IN NORTH-EASTERN ITALY

C. Duso, P. Fontana

Istituto di Entomologia agraria, Università di Padova, Italy

The mite fauna occurring in vineyards and on the surrounding vegetation was monitored in different areas of North-Eastern Italy. Phytoseiids were a major component of the mite communities on wild vegetation and in vineyards. A total of 13 different species were found on the wild vegetation. Leaf morphology appeared to be important in affecting phytoseiid colonization. Six phytoseiid species were found on grapevines throughout the sites. A correlation between the dominance of some predatory mites on wild vegetation and in vineyards was found in some cases and, in particular, the economically important *Amblyseius aberrans*, *A. andersoni* and *Typhlodromus pyri* were involved.

The Tydeidae were widely diffused on wild plants and in vineyards and the same species were frequently recorded on both. Phytophagous mites (Tetranychidae, Tenuipalpidae and Eriophyidae) were rarely abundant on wild vegetation and in vineyards. The fungivore Winterschmidtidae were common on wild plants but not in vineyards. In various localities and years the phytoseiid densities were significantly higher in mid season than in late season on the wild vegetation while they were more abundant in early season in vineyards. The mechanisms affecting the persistence and abundance of phytoseiids on wild plants may suggest strategies for successfully managing their populations in vineyards.

15-076

Impact of Rice Water Weevil, *Lissorhoptrus oryzophilus* Kuschel, (Coleoptera: Curculionidae) Larval Injury on Rice Plant Photosynthesis and Biomass Accumulation

L. D. Godfrey and A. T. Palrang

Department of Entomology, University of California, Davis, CA USA

A 3-year field study was conducted in California to determine the effects of rice water weevil infestation on rice plant growth, development, photosynthesis, and yield. Differential larval densities were established by infesting from 0 to 0.6 rice water weevil adults per plant (retained with floating row covers). In 1993 and 1995, rice water weevil larval densities correlated closely with adult infestation levels. The average larval density increased from 1 to 17 per plant over the 0 to 0.6 infestation regimes. In 1994, treatments generally resulted in uninfested plots (a low background infestation of ~1 larva per plant) and in infested plots (averaging ~8.3 larvae per plant). The primary damage from this insect is from the larval injury to the root systems. Reductions in vegetative biomass accumulation were seen at infestation levels ≥ 0.4 adults per plant (= ~7 larvae per plant). The number of tillers per plant, and resulting leaf area per plant, was most severely reduced by rice water weevil larval injury. Rice photosynthetic rates were reduced by the root injury during the period of larval feeding; however, photosynthetic rates of injured plants elevated to that of uninjured plants at and following the time of pupation. This physiological response to root injury is similar to that recorded for other soil-borne insect pests. Grain yield was reduced by rice water weevil larval injury by up to 45% in 1993 and by 33% in 1995 by the highest infestation levels. A linear relationship best described the yield loss/larval density relationship with a 2.9% yield loss per larvae. In 1994, the maximum yield loss was 21%. It was not possible to form a significant relationship between larval density and yield because of the lack of a range of rice water weevil larval densities in 1994.

15-078

THE RUSSIAN WHEAT APHID, *DIURAPHIS NOXIA* IN CHILE: DISTRIBUTION AND YIELD LOSSES

H. Norambuena, M. Gerding¹, K. Pike²

CRI Carillanca-INIA. Temuco, Chile - 1 CRI

Quilamapu-INIA. Chillán, Chile - 2 Washington State

University, Irrigated Agriculture Res.& Ext. Ctr.

Prosser, WA, USA.

The Russian wheat aphid (RWA) was first discovered in Chile in 1987. Because of heavy infestations and serious economic losses caused by the aphid in South Africa and USA, a survey together with yield losses assessments were conducted throughout the main small grain growing areas of Chile.

Presently, RWA occurs in most grain production areas of the country (Parallels 29°53' to 38°56'S), including localities with rainfall as nearly 1400 mm. However, the aphid has not adversely affected wheat production or quality in south-central Chile, except in extremely delayed plantings.

15-077

THE PEA LEAFMINER, *LIRIOMYZIA HUIDOBRENSIS* (DIPTERA: AGROMIZIDAE), AS A PEST OF LEAFY VEGETABLE CROPS IN THE SALINAS VALLEY OF CALIFORNIA, U.S.A.

W. E. Chaney

University of California Cooperative Extension, Salinas, California, U.S.A.

The pea leafminer has become the most serious insect pest of leafy vegetables in Salinas Valley of California. The reason for the change in pest status from a sporadic, easily controlled pest to one that is responsible for the destruction of many entire fields of spinach and an 300% increase in insecticide costs in lettuce has been examined in a number of field and laboratory investigations.

The role of insecticidal resistance, changing cultural practices, the parasitoid complex and host preference shifts in this pest species have all been examined. It has been shown that the leafminer populations in this area are resistant to many of the products used for their control. Resistance to permethrin applied to control adults was found to be so high as to lead to total field control failure. It was also shown that lettuce has become the most important host in the system for this pest. Whole plant samples from lettuce fields at harvest in August 1995 were found to have an average of 660 leafminer larvae per plant, despite 14 applications of insecticides applied to the field. The role of cultural practices and the parasitoids seem to be less important.

15-079

PREMATURE FRUIT DROP CAUSED BY THE ALMOND SEED WASP *EURYTOMA AMYGDALI* ENDERLEIN (HYMENOPTERA: EURYTOMIDAE) TO THREE ALMOND VARIETIES

M. E. Tzanakakis, B. I. Katsoyannos, N. T. Papadopoulos, G. N. Drakos, E. Manolakis

Laboratory of Applied Zoology and Parasitology, College of Geotechnical Sciences, Aristotelian University of Thessaloniki, Thessaloniki, Greece

The main if not the only damage caused by the almond seed wasp, *Eurytoma amygdali* Enderlein (Hymenoptera: Eurytomidae), has been known to be the erosion of the seed by the larva. Infested fruit containing grown larvae become mummified and remain on the tree beyond harvest. To ascertain suspected additional damage to infested fruit in the form of premature drop, almonds on trees of three varieties were oviposited on different dates and for different periods of time by released adult wasps or by the natural orchard population, and fruit dropping were recorded weekly.

Infested fruit suffered heavy premature drop in Texas (Mission) and Ferragnes, but not in the Truoto variety.

The results suggest a change of the established strategy of control, to prevent substantial oviposition in varieties that suffer such premature fruit drop.

15-080

THE BIOLOGY OF *SEJANUS ALBOSIGNATUS* IN ORGANIC APPLE ORCHARD IN CANTERBURY, NEW ZEALAND: FRIEND OR FOE?

P. Daur, R.R. Scott, S.P. Worner

Department of Entomology and Animal Ecology, Lincoln University, Canterbury, New Zealand.

The distribution of *Sejanus albosignatus* (Hemiptera: Miridae) in conventionally and organically managed orchards is described. The seasonal phenology was investigated over the summers of 1993/94, 1994/95 and 1995/96 in an organic orchard.

Characteristically, there are two generations per year. The first emerges from overwintering eggs in early spring, passes through five nymphal instars and reaches adulthood by early summer. The second generation, which is smaller than the first in size, emerges in late December - early January and adults appear by early February. Egg diapause appears to affect a proportion of the first generation eggs and all of the second.

The effect of herb understorey on the biology of *Sejanus* is discussed. The damage to fruit and the effect of apple variety on its incidence are described as is the mirid's predation on other apple pests.

15-081

NYMPH AND ADULT PERFORMANCE OF THE SOUTHERN GREEN STINK BUG (HETEROPTERA: PENTATOMIDAE) ON JAPANESE PRIVET COMPARED TO OTHER SELECTED FOOD PLANTS

A.R. Panizzi, L.M. Vivan, B.S. Corrêa-Ferreira, L.A. Foster¹
Centro Nacional de Pesquisa de Soja (CNPSo), EMBRAPA, Caixa Postal 231, Londrina, PR, 86001-970, Brasil - ¹Departamento de Zoologia, Universidade Federal do Paraná, Caixa Postal 19020, Curitiba, PR, 81531-970, Brasil

Laboratory studies with the southern green stink bug, *Nesara viridula* (L.) indicated that nymphs performed better when fed on immature fruits of soybean, *Glycine max* (L.) Merrill (Leguminosae), than on immature fruits of Japanese privet, *Ligustrum japonicum* Thunb. (Oleaceae). Female and male nymphs required 6.7 and 4.6 d more to complete development on Japanese privet than on soybean, with greater mortality (38.7%) on the former than on the later (20.0%) food plant. At emergence adult fresh body weight was ca. 34-40% greater on soybean than on Japanese privet. In contrast to nymphs, adults *N. viridula* performed better on Japanese privet than on soybean, with greater % of females ovipositing on the first (62.5) than on the second (45.0) food. Fecundity was 2-3X greater on Japanese privet [alone or supplemented with dried soybean seeds+shelled peanuts, *Arachis hypogaea* (L.)], than on soybean fruits or vegetative plants, or on water cress, *Nasturtium officinale* L. (Brassicaceae) leaves, these last two foods supplemented with dried soybean seeds+peanuts. Fresh body weight gain up to the 4th week of adult life was ca. 3X greater on Japanese privet than on soybean fruits. Total longevity of females and males was similar on Japanese privet or soybean fruits, but it was greater on Japanese privet than on water cress, both supplemented with soybean seeds+peanuts.

15-082

THE DRAMATIC SHIFT OF THE WESTERN CORN ROOTWORM, *DIABROTICA VIRGIFERA VIRGIFERA* LECONTE (COLEOPTERA: CHRYSOMELIDAE), TO MAIZE IN ROTATION WITH SOYBEANS IN INDIANA

C.R. Edwards, L.W. Bledsoe, J.L. Obermeyer
Purdue University, West Lafayette, Indiana, USA

The primary means for managing the western corn rootworm, *Diabrotica virgifera virgifera* LeConte, in Indiana over the past 20 years has been through crop rotation. This has resulted in a soil insecticide usage-reduction of 340,500 kilograms of active ingredient per year.

In 1993, a few reports of rootworm larval feeding damage in maize fields following soybeans were received. Since rootworm eggs are laid in late summer prior to hatch the next spring, the adults had to have moved into soybean fields to lay their eggs. Each year since then, more farmers have observed this phenomenon. By 1995, more than one thousand maize fields were reported as having this problem.

It is difficult to say why this is happening. There is speculation that the rootworm beetle may be adapting to the maize/soybean rotational system. It could be that the maize residue on the soil surface is giving off volatiles that are attracting the beetles into the soybeans. Also, earlier maize planting and later larval hatch could be causing the maize and the insect to get out of sync with each other. Perhaps we have a biotype.

Part of the concern is that farmers will return to using soil insecticides as prophylactic treatments. If this happens, much of what we have gained in managing this insect with alternatives to insecticides will be lost. Studies are underway to help us determine why this is happening and what are the appropriate management strategies.

15-083

BEHAVIORAL ADAPTATION OF *HELICOVERPA ARMIGERA* TO THE COSMOPOLITAN WEED, *SONCHUS OLERACEUS* L. (ASTERACEAE)

H. Gu, G.H. Walter¹

Institute of Plant Sciences, Applied Entomology, Swiss Federal Institute of Technology (ETH), Zürich, Switzerland - ¹ Department of Entomology, The University of Queensland, Brisbane, Australia

The common sowthistle, *Sonchus oleraceus*, is a native of Europe and North Africa, but has established in at least 56 other countries. Thus, the original distribution of *H. armigera* overlapped with that of *S. oleraceus*. *Sonchus oleraceus*, therefore, may well be a primary host plant of *H. armigera*. In other words, *H. armigera* may be behaviorally and physiologically adapted to exploited *S. oleraceus*.

Helicoverpa armigera females showed consistent preference for *S. oleraceus*, irrespective of their age and host in the field. Phytochemicals from *S. oleraceus* may play an important role in mediating the behavioral steps leading to selection of the host plant for oviposition, as the solvent extracts of *S. oleraceus* significantly attracted oviposition by *H. armigera* females. On the other hand, there was significant individual variation in oviposition preference and such variation was genetically based.

Empirical evidence from our study, along with field observations, supports the view that *S. oleraceus* is a primary host plant to which *H. armigera* became adapted at the time of speciation. Nevertheless, the existence of significant variation in oviposition preference presumably maintains sufficient flexibility for the observed levels of polyphagy in *H. armigera*.

15-084

LIFE TABLE AND INTRINSIC RATE OF INCREASE OF THE DIAMONDBACK MOTH *PLUTELLA XYLOSTELLA* (L.) LEPIDOPTERA: (YPONOMEUTIDAE) ON FIVE DIFFERENT COLE CROPS.

Usha Chauhan, A.K.Sood and D.P.Bhalla
Department of Entomology, University of Horticulture and Forestry, Solan - 173 230 India.

Out of the major pests the diamondback moth has gained importance recently in Himachal Pradesh by damaging cole crops to a greater extent. In order to understand the population dynamics of the pest its life tables have been constructed on five different cole crops which are cabbage, cauliflower, khol-khol, Brussel's sprout and sprouting broccoli.

Life table studies revealed that the gross reproductive rate of the moth was 114.2, 148.8, 104.5, 153.7 and 157.9 female eggs per female on these crops respectively. In a true generation time of 25.2, 23.2, 25.7, 23.8 and 20.3 days, the moth multiplied 85.7, 116.0, 69.7, 131.1 and 118.9 times on the respective hosts. The true intrinsic rate of increase was maximum (0.236) on sprouting broccoli, thus it can be considered more suitable for rearing this pest in comparison to the other hosts. The finite rate of increase (λ) on these crops was found 1.19, 1.23, 1.18, 1.27 and 1.23 respectively.

15-086

BIOLOGY AND HOST PLANT RELATIONSHIPS OF *SCAPTOMYZA FLAVA* LEAF MINER

Ali Seraj, P.Fenemore¹, M. Harris²
Department of Plant Protection, Shahid Chamran University, Ahwaz, Iran- 1, 2 Department of Plant Science, Massey University, Palmerston North, New Zealand.

The relationship between ovipositional preference of *Scaptomyza flava* Fallen (Diptera: Drosophilidae) and host plant suitability on seven host plant species (Chinese cabbage [*Brassica chinensis*], turnip [*Brassica rapa*], radish [*Raphanus sativus*], hedge mustard [*Sisymbrium officinale*], cauliflower [*Brassica oleracea* var. botrytis], lettuce [*Lactuca sativa*], wheat [*Triticum aestivum*] and prairie grass [*Bromus willdenowii*]) was evaluated. Ovipositional preference of *S. flava* was determined by measuring feeding punctures and egg density after adult female flies were given a simultaneous choice and non-choice of all host plants for feeding and oviposition. All studies were performed under greenghouse conditions. *S. flava* showed distinct hierarchical ordering in their ovipositional preference with turnip, Chinese cabbage and hedge mustard being preferred over all others. *S. flava* is an oligophagous insect with host plants restricted to Brassicaceae. In non-choice tests, females laid more eggs on Chinese cabbage and turnip other Brassicaceae. Egg production was also different between host plants. Females oviposited means of 255, 165 and 48 eggs during their lifespan when maintained on turnip, Chinese cabbage and cauliflower, respectively. There were also significant differences in total developmental times of the insect between three Brassicaceous host plants (cauliflower 41d. Chinese cabbage 33.7d and turnip 31d).

15-085

EFFECT OF LARVAL FOOD PLANT ON ADULT EGG LAYING PREFERENCE OF *SCAPTOMYZA FLAVA* (F.) (DIPTERA: DROSOPHILIDAE) LEAF MINER

Ali . A. Seraj
Department of Plant Protection, College of Agriculture, Shahid Chamran University, Ahwaz, Iran.

To evaluate the effect of larval food plant on adult egg laying preference *S. flava* was reared on 3 plant species, Chinese cabbage, cauliflower, and turnip.

In terms of total feeding punctures and eggs laid, flies reared on Chinese cabbage produced significantly more than those reared on turnip, which in turn produced more than those reared on cauliflower. This suggests that Chinese cabbage is the better quality host plant. Flies reared on turnip produced significantly more feeding punctures ($P \leq 0.01$) and deposited significantly more eggs on turnip than on Chinese cabbage or cauliflower. Flies reared on Chinese cabbage produced an equal number of feeding punctures on Chinese cabbage compared to turnip, but showed a distinct preference for Chinese cabbage for egg laying. However, flies reared on cauliflower showed no preference for cauliflower and made most feeding punctures and laid most of their eggs on Chinese cabbage. Thus, although there was significant preference for both egg laying and feeding on turnip in the case of insects raised on that plant and similar slight preference in the case of Chinese cabbage, this was not the case at all for cauliflower where rearing on that plant induced no preference.

15-087

FACTORS AFFECTING INTERSPECIFIC AND INTERCLONAL VARIABILITY IN APHID PERFORMANCE AND APHID-INDUCED PHYTOCHEMICAL RESPONSES IN WHEAT

E. Gianoli¹, C. M. Caillaud², C. C. Ramirez¹, B. Chaubet², J. P. Di Pietro², H. M. Niemeyer¹

1 Departamento de Ciencias Ecológicas, Facultad de Ciencias, Universidad de Chile, Santiago, Chile - 2 Institut National de la Recherche Agronomique, Laboratoire de la Chaire de Zoologie de l'ENSAR, France

Changes were evaluated in the accumulation of hydroxamic acids (secondary metabolites related to aphid resistance of cereals) in both wild and cultivated wheat following infestation by two clones of the aphid *Sitobion avenae* (Fabr.) markedly differing in their ability to thrive in wheat lines. A statistical interaction between plant genotype and aphid clone feeding behavior was detected. Further experiments including the aphid *Rhopalosiphum padi* (L.) and using electropenetration graphs (EPG) enlightened the relationship between aphid feeding behavior and aphid-induced phytochemical responses. The importance of a threshold of infestation (number of aphids) required to induce phytochemical responses was determined.

15-088

INFLUENCE OF MAIZE VARIETY ON THE CLONAL SELECTION OF *RHOPALOSIPHUM PADI* (HOMOPTERA: APHIDIDAE)

Th. Hance , Ch. Noel

Unité d'Écologie et de Biogéographie, Université Catholique de Louvain, Louvain-la-Neuve, Belgium.

Maize varieties exhibit a large range of susceptibility to aphids. As aphids possess a large genetic polymorphism this could lead to a rapid selection of aphid clones able to thrive on resistant varieties. Our aim was to test this hypothesis by the use of RAPD-PCR to quantify the genetic distances between aphids collected on different varieties but on the same location. It appears that the genetic distances between aphid caught on the same plant is low (15 % of the DNA bands) but between plants of the same variety these distances could reach 38 % of the DNA bands recorded. At the variety level this distances do not increase very much although some clones seem to be more frequent on more resistant varieties.

15-090

NON-CHEMICAL REGULATION OF CEREAL LEAF BEETLE IN ORGANIC GRAIN FIELDS IN EASTERN AUSTRIA

B. Kromp, P. Meindl

L. Boltzmann-Institute for Biological Agriculture and Applied Ecology
Vienna, Austria

The Cereal Leaf Beetle CLB (*Oulema melanopus* L. Chrysomelidae) is an important pest of organic grain production in Eastern Austria.

The effectiveness of preventive cultivation measures (choice of cultivar, compost fertilization) and antagonists in reducing the CLB infestation levels have been investigated in an organic farm in Vienna.

Several cultivars of wheat were tested on CLB susceptibility. Different fertilization regimes (compost, inorganic fertilizers, combined fert.) were investigated in a plot trial towards their effects on CLB population dynamics and feeding damage. Egg-parasitization rates were measured in different vicinity of surrounding natural habitats.

From the obtained results, a non-chemical pest management strategy is derived.

15-089

EFFECT OF CULTIVATION PRACTICES ON THE INCIDENCE OF *HYPOLIXUS HAERENS* (BOHEMAN) (COLEOPTERA: CURCULIONIDAE) ON CULTIVATED AMARANTHS IN SOUTH AFRICA

C.F. van Eeden, W.J. Weeks, S.vd M. Louw¹

North West Agricultural Development Institute, Potchefstroom, South Africa - ¹ Department of Zoology and Entomology, University of the Orange Free State, Bloemfontein, South Africa

Hypolixus haerens (Boheman) seems to be the major stem-boring pest of cultivated amaranths in South Africa. The infestation levels of these weevils were determined at fortnightly intervals for 16 weeks on two similarly cultivated trials of which one received irrigation and the other one was rainfed. Within each trial four fertilizer treatments (viz. no fertilizer, cattle manure, wood ash and chemical fertilizer) were applied in order to simulate growing conditions varying from subsistence to commercial farming. Statistical analysis of the data revealed that significantly more ($p < 0.05$) adult weevils occurred in the rainfed than in the irrigated trial during the first six observations. During the last two observations no significant differences in insect numbers were recorded. No significant differences ($p < 0.05$) in weevil numbers were recorded between the various fertilizer treatments in both trials. The within-season distribution pattern of *H. haerens* was determined by plotting weevil numbers against time. Two definite peaks of occurrence were discernible viz. mid-December and mid-January. Weevil numbers declined sharply from the second week of February, coinciding with the decline in vegetative plant growth. The within-distribution patterns were similar for both trials.

15-091

EVIDENCE ON GEOGRAPHICAL DIFFERENCES IN MALE RESPONSES TO SYNTHETIC PHEROMONE BLENDS IN THE LIMABEAN POD BORER (*ETIELLA ZINCKENELLA* TREITSCHKE) (LEPIDOPTERA: PHYCITIDAE)

M. Tóth, Cooperators

Plant Protection Institute, Hungarian Academy of Sciences, Budapest, Hungary

The limabean pod borer (*E. zinckenella*) is an important pest of fabaceous crops in regions with hot and temperate climate of Europe, Africa, Asia, Australia and the Americas. Several components have previously been identified from the female-produced sex pheromone of populations in Central Europe and Northern Africa. In the present study, field trapping tests were conducted at several geographically distant sites of the area of distribution of the pest using (Z)- and (E)-11-tetradecenyl acetate (Z11-14Ac; E11-14Ac), (Z)-9-tetradecenyl acetate (Z9-14Ac) and some binary and ternary mixtures of these as baits. At sites in Europe very good catches were observed with maximal activity in baits containing a 100:3 mixture of Z11-14Ac and Z9-14Ac. Some activity was also recorded at the above combination in India, whereas at sites in Eastern Asia or in Australia no male catches were recorded to any of the baits. The present results suggest that there are geographical differences in pheromonal response of *E. zinckenella* populations in different areas. At present it seems that pheromone-baited traps developed for monitoring of the pest in Europe and Northern Africa cannot be used in Eastern Asia or Australia, where a reinvestigation of the local populations' pheromone composition is needed in order to develop a pheromone-based monitoring trap.

15-092

CONTROL EFFECT OF A SYNTHETIC SEX PHEROMONE AGAINST COMMON CUTWORM, *SPODOPTERA LITURA* FABRICIUS (LEPIDOPTERA: NOCTUIDAE) ON ROSE IN GREENHOUSE DURING THEIR OVERWINTERING PERIOD

Y. Kobayasi

Agro-Kanesyo Co., Ltd., Kakegawa, Shizuoka, Japan

In rose culture in southern Japan, some kinds of mites, aphids and Common cutworm are dominant. Chemicals are frequently sprayed to control these pests especially the latter. We reported on the practical control effects of the mating communication disruption by using sex pheromones against Lepidopteran pests in greenhouses. The results showed that the effects in greenhouses were greater than those previously reported by others in open spaces, and that the population density was more intensely depressed during their overwintering period than in summer season. The present experiment was conducted to confirm these results in commercial rose greenhouses from October 1989 to January 1990. Five hundred pheromone dispensers were set in a treated house (1000 m², above 17°C) and none in a non-treated one. One month later, the damage ratio of plants in the treated house quickly decreased from 22% to 12%, in contrast to its increase in the non-treated one. The damage ratio in the former kept lowering until the winter, becoming finally zero. In the non-treated house, however, the damage ratio did not lowered to zero. It was concluded that Common cutworm could easily be eradicated by using the sex pheromone in low population density.

15-094

HOST PLANT VOLATILES SYNERGISTICALLY ENHANCE THE CAPTURE OF MALES IN COMMERCIAL SEX PHEROMONE TRAPS FOR VARIOUS MOTH SPECIES

D.M. Light, R.A. Flath

Plant Protection Research Unit, Western Regional Research Center, Agricultural Research Service, United States Department of Agriculture, Albany, CA USA

Since female moths call and release their sex pheromones while perched on their host plants, we isolated and identified host plant volatiles (HPVs), and tested various HPVs for their ability to attract moths and/or modulate the attraction of males to synthetic commercial sex pheromones in both field and orchard crops. To test their inherent attractancy, individual HPVs were placed alone in traps and were found to be nonattractive to both male and female moths. To test the effects of HPVs on sex pheromone attraction, pairs of pheromone-baited traps were placed in close competitive positions, with one of the pheromone traps augmented with a HPV, the other without. When co-emitted with sex pheromone from baited traps, various HPVs were found to synergistically enhance the male attraction and capture efficacy of the pheromones by between 20% to over 300%. The HPVs acted as sex pheromone-synergists, increasing the capture of exclusively male moths and not causing attraction/capture of female moths. Various HPVs were found to synergistically enhance the attraction of commercial pheromones of a wide range of moth species, including Noctuidae (*Helicoverpa zea*, *Heliothis virescens*, *H. phloxiphaga*, *Trichoplusia ni*, *Spodoptera exigua*, *Pseudaletia unipuncta*, *Agrotis ipsilon*, *Peridroma saucia*), Gelechiidae (*Anarsia lineatella*, *Pectinophora gossypiella*), Tortricidae (*Grapholita molesta*, *Platynota stultana*), Olethreutidae (*Cydia pomonella*), Pterophoridae (*Platyptilia carduactyla*), and Plutellidae (*Plutella xylostella*).

The HPVs identified as pheromone-synergists were of various chemical structure, ranging from hydrocarbon monoterpenes and sesquiterpenes to aliphatic alcohols, aldehydes, acetates, and acids. A number of different compounds were identified as pheromone-synergists for various species, e.g. 16 for *H. zea*, 8 for *A. lineatella*, 4 for *T. ni*, and 3 for *G. molesta*.

Night-vision assisted observations in the field suggest that the HPV-enhanced pheromone trap capture of males was due to increased attractancy of pheromone traps and not increased alightment/ensnarement in traps. And for *H. zea*, HPV pheromone-synergists significantly lowered the amount (approx. 50 fold) of synthetic pheromone required to elicit a threshold attractive response in the field.

15-093

SEX PHEROMONE OF THE TOMATO PEST *SCROBIPALPULOIDES ABSOLUTA* (LEPIDOPTERA: GELECHIIDAE)

E.F. Vilela¹, F.A.A. Ferrara¹, A.B. Attygalle², A.E. Eiras³, M.C. Picanço¹, G.N. Jham¹, T.S. Frighetto², A. Svatos², J. Meinwald²

¹ Departamento de Biologia Animal, Universidade Federal de Viçosa, MG, Brasil - ² Baker Laboratory, Department of Chemistry, Cornell University, Ithaca, NY, USA - ³ Universidade Estadual do Norte, Fluminense Campos, RJ, Brasil.

The major sex pheromone component of the South American Tomato Moth, *Scrobipalpuloides absoluta* (Meyrick), was shown recently to be (3E,8Z,11Z)-3,8,11-tetradecatrien-1-yl acetate. Wind tunnel bioassays indicated that a dispenser loaded with 1000 ng of the synthetic ester was found to be highly attractive to conspecific males. In the field, a initial series of experiments was carried out to evaluate the efficacy of five trap designs. In another series, the best trap, baited with 100 µg of the pheromone, caught on average 1200 males per trap per night, while those baited with one-day-old virgin female caught only 201 males. The male response to this pheromone is restricted to the same early-morning time window during which females exhibit calling behavior. The high biological activity of the synthetic pheromone suggests that it will prove useful in monitoring the pest population, and that it may also be useful in mating disruption.

15-095

FIELD TESTS WITH SYNTHETIC PHEROMONE-BAITED (CLICK BEETLE) TRAPS (COLEOPTERA: ELATERIDAE) IN TWO EUROPEAN COUNTRIES.

L. FURLAN, M. Tóth¹, I. Ujváry¹, I. Szarukán², G. Szócs¹

¹ Istituto di Entomologia Agraria, Università di Padova, Padova, Italy - ¹ Plant Protection Institute, Hungarian Academy of Science, Budapest, Hungary - ² Agricultural University, Debrecen, Hungary.

Pheromone-baited traps were tested in Italy and Hungary for catching *Agriotes sputator* L. (geranyl butanoate), *Agriotes ustulatus* Schaller (E,E-farnesyl acetate) and *A. litigiosus* Rossi (geranyl isovalerate). Large numbers of *A. sputator* (Hungary) and *A. litigiosus* (Italy) were captured in the respective traps, while high numbers of *A. ustulatus* were caught in both countries, confirming earlier trapping results in Russia. Traps baited with females caught less *A. ustulatus* than those with synthetic bait traps in a preliminary comparison of female-baited vs. synthetic baited traps. Additional tests in Hungary showed that large numbers of *A. rufipalpis* Brullé can be caught in traps baited with geranyl hexanoate, while the same compound captured specimens of *A. sordidus* Illiger in Italy. These are the first indications on the pheromone composition of these species. Preliminary studies on optimal trap design and dosage were also performed on the above species. Recently acquired knowledge regarding *Agriotes* biology and rearing methods, proved to be essential to carry out effective studies on the synthetic pheromones. The latter can be considered suitable for monitoring the swarming period of different *Agriotes* species and giving usable information for Integrated Pest Management.

15-096

A FEMALE-PRODUCED SEX PHEROMONE FOR THE BUG *PHYTOCORIS RELATIVUS* FALLÉN (HEMIPTERA: MIRIDAE).

J.G. Millar, Q. Wang, R.E. Rice¹, and Y.-J. Du
Department of Entomology, University of California, Riverside, California, U.S.A. - ¹Department of Entomology, University of California, Davis, California, U.S.A.

The bug *Phytocoris relativus* Fallén has been associated with nut damage in pistachio orchards in California. Bugs can move into a crop quickly, and infestations can be difficult to detect by currently available sampling methods (e.g., beating tray samples) until significant damage has occurred. Consequently, our goal was to identify attractants for use in monitoring *P. relativus* populations.

Preliminary investigations determined that virgin female bugs were attractive to males. Comparison of volatiles collected from virgin females and males revealed that females produced five sex-specific compounds. A series of field bioassays was used to determine that only two female-produced compounds were required for attraction of males. Furthermore, the attraction was highly specific; only mature conspecific male bugs were attracted by the pheromone.

15-098

INSECTICIDAL TOXICITY AND REPELLENCY PROPERTIES OF NEEM EXTRACT (AZADIRACHTIN) ON QUEENSLAND FRUIT FLY *BACTROCERA TRYONI* (FROGGATT) DIPTERA : TEPHRITIDAE

E. Hassan, W. Heimoana. University of Queensland Gatton College, Lawes, Australia.

A methanolic neem extract (7% Azadirachtin) was evaluated for its efficacy as an insecticide to control eggs, larval instars and pupae of Queensland fruit fly *Bactrocera tryoni* (Froggatt). One hundred specimens of each life stage (egg, first instar, second instar, third instar and pupa) were dipped for 60 seconds in 80 ppm, 100 ppm, 120 ppm and 140 ppm, respectively. A 60 second dip in 400 ppm dimethoate, a standard fruit fly treatment, was used as a basis for comparison. Eggs and larval stages were retained on carrot media at 26°C until adults emerged. Pupae were held at 26°C on moist filter paper until exclusion. The number of emerged adults was recorded to evaluate survival.

Repellency of methanolic neem extract at concentrations of 80 ppm, 100 ppm, 120 ppm and 140 ppm was evaluated against adults of Queensland fruit fly on persimmons. Fruit was dipped in extract for 90 seconds and subsequently exposed to caged mature flies for 2 hours. Untreated persimmons were exposed concurrently. The number of egg batches per fruit was evaluated as an indication of repellency efficacy. Statistical evaluation of the data showed no significant differences between dipping at different concentrations or between untreated fruit. Differences between treated and untreated fruit were significant at the P = 0.01 level. The mean of egg batches recorded in untreated fruit ranged from 17.8 to 26.8. Mean egg batches for fruit dipped in 80, 100, 120 and 140 ppm were 3.2, 3.4, 2.0 and 2.8 respectively.

15-097

BOTANICAL INSECTICIDES: STUDIES ON AN OIL EXTRACTED FROM IDIOBLAST CELLS OF THE AVOCADO FRUIT

C. Rodriguez-Saona and J.T. Trumble
Department of Entomology, University of California, Riverside, CA, 92521

Natural plant compounds have proven to be effective in insect control. A subset of these compounds, antifeedants, offers a potential approach for pest management by rendering plants unattractive or unacceptable to pest insects. *Spodoptera exigua* (Hübner), a generalist feeder and a major pest in many vegetables in California, has a long history as a key herbivore on lettuce, celery, and tomato. In an attempt to find alternatives to conventional chemicals for *S. exigua* control, the insecticidal activity of an oil extracted from idioblast cells of the avocado fruit was evaluated. In diet incorporation studies, the oil was toxic to both early (LC₅₀ = 0.16% by volume) and late instars (LC₅₀ = 0.51%). Larval weights of third instars were significantly reduced after feeding for 5d on diet containing 0.30% oil (28.95 mg/larva) as compared to a control diet (231.91 mg/larva). The oil also acted as a feeding deterrent. Choice tests initiated with neonates showed a significantly greater proportion of larvae on control diet rather than oil-containing diet for concentrations of 0.10% or greater. Similar results were obtained for choice tests initiated with third instars for oil concentrations of 0.20% or greater. In these tests the larvae consumed significantly more diet than treated diet. Experiments to determine the active compounds in the oil are being performed.

15-099

EVALUATION OF SOME EUPHORBIA SPECIES EXTRACTS AS A TOXIC BAIT AGAINST THE BLACK CUTWORM *AGROTIS IPSILON* (HUFN.).

Aziza Sharaby¹, M.M. El-Missiry², S. Abdel-Hamed³
^{1,3}, Pests and Plant Protection Department, National Research Centre, Dokki, Cairo, Egypt.
², Pharmaceutical Sciences Department, National Research Centre, Dokki, Cairo, Egypt.

Acetone and ether extracts of *E. paralias* and *E. papulus* gave 100 % larval mortality to the 2nd instar larvae of *A. ipsilon* after 10 days from feeding of the treated bait diet containing 5 % extract concentration. Also ether extract of *E. retusa* and *E. geniculata* causes 100 % mortality after 15 days. Alcoholic extracts of *E. geniculata*, *E. papulus*, *E. helioscopia*, *E. retusa* and *E. paralias* gave retradation in the larval development and causing percentage of total mortality through larval and pupal stages ranged from 30-60 %. The most effective extract of the five tested Euphorbia species were acetone followed by ether and hexane. The isolated materials from *E. species* (Fatty alcohol, B-Amyrin and B-sterol) were more toxic at 0.1 % conc. in the bait died against *A. ipsilon* where 100 % mortality for the larvae were observed after five days from feeding on the treated bait diet.

15-100

EFFECTS OF IMIDAZOLE FUNGICIDES AND PLANT GROWTH REGULATORS ON FEEDING AND CYTOCHROME P450 IN A HERBIVOROUS INSECT, *SPODOPTERA ERIDANIA* (CRAMER) (LEPIDOPTERA: NOCTUIDAE)

L. B. Brattsten

Rutgers University, Department of Entomology,
J.B. Smith Hall, Georges Road, New Brunswick,
N.J. 08903-0231, USA

Fungicides and herbicides that interfere with cytochrome P450 in fungi and plants also interfere with cytochrome P450 in insects. Several of these compounds, uniconazole, diniconazole, propiconazole, triadimefon, and pachlobutrazole inhibit cytochrome P450 activities *in vitro*. Some of the compounds induce activities *in vivo*. Some of the compounds are feeding deterrents for *S. eridania*. These interactions can have significant practical effects on insects in fields where several pesticides are applied.

15-102

THE EFFECTS OF FEEDING PROTEASE AND α -AMYLASE INHIBITORS, SINGLY AND IN COMBINATIONS TO THREE SPECIES OF LEAFROLLERS (LEPIDOPTERA: TORTRICIDAE)N.P. Markwick¹, W.A. Laing¹, J.T. Christeller², J.Z. Maxwell³ & M.R. Newton¹

The Horticultural and Food Research Institute of New Zealand Ltd, Auckland¹ and Palmerston North², New Zealand
Australian National University³.

The larvae of three leafroller species - *Epiphyas postvittana* (Walker), *Planotortrix octo* (Dugdale) and *Ctenopseustis obliquana* (Walker) - were chronically fed six digestive enzyme inhibitors in artificial diets over a two-week period from hatching, and their growth rate and digestive enzyme activities were measured. The inhibitors were fed singly and in combinations set to target most of the digestive enzyme groups present in these leafrollers. Of the four protease inhibitors (PIs), three were extracted from potatoes (POT1, 2, and 4) and the fourth was bovine pancreatic trypsin inhibitor (BPTI). The two α -amylase inhibitors (α Als) were extracted from wheat, the dimer (WD) and tetramer (WT). Previous trials had shown these inhibitors to be the most effective from a range of 21 PIs and 6 α Als.

POT1 significantly affected the growth rate of all three leafrollers and BPTI was effective against *E. postvittana* and *P. octo*. Most combinations of inhibitors did not reduce the growth rate further than the single most effective constituent, i.e. inhibitors presented singly in the diet were generally more effective in reducing the growth rate. One exception to this was a combination of POT1, BPTI and WT against *P. octo*.

All digestive enzyme activity was affected by the presence of the inhibitors in the diets. α Als increased α -amylase activity between 1.5 and 10 times. BPTI, either singly or in combination, dramatically reduced trypsin activity (10 times) and raised elastase activity (about 1.5 to 3 times) in all species. Since larval growth rate was so little affected whilst all enzyme activities were greatly altered, the question of compensation of one digestive enzyme for another, is discussed.

15-101

PHYTOCHEMICALS WITH ANTIFEEDANT ACTIVITY AGAINST CEREAL APHIDS

Glen Powell¹, Jim Hardie¹, John A. Pickett².

1 Aphid Biology Group, Department of Biology, Imperial College at Silwood Park, Ascot, UK - 2 Department of Biological and Ecological Chemistry, IACR-Rothamsted, Harpenden, UK

The bird cherry-oat aphid (*Rhopalosiphum padi* L.) and the grain aphid (*Sitobion avenae* F.) damage their cereal host plants directly, during feeding, and by acting as vectors of barley yellow dwarf virus. Both feeding and virus transmission occur when the aphid stylets are in contact with phloem sieve elements, but application of antifeedants to leaf surfaces can deter the insects at an earlier stage in host plant selection. Phytochemicals from a variety of sources were prepared at 0.1% in ethanolic solution and painted onto excised oat leaves. Groups of aphids were offered treated leaves in choice tests with control, ethanol-treated leaves. Several compounds caused antifeedant effects on both aphid species, with significantly more individuals recorded on control leaves than treated leaves after experimental access periods of 15min-24h. Treatments which were active in choice tests (a drimane sesquiterpenoid, (\pm)-polygodial, an indolizidine alkaloid, castanospermine, and α and β hop acids) were also presented in no-choice tests, where insects had no access to control-treated leaf material. Some compounds were no longer effective in no-choice conditions, but treatment of leaves with polygodial and the hop β acid colupulone effectively reduced the number of aphids settling.

15-103

EFFECTS OF AN AZADIRACHTIN BASED COMPOUND ON THE FECUNDITY OF MEDITERRANEAN FRUIT FLY *CERATITIS CAPITATA* (WIEDEMANN) (DIPTERA: TEPHRITIDAE): STRUCTURAL AND ULTRASTRUCTURAL ANALYSISM. Cristofaro, V. Di Ilio, D. Marchini¹, P. Nobili, R. Dallai¹, U. Cirio

Enea C.R. Casaccia Dipartimento Innovazione, Settore Biotecnologie e Agricoltura, Divisione Agricoltura Ecocompatibile, Roma, Italy -
1 Dipartimento di Biologia Evolutiva, Università di Siena, Italy

The aim of this work was to analyze the effects of a neem extract on the fecundity of adults of *Ceratitis capitata* under laboratory condition.

Several compounds with biological activity were isolated from the neem tree (*Azadirachta indica* A. Juss, Meliaceae). The most known of them is a tetranortriterpenoid named azadirachtin, producing its action in different ways, such as antifeedant, interfering with the oogenesis, with the larval development and with the metamorphosis.

A series of no-choice tests were carried out in order to observe the induced influence on the development and on the functionality of the female reproductive system. Adults of med fly were fed with an aqueous solution of neem extract mixed with the rearing diet.

The oviposition rate of treated females was extremely low, versus a longevity rate statistically not different from the control.

Females treated since their emergence or after sexual maturity showed atrophic or abnormal ovaries with disorganized ovarioles. Nurse and follicular cells appears to be modified in number and polarity. Vitellogenesis and choriogenesis were altered with oocytes showing an irregular shape due to the paucity of yolk material.

15-104

IMPACT OF *BACILLUS THURINGIENSIS* INSECTICIDES ON THE POPULATION DYNAMICS OF COLORADO POTATO BEETLE, *LEPTINOTARSA DECEMLINEATA*, AND ITS PRINCIPAL PREDATOR *COLEOMEGLA MACULATA* (COLEOPTERA: CHRYSOMELIDAE - COLEOPTERA: COCCINELLIDAE)

A. Hilbeck, C. Eckel¹, G. G. Kennedy²

Department of Entomology, Swiss Federal Research Station for Agroecology and Agriculture, Zurich, Switzerland - 1 Merck & Company Inc., Three Bridges, NJ, USA - 2 Department of Entomology, North Carolina State University, NC USA.

In field studies in 1992 and 1993, plots of comparable densities of overwintered Colorado potato beetle (CPB) adults were treated with *Bacillus thuringiensis* (Bt) insecticides. As a control, a number of plots were left untreated. Oviposition and larval population development of CPB as well as predation on CPB egg masses and densities of *C. maculata*, the principal predator of CPB in North Carolina, were monitored throughout the oviposition period of 1. generation CPB adults.

During both years, CPB egg mass recruitment declined earlier in Bt-treated plots than in untreated control plots. Further, significantly fewer large CPB larvae developed in Bt-treated plots than in the untreated control. No impact of the Bt-treatments or the earlier decline in prey densities (CPB egg masses) in Bt-treated plots on *C. maculata* abundance was observed during first generation CPB population dynamics. Consequently, predation of CPB egg masses was not affected by the Bt-treatments. The utilization of Bt-insecticides was compatible with naturally-occurring biological control in North Carolina potato crop systems.

15-106

RAPD-PCR ANALYSIS OF GENETIC VARIATION IN SWEETPOTATO WHITEFLY (*BEMISIA TABACI* GENNADIUS, HOMOPTERA: ALEYRODIDAE) POPULATIONS

A. C. Bartlett

U. S. Department of Agriculture, Agricultural Research Service, Western Cotton Research Laboratory, Phoenix, AZ USA

Individual whiteflies from Mexico, Guatemala, Venezuela, Bermuda, Puerto Rico, Brazil, Ecuador, Dominican Republic, India, Nicaragua, Chili, Spain, Germany, Israel, Zimbabwe, Pakistan, and several areas in the United States have been analyzed for variation in RAPD-PCR DNA banding patterns. These collections represent 50 different geographic locations or hosts. RAPD patterns were examined for each of three different 10-mer primers. Each RAPD-PCR run contained three to five individuals from samples of whiteflies collected in Arizona from 1981 - 1986 to represent the "A-type" RAPD patterns, plus three to five individuals from collections made in 1994 and 1995 in a three-acre cotton field adjacent to the Western Cotton Research Laboratory to represent the "B-type" RAPD patterns along with one to five individuals of the various collections mentioned above. Samples of whiteflies from Puerto Rico, Mexico, and India contained individuals which yielded the "A-type" patterns, but this occurred only rarely. Genetic analysis of the patterns showed that most of the collections did not fall clearly within the "A" or "B" types, but rather fell in a continuous distribution of genotypes between those two extremes. Viewed as world-wide organism, *B. tabaci* may be a variable collection of heterogeneous populations rather than a homogeneous collection of genotypes.

15-105

DISCOVERY OF MALE ACOUSTIC SIGNALS IN WHITEFLY GENERA, *BEMISIA*, *TRIALEURODES* AND *PEALIUS* (HOMOPTERA, ALEYRODIDAE)

K. Kanmiya

Biological Laboratory, Kurume University, Fukuoka, Japan

Courtship-like signals produced by male whiteflies during mating behavior were recognized for the first time. Synchronous audio-video recordings ascertained that sexually matured males of *Bemisia tabaci*, *B. argentifolii*, *Trialeurodes vaporariorum* and *Pealius rubi* produced substrate-borne vibrations by rapidly oscillating their abdomens in a stereotyped rhythm accompanied with a short moving action around the female. Signals of *B. tabaci* and *argentifolii* were a single burst with a high frequency modulation. *B. tabaci* is characterized by a longer burst of 443.4 ± 21.0 msec duration, modulated only on posterior 1/3, with 6 harmonics of 252 ± 10.8 Hz fund. frequency. *B. argentifolii* is characterized by a shorter burst of 258.0 ± 16.4 msec duration, modulated on posterior half, with 3 harmonics of 331.6 ± 13.9 Hz fund. frequency. *T. vaporariorum* is consisted of a sequence of discrete bouts of chirps with 10~20 pulses, varying in number in the courtship progress, with 255.8 ± 11.7 Hz fund. frequency and 1081.8 ± 82.2 msec duration. *Pealius rubi* is characterized by a single burst of constricted trimodal waves, of 120~124 msec duration and about 305 Hz peak frequency. Prolonged courtship behavior might be due to the necessity of sexual stimulation for female by repeated emission of the male acoustic signals. These acoustic data could be used to separate the species precisely, and were assumed to be a species-specific cue towards female in the premating behavior.

15-107

INTRA-AND INTER-CROP DISPERSAL OF THE COTTON WHITEFLY *Bemisia tabaci* Gennadius IN POLYCROP SYSTEMS IN TAMIL NADU, INDIA.

S. Uthamasamy and M. Murugan.

Department of Entomology, Tamil Nadu Agricultural University, Coimbatore, India.

The cotton whitefly, *Bemisia tabaci* is a serious pest in this part of the country. The polyphagous nature, high fecundity, quick dispersal and undefying behaviour with chemical pesticides has led to total loss of crops. Behavioural patterns of the adults towards sticky traps, barrier crops and *in situ* observations were studied.

The dispersal pattern depended on the availability of host crop in agroecosystems. Intra crop movement was more within a height of 30 cm from soil level. Ladies finger (*Abelmoschus esculentus* Linn.) Moench and egg plant (*Solanum melongena* Linn.) were favourable hosts during April-May. With the commencement of the monsoon during June-July the pest established on sesame (*Sesamum indicum* Linn.), sunflower (*Helianthus annuus* Linn.) and groundnut (*Arachis hypogaea* Linn.). From August it dispersed to cotton wherein outbreaks occurred. It also established on groundnut, sesame, sunflower and soyabean (*Glycine max* Linn.) during November to January. During off-seasons weed hosts viz., *Boerhaavia diffusa*, *Parthenium hysterophorus* and *Trianthema portulacastrum* sustained the pest.

It is observed that i) yellow sticky traps could be effectively used for monitoring (ii) there are seven broods in a year and (iii) maize (*Zea mays* Linn.), bajra (*Pennisetum typhoides* (Burm.) Stapf. & Hubb.) and sorghum (*Sorghum bicolor* Pers.) could be used as effective barrier crops to check the immigration and spread of the pest.

15-108

KINETICS OF TOMATO YELLOW LEAF CURL GEMINIVIRUS (TYLCV) DNA IN THE WHITEFLY VECTOR *BEMISIA TABACI* (GENNADIUS) (HOMOPTERA: ALEYRODIDAE)D. Bosco, P. Caciagli¹

Dipartimento di Entomologia e Zoologia applicate all'Ambiente "Carlo Vidano", Università di Torino, Italy - 1 Istituto di Fitovirolologia Applicata, CNR, Torino, Italy

The kinetics of TYLCV DNA were studied in the vector *Bemisia tabaci* (Gennadius) by means of quantitative chemiluminescent dot-blot assay, using digoxigenin-labeled specific DNA probes. DNA amount was calculated by calibration of each membrane with a reference standard of viral DNA. Large batches of female whiteflies were allowed to feed for 12, 24 or 48 h on TYLCV-infected tomato plants, then transferred to cucumber plants, immune to the virus. Insects were sampled at different times during and after acquisition. The analysis was done either on whole insects or on head+thorax (including salivary glands) and abdomen separately.

The proportion of insects having a detectable amount of viral DNA (positives) was more than twice the proportion of insects, taken from the same population, which transmitted TYLCV in infectivity tests (infectives). The maximum amount of viral DNA, averaging from 0.5 to 1.6 ng per positive insect, was always attained at the end of the acquisition. The mean amount then decreased by about 2% per day, remaining clearly detectable up to 20 days from the end of acquisition, whereas insects ceased to be infective 13 days earlier. Analysis of dissected insects showed that only some of the whiteflies with positive abdomens had positive head+thorax. The proportion of the head-thorax positive insects was similar to the proportion of infective insects. In both parts of the body, the viral DNA remained detectable up to 18 days after the end of acquisition, showing that the virus remains in different insect tissues much longer than infectivity would indicate.

15-110

SEASONAL AND ANNUAL DYNAMICS OF *BEMISIA TABACI* (GENN.) POPULATION RESPONSES TO INSECTICIDES IN CALIFORNIA (HOMOPTERA: ALEYRODIDAE)S. J. Castle, N. Prabhaker¹, T. J. Henneberry², N. C. Toscano¹

USDA, ARS, Irrigated Desert Research Station, Brawley, CA - 1 University of California, Riverside, CA - 2 USDA, ARS, Western Cotton Research Lab, Phoenix, AZ, USA

The B biotype of *Bemisia tabaci* was introduced into California sometime in the late 1980s, with infestations initially limited to floricultural operations in greenhouses. The first agricultural infestations were detected in the Imperial Valley in 1990, leading to the destructive outbreak of 1991 that caused \$129 million direct crop losses, principally to muskmelons, broccoli, cauliflower, cabbage, lettuce, cotton and alfalfa. The breadth of crops damaged in 1991 and in subsequent years in the Imperial Valley reflect the broadly polyphagous nature of *B. tabaci* and the potential for damage in far-ranging agricultural regions with warm-temperate or subtropical climates.

The succession of host crops of *B. tabaci* in the Imperial Valley throughout the annual cycle has made possible year-round monitoring of their responses to insecticides. Beginning in 1993, populations have been sampled seasonally from three crops: spring muskmelons, summer cotton and fall-winter cruciferous crops. Bioassays of field-collected adult whiteflies have been performed for various insecticides as either single or mixed treatments using the yellow-sticky card technique. This bioassay method uses 7.6x12.7 cm yellow cards lightly coated with Tanglefoot[®], then sprayed with a concentration of insecticide representing one of 5-6 doses for each treatment. Collections of adult *B. tabaci* are facilitated by their attraction to yellow, alighting on the sticky cards after being flushed from crop foliage. Mortality is scored 24 h later under a microscope, and LC₅₀s are generated by probit analyses and interpreted as the response of the sample population to a given insecticide treatment.

No progression to higher resistance levels was observed over three consecutive years (1993-95) of monitoring adult *B. tabaci* populations in the Imperial Valley. Regressions of LC₅₀s against time for each year's bioassay data indicated a lower mean response in 1995 compared to 1993 for bifenthrin and endosulfan in spite of continued use of both insecticides. Negative slopes significantly different from zero ($P < 0.05$) for the cotton crop LC₅₀s indicated higher susceptibilities at the end of the cotton season, whereas the opposite was true for the melon crop bioassay data. Differences in LC₅₀s between crop seasons suggested the potential role of host plant effects on adult whitefly susceptibilities to certain insecticides. Interseasonal dynamics of LC₅₀s suggest the involvement of ecological factors in addition to genetic factors in responses of *B. tabaci* populations to insecticides.

15-109

GENES ON BOTH DNA A AND B CONTRIBUTE TO ACQUISITION AND TRANSMISSION OF GEMINIVIRUSES BY THE WHITEFLY *BEMISIA TABACI* (GENNADIUS) (HEMIPTERA: HOMOPTERA: ALEYRODIDAE).

Sijun Liu, Ian D Bedford, Peter G Markham

Department of Virus Research, John Innes Centre, Norwich, U.K.

African cassava mosaic virus (ACMV) and other bipartite geminiviruses have been used to investigate the molecular basis of transmission by the whitefly vector, *Bemisia tabaci*. Isolates and clones of insect transmissible and non-transmissible viruses have been compared biologically and at the molecular level. The biotype of whitefly and the feeding behaviour play a significant role. Viruses, which are potentially transmissible by the vector, can be acquired by non-vector species of whitefly and by other taxa. The coat protein of the virus determines if it will be transmitted. This is demonstrated by chimeric and pseudorecombinant DNA A components between different clones. Similar studies using chimeric or pseudorecombinant DNA B components showed that a movement protein plays a significant role in the acquisition of the virus. DNA B also affects symptom phenotype. ACMV symptoms differed with the genotype of the virus and they were reflected in the transmission results. In several cases, although an insect transmissible virus might cause severe symptoms, insects were subsequently unable to transmit. The environmental conditions, such as light and temperature, also affect the transmission process.

INSECTICIDE RESISTANCE MANAGEMENT OF WHITEFLIES IN IMPERIAL VALLEY, CA, USING INSECTICIDE ROTATIONS AND MIXTURES (HOMOPTERA: ALEYRODIDAE)

N. Prabhaker, N. C. Toscano, S. J. Castle¹ and T. J. Henneberry¹

Department of Entomology, University of California, Riverside, CA - 1 USDA, ARS, Western Cotton Research Laboratory, Phoenix, AZ, USA

In the USA, California and Arizona have been affected the most by intense and consistent infestations of *Bemisia tabaci*. Because of the temporal sequence and overlapping of crops, successive generations of whiteflies are exposed to insecticides on a continuous basis. Heavy reliance upon insecticides for reducing infestations in cotton and other crops heightens concern about the development of insecticide resistance in whitefly populations. To evaluate potential antiresistance strategies for whitefly populations, two principle approaches, insecticide rotations and insecticide mixtures, have been studied in both greenhouse and field settings. High levels of resistance (>500-fold) to bifenthrin were recorded for whiteflies in greenhouse colonies subjected to continuous bifenthrin exposure. Resistance increased to moderate levels (>30-fold) to endosulfan and chlorpyrifos under continuous selection pressure. However, only low levels of resistance (5- to 10-fold) were observed in colonies exposed to similar insecticide pressure, but in a rotational scheme using the same three insecticides. Similar contrasts in resistance levels were observed favoring mixtures of two insecticides over single compounds.

Field trials were conducted in 1994 at two sites in the Imperial Valley, CA, and in 1995 at sites in Imperial Valley and Yuma, AZ, to evaluate insecticide rotations and mixtures as resistance management strategies for whiteflies in an agricultural setting. Insecticide treatment regimens included continuous treatment plots with single insecticides using bifenthrin, endosulfan, chlorpyrifos and amitraz, rotation plots with the same four insecticides, a mixture treatment with bifenthrin and endosulfan, and untreated control plots. Ten consecutive weeks of bioassay results with the yellow sticky card technique failed to yield discernible differences in the insecticide treatment regimens (continuous, rotation, or untreated). However, there appeared to be a general trend of decreasing LC₅₀'s through time in most of the treatment plots. Whiteflies from Imperial Valley exhibited lower LC₅₀'s in 1995 to all the insecticides indicating they were more susceptible than in the previous year. Populations from Yuma were more susceptible than the Imperial Valley populations.

15-112

DENSITIES OF OVERWINTERING CARABIDS AND STAPHYLINIDS (COLEOPTERA: CARABIDAE AND STAPHYLINIDAE) IN CEREAL AND GRASS FIELDS AND THEIR BOUNDARIES.

A. Andersen

The Norwegian Crop Research Institute, Plant Protection Centre, Department of Entomology and Nematology, Aas, Norway

Abundances of carabids and staphylinids were measured during four winters in four fields with grass or autumn ploughed spring cereals, and in their boundaries. Most species were significantly more abundant in the boundaries than in the fields, indicating the high importance of boundaries in the agricultural landscape for these predator groups. Only the carabid *Clivna fossor* and staphylinids belonging to the genus *Lathrobium* were evenly distributed throughout the entire area.

As none of the species with higher populations in the grass fields and their boundaries were among the important predators of insect pests in agricultural fields, it was concluded that the grass fields were of limited importance as a reservoir for the predatory beetles.

15-114

STYLET ACTIVITIES ASSOCIATED WITH ACQUISITION AND INOCULATION OF BARLEY YELLOW DWARF VIRUS BY APHIDS.

Glen Powell, Jim Hardie

Aphid Biology Group, Department of Biology, Imperial College at Silwood Park, Ascot, UK

Phloem-restricted barley yellow dwarf viruses (BYDV) are acquired by aphid vectors during ingestion of phloem sap, and inoculated during injection of saliva into plants. We used the electrical penetration graph (EPG) technique to investigate the aphid stylet activities which are associated with acquisition and inoculation of BYDV-MAV by the grain aphid, *Sitobion avenae* (F.). Periods of intracellular stylet tip location are registered as potential drops during EPG recording; these may be short (all cell types) or long (phloem sieve elements only). Two waveforms occur during extended phloem sieve element penetration; firstly E1, which may be followed by E2 (E1+E2). All aphids which subsequently transmitted virus to oat test plants showed E1+E2 during recorded penetration of a BYDV-infected plant. Separate analysis of E1 and E2 durations suggested that E2 is associated with virus acquisition, as insects which transmitted to test plants showed longer total E2 occurrence on the infected plant than non-transmitting aphids. Most aphids which transmitted to a test plant during recorded inoculation access showed either E1 alone or E1+E2, and inoculations tended to coincide with longer periods of E1. However, some insects which transmitted virus showed E1 for <5min, and 10% of inoculations were effected by aphids that showed no E1/E2, indicating that transient phloem punctures occur which are indistinguishable from penetration of other cell types using EPG recording. The results suggest that BYDV-MAV acquisition by aphids requires sustained periods of phloem contact, but inoculation of the virus can occur during very brief punctures of phloem tissue.

15-113

INVESTIGATIONS OF EFFECTS OF CHANGING FARMING SYSTEM AND LANDSCAPE STRUCTURE ON THE GROUND BEETLES (COLEOPTERA, CARABIDAE) OF A LOESS SITE IN THE CENTRAL GERMANY DRY REGION

Th. Kreuter

Institute of Plant Breeding and Plant Protection, Agricultural Faculty, Martin-Luther-University Halle-Wittenberg, Halle/Saale, Germany

A long-term research project is run to investigate the effects first of the transition from conventional to ecological farming and second of structuring the landscape by means of field baulks and hedges on the entomo-fauna. The following working hypotheses are tested:

- 1.: The insects of an agroecosystem are decisively influenced by the intensity of land management as well as by the landscape structure.
- 2.: The ecological farming and the involved structuring of "cleared" areas will promote faunal diversity.
- 3.: An extending diversity of animal species stimulates self-regulating processes in the agroecosystem and thus helps to stabilize the ecosystem.

Carabids occupy a special place in the group of insects, studied in this project. They often occur in high numbers of species and individuals on fields and are seen to be indicators of the quality of various environmental impacts.

Despite large field sizes and generally large-scale landscape structures, the initial situation on the until that moment conventionally managed fields of the ecofarm was characterized by broad diversities and high activity densities of carabid communities. This fact may be attributed to the principally lower intensity of arable farming in the former East Germany. However, the large number of species as observed at present on fields in the Central Germany dry region is a result of favourable climatic conditions in that area.

15-115

DISTRIBUTION OF GEMINIVIRUSES IN MONOCOTYLEDONS AND *CICADULINA* SPECIES IN ECOLOGIES IN MAIZE GROWING REGIONS OF KENYA (HOMOPTERA: CICADELLIDAE)

B.O. Odhiambo¹, R.W. Gibson², P.G. Markham³

-1 National Agricultural Research Laboratories, Kenya Agricultural Research Institute, Nairobi, Kenya -2 Natural Resources Institute, Chatham, U.K -3 Virus Department, John Innes Centre, Norwich, U.K.

The distribution of geminiviruses and *Cicadulina* species was studied in the main maize growing regions of Kenya. The diverse ecologies in the central highlands of Kenya, particularly on the eastern and southern fringes of Nyambene Hills, Mount Kenya and Aberdare Range produced the most significant data. Geminiviruses were recorded in different agro-ecological zones (AEZs). Maize streak virus (MSV) prevailed in maize planted in AEZs where mean annual soil moisture availability was above 25%; whereas MSV, panicum streak virus (PanSV) and sugarcane streak virus (SSV) infected grasses were distributed in AEZs having above 50% moisture regime. The viruses were restricted to a 300-kilometre wind corridor lying between Nyambene Hills, in the north east, where less than one percent MSV occurred, to the environs of Nairobi, in the south west, where MSV was 100% in individual fields, with most infections appearing early rather than late in each of the growing season. The spatial and temporal distribution of the geminiviruses reflected the route and times of dispersal of migrant populations of *Cicadulina* vectors.

The data (which will be presented) on the distribution of geminiviruses and vectors suggest a model where MSV is a disease of annual grasses distributed to crops during seasonal migrations.

15-116

APHID POPULATION DYNAMICS AND VIRUS SPREAD ON SEED POTATO CROPS IN ITALY

C. Cerato, D. Rongai, R. Martelli
Istituto Sperimentale per le Colture Industriali, Bologna, Italy

Systematic observations were carried out in various Italian potato-growing areas over the past four years to define the best moment for haulm destruction.

Results indicated that there were great variations between localities and from year to year regarding to the numbers of aphid species, total number caught in the yellow traps and aphids counted on potato leaves. Potato virus Y was the most widespread virus, followed by Potato virus S, while Potato leaf roll virus had almost disappeared.

In the north, the high number of aphids caught and the great variations in the aphid populations made it impossible to correctly define the moment for haulm destruction. On the contrary, in the south of Italy, in the Sila Highland, where the conditions are more similar to those north of the Alps and the number of aphids and species were lower, it was easier to adopt the *Myzus persicae* and *Macrosiphum euphorbiae* count to decide the date for haulm destruction.

15-117

VARIATION OF TRANSMISSION EFFICIENCY OF SOYBEAN DWARF VIRUS AMONG LOCAL CLONES OF *AULACORTHUM SOLANI* (KALTENBACH) IN JAPAN (HOMOPTERA: APHIDIDAE)

K. Honda, S. Kanematsu, S. Miyai

Tohoku National Agricultural Experiment Station, Morioka, Japan

Soybean dwarf virus (SDV) is a pathogen of soybean dwarf which causes serious yield losses in soybeans. This virus is transmitted by the foxglove aphid, *Aulacorthum solani*, in a persistent manner. Although the vector insect is distributed commonly throughout Japan, the occurrence of SDV is restricted to the northern parts of this country, Hokkaido Island and north-eastern Honshu Island. To find a possible reason for this distributional discrepancy between SDV and the vector, we examined differences in transmission efficiency among local populations of *A. solani*. Twenty-six local clones of *A. solani* were collected from Hokkaido Island and Honshu Island which includes SDV absence regions, and their transmission efficiency of the virus was compared. All aphid clones could transmit SDV but the transmission efficiency was remarkably different among them. A clone from Naganuma in Hokkaido Island transmitted the virus most efficiently (average transmission rate = 0.65) and the transmission rate of a clone from Kurosaki in Niigata prefecture was the lowest (average transmission rate = 0.03) in the 26 clones. A geographical trend was observed on the extent of SDV transmission efficiency of the aphid clones. Almost all aphid clones from the Japan Sea side of northern Honshu Island showed lower virus transmission efficiency and, on the other hand, many clones from the Pacific Ocean side of the island attained relatively higher transmission efficiency. This geographic differences in SDV transmission efficiency among vector populations may partly explain the restricted distribution of SDV.

15-118

SPREAD OF ZUCCHINI YELLOW MOSAIC VIRUS (ZYMV) IN RELATION TO APHID POPULATIONS AND ITS TRANSMISSION BY DIFFERENT APHID SPECIES

N. Katis, D.P. Lykouressis¹, J.A. Tsitsipis² and A. Papapanayotou
Laboratory of Plant Pathology, Faculty of Agriculture, Aristotle University of Thessaloniki, Thessaloniki, Greece - 1 Laboratory of Agricultural Zoology and Entomology, Agricultural University of Athens, Athens, Greece - 2 Laboratory of Entomology and Agricultural Zoology, Faculty of Crop and Animal Production, University of Thessalia, Volos, Greece

Zucchini yellow mosaic potyvirus (ZYMV) is transmitted by aphids in non-persistent manner and is widespread in cucurbit crops, such as: zucchini, squash, melon, watermelon. In order to understand its epidemiology we studied its spread in zucchini crops, hybrid Jedida, in relation to aphid population in Vassilika, Thessaloniki. We tested, in lab experiments, its transmission by of different apterae aphid species, such as: *Aphis nerii*, *Aphis fabae*, *Brevicoryne brassicae*, *Myzus persicae*, *Rhopalosiphum maidis* and *Rhopalosiphum padi*. These species were tested because of their abundance either in Moericke traps, in zucchini crops, and/or Rothamsted suction traps. All species tested transmitted ZYMV, although they differed in transmission efficiency. *M. persicae* was the most efficient vector whereas *B. brassicae* was the most inefficient. *M. persicae* was the most abundant species caught in both Moericke (Vassilika Thessaloniki) and suction traps (Thessaloniki, Velesino Thessalia, Kopais Boiotia). Its high incidence in conjunction with its high transmission efficiency make it an important vector of ZYMV. All the other species tested are reported for the first time as vectors of ZYMV. Despite their low transmission efficiency, compared to *M. persicae*, they may contribute to ZYMV spread in areas where they occur in high numbers.

15-119

SEASONAL FLIGHT PATTERN OF *Circulifer haematoceps* (M. ET R.) (HOM., CICADELLIDAE) IN YOUNG CITRUS ORCHARDS

U. Kersting

Dept. of Plant Protection, University of Çukurova, Turkey

Citrus stubborn disease (CSD), caused by *Spiroplasma citri* Saglio et al., is a most serious disease in the Mediterranean and the Near East. In the east Mediterranean citrus-region of Turkey, CSD is exclusively vectored by the leafhopper *Circulifer haematoceps* (M. et R.) And apparently only young citrus is subjected to natural infection. Therefore the seasonal flight patterns of *C. haematoceps* were monitored by yellow sticky-traps in four young citrus orchards and three nurseries in the east Mediterranean region of Turkey during 1993-1995. Furthermore, interactions of the pest and the virus were examined.

The flight activity of *C. haematoceps* was characterized by a major peak in May and a second smaller peak in November. This specific flight pattern was identical at all locations, for all years and regardless to orchard age. *C. haematoceps* did not settle in the orchards but migrated from and to overwintering sites in May and November. Interestingly, the total number of *C. haematoceps* caught per year was 5-fold higher in newly established orchards compared to 3-4 year old orchards. This significant change in the flight behaviour of *C. haematoceps* may explain why only young orchards are subjected to natural infection of *S. citri*. Furthermore, the number of leafhopper vectors on yellow sticky-traps placed near ground was 20-fold higher than the number of *C. haematoceps* trapped in young trees (1.2 m height), indicating that most of the individuals move in lower strata, minimizing the risk of disease spread.

15-120

THE ROLE OF SYMBIONIN, AN APHID ENDOSYMBIONT-DERIVED PROTEIN, IN THE TRANSMISSION OF POTATO LEAFROLL VIRUS

S. A. Hogenhout^{1,2}, M. Verbeek¹, F. van der Wilk¹, R. Goldbach² and J. F. J. M. van den Heuvel¹

¹DLO Research Institute for Plant Protection (IPO-DLO), Wageningen, The Netherlands - ²Department of Virology, Wageningen Agriculture University, Wageningen, The Netherlands.

Luteoviruses are single-stranded RNA viruses which infect a wide range of mono- and dicotyledonous plants in which they replicate almost exclusively in the phloem tissue. They are transmitted by aphids in a circulative manner. Briefly, this implies that virus particles are ingested along with phloem sap from infected host plants and transcellularly transported through the gut into the haemocoel. The acquired virus particles are retained in an infective form in the haemolymph for the aphids' lifespan, apparently without replication. Upon contacting the accessory salivary glands, they may be transported through this gland, eventually arriving in the salivary duct from which they are excreted with the saliva during feeding of the aphid. Luteoviruses display a high degree of vector specificity at the various transmission barriers in the aphid. These well-developed specificities suggest an intimate association between a luteovirus and its vector in which both surface domains of the viral capsid and sites or substances in the aphid are involved. Recently, we have demonstrated that symbionin, a protein abundantly produced by the intracellular symbiotic bacteria of *Myzus persicae* (Sulz.), and released into the haemolymph, determines the persistent nature of PLRV in the aphid. The virus exhibits a high specific affinity for symbionin in *in vitro* binding assays. Here, we report on the identification of the protein domains of symbionin involved in virus binding.

15-122

TRANSMISSION CHARACTERISTICS OF *SPIROPLASMA CITRI* AND ITS EFFECT ON LEAFHOPPER VECTORS FROM THE *CIRCULIFER TENELLUS* COMPLEX

Lynette de Almeida¹, B. Raccach², M. Klein²

University of Faro, Portugal - ¹Institute of Plant Protection, the Volcani Center, Israel - ²

Several leafhopper variants of the *Circulifer tenellus* complex were collected in "stubborn" affected areas in Israel. Two of these variants transmitted the disease agent to *Matthiola incana* after being injected with *Spiroplasma citri*. The variant from *Atriplex halimus* was collected in the Jordan Valley and designated *Circulifer tenellus*-A (CTA). The other leafhopper variant reproduced on *Portulaca oleracea* and been collected both in the Jordan Valley and in the Coastal Plains and designated *Circulifer tenellus*-P (CTP). Transmission characteristics were determined for both variants. A high rate of transmission (43.3%) was obtained by single leafhoppers of the CTA variant that were injected with the Amiad *S. citri* isolate deriving from the Upper Galilee, compared with 7% transmission that were obtained by the CTP leafhoppers. The *S. citri* isolate from Gilgal in the Jordan Valley, was not transmitted by either the CTA or the CTP leafhopper variants. Injection was found to be more effective than acquisition access feeding to render the leafhoppers infective either for the CTA or the CTP leafhoppers. The minimum acquisition access period (AAP) needed for the CTA variant to transmit the Amiad isolate was 1 hr. Longer AAPs did not always result in a higher rate of transmission. The minimum incubation period was 6 days and the time required for 50% of the population to acquire the pathogen (=LP₅₀) was 26 days. The minimum inoculation access period (IAP) was 1 hr. After an IAP of 5 days 54.1% of the plants were infected. We failed to determine the same transmission parameters for the CTP variant, as no transmission was obtained even when groups of 5-6 insects were placed on a single plant. The significance of these findings in the disease epidemiology in the Near East, is discussed.

15-121

COMPARATIVE EPIDEMIOLOGY OF THREE MAIZE VIRUSES IN REUNION ISLAND IN RELATION TO THE POPULATION DYNAMIC OF THEIR VECTORS, *CICADULINA MBILA* AND *PEREGRINUS MAIDIS*

B. Reynaud (1) D. Fargette (2) M. Peterschmitt (3)

(1) Centre de Coopération Internationale en Recherche Agronomique pour le Développement, département des Cultures Annuelles, St Pierre, La Réunion, France - (2) LPRC (Laboratoire de Phytovirologie des Régions Chaudes), Orstom/Cirad, Montpellier, France - (3) Cirad CA (Cultures Annuelles), Cirad, Montpellier, France.

The simultaneous presence of maize streak virus (MSV), maize stripe virus (MSpV) and maize mosaic virus (MMV) in Réunion has enabled us to study their comparative epidemiology.

Symptomatological ratings were taken through three years of culture on weekly sowings of the temperate hybrid INRA 508 and the composite variety IRAT 297.

Fluctuations of emigrant populations of *C. mbila* and *P. maidis* and climatic factors (temperature, rainfall and relative humidity) were measured and analysed by time series and stepwise regression analyses. Streak is the dominant disease, particularly during the warm rainy season and MMV was less frequent. Highest autocorrelations were observed with a time-lag of 12 months, confirming the annual periodicity of the fluctuation.

Pattern of change of insect numbers was positively correlated with the change in disease incidence (correlations ranging from 0.65 to 0.87). Disease incidence and vector numbers always remained constant or increased slowly with temperature up to 24°C and increased rapidly above 24°C. The relationship between rainfall, relative humidity, disease incidence and vector numbers is less clear.

Depending on the series, from 63% to 80% of the variance of disease incidence was explained by the stepwise regression with vector numbers, and (sometimes) temperature, rainfall or relative humidity. Therefore, the close adjustment found between observed and data calculated with the resulting regression allowed us to propose a simple epidemiological model.

Epidemiological data especially from Africa are compared in order to better understand the epidemiology of these viruses. Further work is needed to confirm the validity of the model. The rate of plants infected by the three viruses and the number of *P. maidis* per plant were significantly lower ($P = 0.0001$) on IRAT 297 than on INRA 508. The resistance behavior of IRAT 297 under natural conditions points to its utilization as resistance donor in breeding program geared toward obtaining multi-resistance maize genotypes.

15-123

THE OCCURRENCE OF CITRUS THRIPS, *SCIRTOTHRIPS AURANTII* FAURE IN MANGO ORCHARDS IN SOUTH AFRICA AND THE RESULTING IMPLICATIONS FOR PEST MANAGEMENT

T. Brink, J.H. Giliomee¹ & K.L. Pringle¹

Institute for Tropical and Subtropical Crops, Nelspruit, South Africa - ¹University of Stellenbosch, Stellenbosch, South Africa

The citrus thrips, *Scirtothrips aurantii* Faure (Thysanoptera: Thripidae) is the most important thrips species found on mangoes in South Africa. *S. aurantii* causes lesions on the fruit and render it unsuitable for the export market. Leave malformation and stunting of new growth is also caused. In order to control *S. aurantii* effectively on mangoes, population levels should be monitored regularly. The objective of this study was to determine when *S. aurantii* occurred in abundant numbers in mango orchards, when fruit were infested and when lesions were caused.

Weekly monitoring was conducted in different localities in the Mpumalanga Province from 1992 - 1995. *S. aurantii* were monitored by means of yellow card traps and by counting thrips on the fruit. The percentage fruit displaying lesions were annotated and fruit size was also measured.

Monitoring *S. aurantii* by means of card traps and fruit counts were effective and were correlated with fruit displaying lesions. High numbers of *S. aurantii* were present when mango fruit were small and during flushing periods. Results indicated that lesions were caused from fruit set and highest number of thrips were present when fruit were between 20 - 50 mm in length. Towards the end of the fruiting period, virtually none were present on the fruit. It is therefore important for producers to do regular orchard inspections from fruit set until the fruit are approximately 50 mm in length.

15-124

BIOLOGICAL STUDY ON WHEAT THRIPS

HAPLOTHRIPS TRITICI KURD. (THYS. PHLAEOTHRIPIDAE)

IN TEHRAN PROVINCE, IRAN

BY: P. AZMAYESH FARD

ENTOMOLOGY DEPARTMENT COLLEGE

OF AGRICULTURE TEHRAN UNIVERSITY KARAJ-IRAN

Biological researches on wheat thrips in Tehran province revealed that *Haplothrips tritici* Kurd. attacks wheat and barley fields. Its life cycle includes 2 nymphal 1 prepupal, 2 pupal and adult stages which are easily separated by the descriptions presented. The female insects appear in early May and feed on host leaves, mostly terminal ones, but after heading they all move to ears. It seems that parthenogenesis to be a common way of reproduction in this species. The eggs are laid in 2-15 batches in spikes exactly beneath the glumes. A female which has a preovipositional period of one month, lays 130-5 eggs during the life time. The developmental time of different stages were determined in laboratory and field.

Population dynamic and seasonal variability of all stages of the insects are also studied. The insect overwinters as second instar nymphs in soil at the depth of 5-10 cm or inside the wheat stubbles.

15-125

POPULATION PARAMETERS OF REPRODUCTIVE BIOTYPE IN *THRIPS TABACI* (THYSANOPTERA: THRIPIDAE)

T. Murai

Section of Entomology, Shimane Agricultural Experiment Station, 2440 Ashiwata, Izumo, Shimane, 693 Japan

It is well known that parthenogenetic reproduction occurs in many thrips species. Both arrhenotokous and thelotokous parthenogenesis occurs in *Thrips tabaci*. Both reproductive biotypes were found in Shimane and Miyagi of Japan. Population parameters of those biotypes were compared. There was no difference in developmental duration and a big difference in produced egg number between two biotypes. Sex ratio of arrhenotokous type was 0.73. Therefore, arrhenotokous type produced females as same as thelotokous type. Parameters of population increase of arrhenotokous and thelotokous type were as follows; Mean generation time was 17.7 and 21.1, Net-reproduction rate (R_0) was 79.3 and 78.4, intrinsic rate of population (r_m) was 0.2387 and 0.2704, respectively.

Arrhenotokous type could be distinguished from thelotokous type by esterase zymogram of every stages of thrips. There were eight bands on esterase zymogram of *T. tabaci*. Each biotype has characteristic band, No. 7 in arrhenotokous and No. 6 in thelotokous.

15-126

A TRIAL OF WINTER REGIONAL CONTROL FOR *FRANKLINIELLA OCCIDENTALIS* (PERGANDE) (THYSANOPTERA: THRIPIDAE) IN JAPAN.A. Tataru, K. Imigi¹, T. Sagisaka¹

Shizuoka Tea Experiment Station, Kikugawa Shizuoka, Japan -1 Shizuoka Seibu Agriculture and Forestry Office, Hamamatsu Shizuoka, Japan

F. occidentalis invaded to Japan in 1990. Since that, this species has become one of major pest of mandarin orange and vegetables in greenhouse and flowers in commercial production in greenhouse and field in Shizuoka prefecture. Since more than 200 species of plants have recorded as host plant for *F. occidentalis* (Bryan and Smith, 1956) and the thrips bore the impact of low temperature, nursery stocks of cultivating chrysanthemum and many winter annual weeds around the field and the greenhouse were suitable overwintering places for *F. occidentalis*. The overwintering populations rapidly increase in early spring, causing severe damage of flowers, strawberry and Chinese-lantern plant in Shizuoka. To oppress the occurrence in spring, a trial of winter regional control experiment was done in 100 ha of the chrysanthemum cultivation zone in Hamamatsu, Shizuoka in 1993. The recommended regional control program was as follows.

- 1) Remove extra chrysanthemum stocks till late January.
- 2) Burn the leavings of chrysanthemum or bury them into soil.
- 3) Remove the all flowers from the nursery chrysanthemum stocks.
- 4) Remove weeds around the fields and the greenhouses till late January.
- 5) Spray pesticide to the nursery stocks, flowers in field and greenhouse, and flowers in home gardens at the same time, on February 1 and February 8.

Density of *F. occidentalis* in control area after above treatments was lower than uncontrolled area. However, it is considered that more pesticide treatment in March is necessary because the density of *F. occidentalis* in control area in early March became to be high from early February.

15-127

THRIPS *FRANKLINIELLA OCCIDENTALIS* (PERGANDE) OF ROSES IN GREENHOUSES IN EASTERN PART OF CROATIA

E. Raspudić, M. Ivezić

University of Josip Juraj Strossmayer in Osijek, Faculty of Agriculture, POB 117, 31000 Osijek, Trg Sv. Trojstva 3, Croatia

The western flower thrips *Frankliniella occidentalis* (Pergande) is permanent cause of the products problem. This cause is present on the roses and weeds (*Stellaria media* (L.) Vill., *Convolvulus arvensis* L.) which are in the greenhouses in the eastern part of Croatia.

The investigation was carried out in the greenhouses "Orhideja" Magadenovac, where the main products are roses. They have had problems on roses since 1990 and this pest is present in every production. Many cultivars and weeds that are surrounding the greenhouses are good hosts for *F. occidentalis*. The presence of the plants suitable for the thrips food permits the easily developing of the thrips.

Control measures were provided by insecticides: Karate 2,5 EC, Dilon 50 EC, Lannate L, Evisect S and Vertimec EC. All insecticides reduced population of the thrips. Vertimec EC gave the best results and population was reduced by 85%.

The population of the thrips on the roses in the greenhouses is successfully performed by the profilactical and the chemical control measures.

15-128

FRANKLINIELLA SCHULTZEI (THYSANOPTERA: THIRIPIDAE) ASSOCIATED WITH TOMATO SPOTTED WILT VIRUS INCIDENCE IN SOLANACEOUS VEGETABLES FROM NEW SOUTH WALES AUSTRALIA

V. Rajakulendran, L. Tesoniero, A. Clift, M.A. Terras
Biological & Chemical Research Institute, NSW Agriculture, Rydalmere, NSW Australia

Both *Thrips imaginis* Bagnal and *T. tabaci* Lindeman were found associated with seed potato crops in the Crookwell district (-34° 28', 149° 29'; altitude 700 m), 1990-93, but only *T. tabaci* transmits Tomato Spotted Wilt Virus (TSWV). TSWV incidence was below 0.1%. A wider survey throughout NSW in 1994 identified three potato crops infested by *Frankliniella schultzei* (Trybom) with 50-100% infection levels. During petroleum spray oil (PSO) field experiments on processing tomatoes at Leeton (-34° 33', 146° 24'; altitude 140 m) during the 1994/95 season, *F. schultzei* was associated with between 16 and 80% infection with TSWV in tomatoes and capsicums, depending on the effectiveness of insecticide use. High volume, over 1,000 L/ha, of 1% PSO restricted the incidence of TSWV to less than 20% of plants. There was an exponential increase in TSWV incidence with increasing density of thrips.

These observations emphasise the potential for a migratory thrips like *F. schultzei* to infect a high proportion of crops over a wide area with TSWV.

15-130

FACTORS CONTRIBUTING TO INCREASES OF BEMISIA TABACI (GENN.) POPULATIONS: DEFINING THE OUTBREAK PYRAMID (HOMOPTERA: ALEYRODIDAE)

S. J. Castle and T. J. Henneberry
U.S. Department of Agriculture, Agricultural Research Service, Western Cotton Research Laboratory, Phoenix, AZ 85040, USA

The rise in status of *Bemisia tabaci* as a world-wide pest of agriculture and floriculture has accelerated over the past 15 to 20 years. Explanations for this rise have been varied, but in many cases have implicated the pervasive use of insecticides as a major contributing factor. Resistance to insecticides has been documented in many crop situations and countries, although the connection between the identification of resistance (often based on laboratory-defined resistance through comparisons to inbred reference strains) and loss of field control has not always been clear. Other insecticide-related effects such as depredation of natural enemy populations and/or hormoligosis due to sub-lethal pesticide residues may also have contributed to *B. tabaci* outbreaks.

Three consecutive years of monitoring responses of *B. tabaci* populations to insecticides in the Imperial Valley, CA failed to detect progression to higher resistance levels. Bioassay data indicated instead that susceptibility to most insecticides increased during this period, while insecticide field trials demonstrated good field efficacies for many insecticide treatments against whiteflies. Natural control has been inadequate even in organically-grown crops, and there has been no indication of accelerated population growth due to hormoligosis. However, whitefly populations still have grown to outbreak proportions, demanding a more comprehensive consideration of factors that contribute to *B. tabaci* outbreaks other than just insecticide-related factors.

The outbreak pyramid is a conceptual presentation of four principle components that contribute to whitefly outbreaks. At the base of the pyramid is (1) climate, the most fundamental and unalterable component, which can accelerate whitefly generation times to 2.5 weeks under hot, rainless conditions. Built upon the climate base is the (2) agriculture, the types of crops, their sequences and relative acreages that determine the quality of the resource base available for whitefly populations to exploit. The third component is (3) biotic, or the intrinsic potential of *B. tabaci* to grow and increase its numbers within its environment. At the top of the pyramid is the (4) management component, which may not be adequate to contain *B. tabaci* populations depending on the collective potential contained within the bottom three levels of the pyramid. It is argued that a lush agricultural system in a hot, arid climate can increase *B. tabaci* populations at a rate whereby they escape their natural enemies, and, in some cases, is beyond the economic and/or practical feasibility of management inputs to suppress whitefly populations below economically damaging levels.

15-129

MONITORING GEMINIVIRUS ACQUISITION AND TRANSMISSION BY WHITEFLIES IN ARTIFICIAL FEEDING CHAMBERS USING POLYMERASE CHAIN REACTION

R. C. Rosell, I. Torres-Jerez and J. K. Brown
Department of Plant Sciences, University of Arizona, Tucson, AZ USA

The ability of adult whiteflies to ingest squash leaf curl virus (SqLCV) from infected plants was monitored by polymerase chain reaction (PCR) using an artificial feeding assay. *Bemisia tabaci* (vector) and *Trialeurodes vaporariorum* (non-vector) adult whiteflies were allowed an acquisition access period (AAP) of either 2, 8, 24 and 48 h on healthy or SqLCV-infected pumpkin, and a 24 hr (simulated) inoculation access period (IAP) on sucrose feeding substrate in artificial feeding chambers. The presence of SqLCV DNA was monitored by PCR in plant extracts, whole body whitefly extracts, sucrose feeding substrate containing saliva, and honeydew. PCR primers that amplify a 550 bp fragment of the SqLCV coat protein gene were used in PCR assays to ascertain virus presence. Virus was detectable in adult whiteflies fed on SqLCV-infected plants and in infected plants, but not in non-viruliferous whiteflies or in healthy plant controls. SqLCV DNA was also detectable in saliva/sucrose, honeydew, and whole body extracts of *B. tabaci*, allowed 8-48 hr AAP's with 24 hr IAP on sucrose. However in *T. vaporariorum*, viral DNA was detected in honeydew and whole body extracts, but not in the saliva/sucrose. This study provides the first direct evidence of geminivirus in vector whitefly saliva, and demonstrates that some form(s) of virus/viral DNA is (are) ingested, and passed through, both vector and non-vector adult whiteflies, given a sufficient AAP.

15-131

ASSAYS FOR WHITEFLY (HOMOPTERA: ALEYRODIDAE) RESISTANCE IN MELON, *Cucumis melo*

A.M. Simmons, J.D. McCreight¹
USDA-ARS, U.S. Vegetable Laboratory, Charleston, SC USA - 1
USDA-ARS, U.S. Agricultural Research Station, Salinas, CA USA

Whiteflies cause much damage to vegetable and row crops in several countries. The problem has been exacerbated in recent years by the presence of a recently described species, *Bemisia argentifolii* (also called strain-B *Bemisia tabaci*). Host plant resistance in melon and other vegetables is a desired, but under accomplished, management tool against whiteflies. In developing a resistance breeding program, having a rapid and reproducible method for screening germplasm for resistance to whiteflies is essential.

Multiple assays were conducted in field, greenhouse, and laboratory conditions for evaluating melon germplasm for resistance to *Bemisia argentifolii*. Field tests with many melon entries were conducted in southern California and Arizona where high natural infestations occurred. The more promising resistant field entries, based on plant condition and plant size, were evaluated in greenhouse and laboratory tests, respectively. Plant growth response (biomass, size and vigor) to infestation, and whitefly attractiveness to melon entries for feeding and oviposition were examined within two weeks after plant emergence. Survival from egg to adult emergence was determined on live plants. Entries were compared with 'Top Mark,' a susceptible commercial entry.

15-132

DETECTION OF GEMINIVIRUS IN THE WHITEFLY *BEMISIA TABACI* (GENNADIUS) (HOMOPTERA: ALEYRODIDAE)W.B. Hunter, E.Hiebert¹, S.E.Webb², J.E. Polston³, J.H. Tsai⁴

Plant Pathology Department, University of Florida, Bradenton, FL USA- 1 Plant Pathology Department, University of Florida, Gainesville, FL USA- 2 Department of Entomology, University of Florida, Leesburg, FL USA- 3 Plant Pathology Department, University of Florida, Bradenton, FL USA- 4 Department of Entomology, University of Florida, Ft.Lauderdale, FL USA

Detection of geminiviruses in the whitefly vector, *Bemisia tabaci* (Gennadius) (Homoptera: Aleyrodidae) B-biotype, was examined by light, scanning- and transmission electron microscopy, fluorescent and confocal laser microscopy to elucidate the location and movement of virus within whiteflies. Two different geminiviruses, tomato mottle virus (TMOV), and a cabbage geminivirus were examined. Geminiviruses were detected by indirect fluorescein conjugated antibody technique in the anterior region of the midgut, filter-chamber, and primary salivary glands of whiteflies. These are most likely the sites where virus passes through membranes before transmission can occur. Virus detection was low for both geminiviruses (3-20%). The difficulty of detecting virus after insects fed on healthy plants suggests that virus titers were low within individuals under these conditions, which may be due to a lack of virus replication within the vector. A model for Virus movement during acquisition is discussed.

15-134

DAMAGE ON "HASS" AVOCADO LEAVES, WEBBING AND NESTING BEHAVIOR OF *OLIGONYCHUS PERSEAE* TUTTLE, BAKER AND ABBATIello (ACARI: TETRANYCHIDAE)

1

O. Aponte L. and J. A. McMurtry.

1Department of Entomology, University of California, Riverside, California, USA.

The damage of *Oligonychus perseae* Tuttle, Baker and Abbatiello on avocado trees occurs mainly on the underside of the leaves along the midrib, main veins and leaf depressions. the lower epidermal, spongy parenchyma and palisade parenchyma cells of the leaf tissues are destroyed. Large necrotic areas on the underside of the leaf result from feeding by high population levels of the mite. Feeding and reproduction takes place in "nests" of silken webbing, which also provide protection from some predator mites and other natural enemies. *O. perseae* shows a modification of the life type web-nest (WN-c). The highest number of nests built/female was 12.17 at 20 °C, and the highest number of eggs/female/nest was 5.20 at 25 °C

15-133

BIOLOGY, LIFE TABLE AND MATING BEHAVIOR OF *OLIGONYCHUS PERSEAE* TUTTLE, BAKER AND ABBATIello (ACARI: TETRANYCHIDAE)

1

O. Aponte L., J. A. McMurtry

1 Department of Entomology, University of California, Riverside, CA. USA.

The biology of *Oligonychus perseae* Tuttle, Baker and Abbatiello was studied at four different temperatures on excised "Hass" avocado leaves (*Persea americana* Mill.). The time required for development from egg hatch to adult was : 34.89, 16.90, 13.8 and 9.81 days, at 25, 20, 25 and 30 °C, respectively. The highest fecundity (45.80 eggs/female) occurred at 25 °C, and the highest oviposition rate (1.84 eggs/female/day) was at 30 °C. The highest mortality for development was 32.30 % for the combined stages at 30 °C. The theoretical lower threshold temperature for development was 7.80 and 9.00 °C, for the combined stages of female and male, respectively. The thermal constant for completion of development was 200 and 166 day-degrees for the female and male, respectively. The sex ratio ranged from 1.82:1 to 239:1 (female:male). The calculated intrinsic rate of increase was highest (0.1440) at 30 °C. The net reproductive rate was highest (25.80) at 25 °C. The shortest mean generation time (18.38) occurred at 30 °C.

15-135

SOME BIOLOGICAL AND MORPHOLOGICAL DIFFERENCES BETWEEN GALL AND VAGRANT FORMS OF *PHYTOPTUS AVELLANAE* NAL.(ACARINA: ERIOPHYOIDEA)

S.K. Özman

Department of Plant Protection, Faculty of Agriculture, Ondokuz Mayıs University, Samsun , Turkey.

Big bud mite (*Phytoptus avellanae* Nal.), which is one of the most important pests of hazelnut, has two forms, gall and vagrant. The gall form of *P. avellanae* lives in big buds. It has a simple life cycle and a single nymph type. The vagrant form of *P. avellanae* lives on vegetative and generative organs and in big buds. The latter has a different and rather complex life cycle and two nymph types.

In this study gall and vagrant forms of *P. avellanae* were examined biologically and morphologically. Biological studies were performed at 20±1°C, 24±1°C and 70 % R.H. in the laboratory and mites were reared on leaf discs and duration of the different stages were determined. Gall form can not survive on the leaf disc after the first instar nymph stage while the vagrant form lives on the leaf disc. Morphological comparisons showed that gall and vagrant form were significantly different from each other in size, shape and colour.

15-136

INFESTATION PROCESS OF LOQUAT RUST MITE (TENTATIVE NAME) *ACERIA* SP. ON LOQUAT FRUIT

N. OHKUBO

Nagasaki Fruit Tree Experiment Station, Nagasaki Prefecture, Japan

Loquat rust mite (tentative name), *Aceria* sp. is one of the important pests of loquat in Japan, especially in growing in green house. It widely distributes at loquat cultivated areas in China and Japan. Host plant is restricted only loquat, *Eriobotrya japonica*, including almost of the cultivated and wild varieties. This pest cannot live on other *Eriobotrya* species, for example *E. deflexa*, etc. It inhabits inside of flower cluster and other sheltered part of bud and base of leaf, and causes so-called **Tateboya** symptom, brownish injury of fruit surface from pedicel to apex. In Japan damage occurs especially in green house, because rust mite is able to increase rapidly by suitable temperature for development. After standing of flower bud from August, it increases inside of flower cluster and attacks on surface of young fruit. **Tateboya** symptom occurs just before the bagging of fruit. This damage can be lightened by one time of spray of acaricide, for example **Pyridaben**, etc or fungicide **Thiophanate-methyl** during flowering period of loquat.

15-138

MITES ASSOCIATED WITH CULTIVATED MUSHROOMS IN TÜRKİYE

N. Madanlar, F. Ünder

Ege University, Faculty of Agriculture, Department of Plant Protection, 35100 Bornova, İzmir, Türkiye

The world acarofauna of cultivated mushrooms is extremely rich. In the studies were made in Türkiye nine harmful and five beneficial mite species were determined. Harmful species were *Pygmephorus allmanni* Krczal, *P. madanlarae* Ramaraju and Madanlar, *P. sellnicki* Krczal, *P. smileyi* Ramaraju and Madanlar, *P. turkiensis* Ramaraju and Madanlar (Prostigmata, Pygmephoridae), *Caloglyphus berlesei* (Michael), *C. rhizoglyphoides* (Zachvatkin), *Mycetoglyphus fungivorus* Oudemans (Astigmata, Acaridae) and *Histiostoma sapromyzae* (Dufour) (Astigmata, Histiomidae). Beneficial species were *Eugamasus butleri* Hughes (Mesostigmata, Parasitidae), *Poecilochirus belkahvensis* Ramaraju and Madanlar, *P. hyatti* Ramaraju and Madanlar, *P. simpliseta* Ramaraju and Madanlar and *P. torbaliensis* Ramaraju and Madanlar (Mesostigmata, Parasitidae). In addition to these beneficial species, some unidentified mites took part in the genus *Arctoseius* (Mesostigmata, Ascidae), the subfamily Laelapinae (Mesostigmata, Dermanyssidae), and the families Ascidae, Digamaselidae, Macrochelidae, Parasitidae (Mesostigmata), Anystidae and Cunaxidae (Prostigmata).

15-137

A NEW SIMPLIFIED METHOD TO ESTIMATE POPULATION DENSITY OF THE RUST MITE (*ERIOPHYES CHIBAENSIS* KADONO) ON JAPANESE PEAR USING STICKY TAPES AND WATER-SENSITIVE PAPERS

H. Izawa

Tottori Horticultural Experiment Station, Daiei, Tottori 689-22, Japan

To estimate the population density of the rust mite (*Eriophyes chibaensis* KADONO) on Japanese pears invisible to the naked eye because of its minuteness, a new simplified method using sticky tapes and water-sensitive papers (Spraying Systems Co.) was developed. The procedures for investigation are as follows.

1. Expanded leaves on the top of elongated shoots were cut into two parts along midrib by knife in May to June.
2. Sticky transparent tapes were pasted on the back of the pieces of leaves.
3. These sticky tapes were peeled from the pieces of leaves and pasted on the water-sensitive papers with strongly rubbing their surface by the finger nail.
4. The parts of crashed mites on the water-sensitive papers were colored blue.
5. The density of the colored spots on the water-sensitive paper was graded as the index of the population density of mites by compared with the practical mite density observed by stereomicroscopy in advance.
6. This method was considered to be useful and effective enough to estimate rust mite populations.

15-139

BIOLOGICAL OBSERVATIONS ON PHYTOSEIID MITES (PARASITIFORMES, PHYTOSEIIDAE) LIVING ON HAZELNUT (*CORYLUS AVELLANA* L.) AT TWO DIFFERENT ALTITUDES IN SICILY

S. Ragusa & H. Tsolakis

Istituto di Entomologia agraria, Università di Palermo, Italy

Surveys on phytoseiid mites living on hazelnut (*Corylus avellana* L.) at two different altitudes (m 500 a.s.l. and m 1000 a.s.l.) were carried out during 1991- 1993. Nineteen species of phytoseiids were recorded as a whole. Among them 8 species (*Kampimodromus aberrans* (Oud.), *Typhlodromus intercalaris* Liv. & Kuzn., *Typhlodromus cryptus* Athias-Henriot, *Typhlodromus rhenanoides* Athias-Henriot, *Amblyseius andersoni* (Chant), *Euseius stipulatus* (Athias-Henriot), *Paraseiulus erevenicus* Wainst. & Arutun., *Phytoseius finitimus* Ribaga) were present in both fields, and the first four were the most frequent. *T. intercalaris* was the dominant one (53%) at m 500 a.s.l., followed by *K. aberrans* (34%), *T. rhenanoides* (8%) and *T. cryptus* (6%), while *K. aberrans* was the dominant one (60%) at m 1000 a.s.l., followed by *T. cryptus* (27%), *T. intercalaris* (13%) and *T. rhenanoides* (1%), showing the preference of *K. aberrans* for higher altitudes and lower temperatures. Moreover the population increased one month earlier at m 500 a.s.l. than at m 1000 a.s.l. Furthermore the distribution of phytoseiids on the plants was also ascertained. For this purpose the trees were divided into three parts: trunk, low branches and tall branches. On the whole the various species did not show any preference for any of the three different parts of the trees as they were uniformly distributed on the trees during the observation periods.

15-140

THE EFFECTS OF PESTICIDES AND OTHER VARIABLES ON PHYTOSEID MITES (PARASITIFORMES, PHYTOSEIIDAE) IN VINEYARDS OF THE REGIONS CAMPANIA AND LAZIO

M. Nicotina, E.A. Cioffi

Department of Agricultural Entomology and Zoology, University of Naples, Portici, Italy

Investigations on phytoseid mites have been carried out between 1992 and 1995 in 26 vineyards in Campania and 22 vineyards in Lazio. During the four years of observation, pesticide control, grape-vine cultivar, vineyard age, cultivation methods and species of nearby plants were registered in each of the 48 vineyards. The population dynamics of phytoseid mites in relation to thermo-hygrometric variations was also noted in several vineyards. The following eight species, listed in decreasing order according to their presence, were found in the vineyards of Campania: *Kampimodromus aberrans* (Oudemans), *Typhlodromus exilaratus* Ragusa, *Amblyseius andersoni* (Chant), *Phytoseius finitimus* Ribaga sensu Denmark (1966), *Typhlodromus criptus* Athias-Henriot, *Amblyseius stipulatus* Athias-Henriot, *Seiulus soleiger* Ribaga, *Typhlodromus kerki-rae* Swirski & Ragusa. The following seven species were found in Lazio: *T. exilaratus*, *P. finitimus*, *K. aberrans*, *A. andersoni*, *Amblyseius californicus* (Mc Gregory), *T. criptus* and *Seiulus amaliae* (Ragusa & Swirski).

It has been noted that, amongst the external elements, pesticide control has assumed a key role on the density of the populations of these beneficial Arthropods causing the total disappearance of phytoseid mites in some vineyards where non-selective pesticides have been used over and over again.

Other external components have affected the phytoseid populations to a lesser extent: cultivars, temperature, humidity, wild and cultivated plants growing near the vineyard.

The method of cultivation, the agronomic practices and the age of the vineyard have no influence on the density of phytoseid populations.

15-141

PEST MITES ON CULTIVATED EDIBLE MUSHROOMS IN JAPAN

Kimiko Okabe

Forestry and Forest Products Research Institute, Kumamoto Japan

Increasingly, several species of mites are becoming serious pests to relatively new cultivation of indoor mushrooms in Japan. Mushroom pest mites have been investigated regularly since 1990. These investigations have concluded that most species recorded belong to Acaridae, Histiogastromatidae or Pygmephoridae.

These mites appeared while mushrooms were being cultivated under temperatures of 18 to 23°C with humidity higher than 80% R.H. In most cases, weed fungi such as *Trichoderma* spp. coappeared in bottles of mushroom cultivation with mites. Under laboratory conditions, *Tyrophagus putrescentiae*, the species recorded most frequently, is observed to excrete more than 10 spores of a weed fungus per a fecal pellet. Because approximately half of the spores are germinative, it is suggested that mites carry these fungal spores into bottles. As control measures, only a temporary stopping cultivation combined with fumigation have achieved success so far.

15-142

THE INCIDENCE OF BROADMITE (*Polyphagotarsonemus latus*) (BANKS, 1904) (ACARI: TARSONOMIDAE) IN NINE BEAN GENOTYPES, IN GREENHOUSE CONDITIONSM.A.G. ORIANI¹, F.M. LARA²

1- Departamento de Biologia, FFCLRP-USP, Ribeirão Preto, SP, Brasil

2- Departamento de Entomologia e Nematologia, FCAVJ-UNESP, Jaboticabal, SP, Brasil (Financial support by FAPESP).

This research intended to evaluate the incidence of broadmite, *Polyphagotarsonemus latus* (Banks), on nine bean genotypes, mainly those that present arcelin. This protein could be associated with the resistance to bruchids, *Zabrotes subfasciatus* (Boh.) and *Acanthoscelides obtectus* (Say). The tests were carried out in greenhouse conditions, with the genotypes: Arc 3s, Arc 5s (wild genotypes with arcelin); Arc 1, Arc 2, Arc 3, Arc 4 (genotypes with arcelin in a breeding program) and Porriolo 70, Bolinha, IAPAR MD 808 (commercial genotypes without arcelin). These genotypes were planted in pots, with two plants per pot and ten repetitions, in dry and wet season. Three leaflets per pot were collected from the top leaves when the plants were 24 day-old. The counting of mobile forms of mites present in the lower surface of the leaflet was carried out in laboratory. In the wet season, the incidence by broadmite was significantly lower on Arc 3s and higher on Porriolo 70 and Bolinha genotypes. In the dry season, Bolinha, Arc 2 and Arc 1 genotypes had the biggest incidence, while the Arc 5s had the smallest incidence.

15-143

EGG MORTALITY OF THE WHITEBACKED PLANTHOPPER, *SOGATELLA FURCIFERA* HORVÁTH (HOMOPTERA: DELPHACIDAE) ASSOCIATED WITH THE FORMATION OF WATERY LESION AT OVIPOSITION SITES ON RICE PLANTS

Y. Suzuki, Y. Seino, K. Sogawa

Kyushu National Agricultural Experiment Station, Nishigoshi, Kumamoto, Japan

Association of the physiological egg mortality of *Sogatella furcifera* with the rice plant response of forming watery lesions at oviposition sites was revealed: egg survival rate dropped to less than 20% in the watery lesion within 2 days after oviposition, while 88.8% of eggs developed to the eye-spot formation stage in the non-watery lesion, on Japonica rice plants 8 weeks after planting. *S. furcifera* eggs laid in large tillers and in the main stem suffered higher physiological mortality than those laid in small tillers on the same plant. The physiological egg mortality increased steadily with progression of the tillering of plants until 10 weeks after planting. Egg density did not affect the mortality. Benzyl benzoate was isolated from the watery lesions. Water solution of benzyl benzoate exhibited ovicidal activity against *S. furcifera* eggs at concentration of ≥ 6.4 ppm. This ovicidal substance was not detected from intact rice plants, *S. furcifera* eggs or non-watery ovipositional lesions.

Newly discovered ovicidal response of rice plants explains annual fluctuations in the population growth rate of *S. furcifera* in paddy fields.

15-144

ARE THE LOPHOPIDAE (HOMOPTERA, FULGOROMORPHA) A PARAPHYLETIC TAXON?

A. G. Soulier*, T. Bourgoin* and M. R. Wilson**
* Laboratoire d'Entomologie et EP 90 du CNRS, Muséum national d'Histoire naturelle, Paris, France. ** Department of Zoology, Museum National & Galleries of Wales, Cathays Park, Cardiff, UK.

Of the twenty families of Fulgoromorpha currently recognised, the Lophopidae is one of the smallest with around 140 described species mainly confined to the Asian and African regions. Three genera are known from South America. The Lophopids is an important family not only from an applied aspect (*Pyrilla* and *Zophiuma* are respectively important pests on sugarcane and coconuts) but also from a fundamental point of view : Lophopidae and its proposed sister group Eurybrachidae are considered as the most recent major division within the Fulgoromorpha (Emeljanov, 1990).

In 1930, Muir proposed a new classification of the Lophopidae genera, based on metatarsal and metatibial characters. This rearrangement was stated by Muir to be "more natural" than the previous arrangements given by Melichar (1903) and Baker (1925). Since then, no improvement has been made to this classification and the monophyly of the different taxa proposed by Muir still requires validation. In the frame of a revision of the Lophopidae family (morphology, phylogeny and biogeography) using the cladistic methodology, the supposed essential characters used by Muir (1930) have been re-examined.

High magnification using microscope observation coupled with SEM studies shows :
• the apical tibial spine characters can not be used to separate *Ptuambara*, *Bisma*, and *Hesticus* from the *Menosca* group ;
• *Elasmoscelis* shows an obvious autapomorphic pattern of the particular metatarsal plate involved from the Lophopini sensus Metcalf (1955) which are then probably paraphyletic. This genus presents also an autapomorphic specialized distal tibial plate ;
• *Lucasa* cannot be separated from the remaining Lophopini genera.

At the family level, those particular characters can also be observed in several other Fulgoromorpha genera (e.g. Tropicuchidae : Huang & Bourgoin, 1991) and particularly in Eurybrachidae. If we consider that the discriminant value of the three characters (width of the vertex, lateral clypeal carinae and width of the frons) used to separate Eurybrachidae from Lophopidae is not exclusive, we conclude on the probable paraphyly of both families Eurybrachidae and Lophopidae.

15-146

MATING BEHAVIOR AND COPULATORY MECHANISM IN *HYALESTHES OBSOLETUS* SIGNORET (HEMIPTERA, FULGOROMORPHA, CIXIIDAE)

R.Sforza and Th. Bourgoin
Laboratoire des mycoplasmes des plantes, I.N.R.A, Dijon, France (R.S) - Laboratoire d'Entomologie & E.P. 90 du CNRS, Museum National d'Histoire Naturelle, Paris, France (T.B).

In palearctic region, *Hyalesthes obsoletus* Sign. is known to be a vector of stolbur phytoplasma, an important plant pathogen. In France, it is involved in transmission of « bois noir » disease occurring in vineyards (Sforza *et al.*, 1996 in prep.). *H. obsoletus* is a monovoltine species, present at adult stage in eastern and southern France from June to August.
Before mating, we observed a characteristic male dance close to female by an intense fluttering of wings periodically repeated. An acoustic communication between male and female participates probably to this mating behavior. During mating, adults are in an opposited and head to foot position. In contrast to the other genus of Cixiidae, we confirmed that male's gonostyli grip the female's gonapophyses VIII by their inner side, as previously observed by Hoch and Remane (1985). In this species, a triple hooking assures maintenance of copulatory position.
An adapted staining allowed us to observe the vagina organized in different lobes. In this manner, aedeagus and two hooked-like endosomal processes are maintained. Presence of those strongly sclerotized processes into female's exit ducts is in relation with strongly sclerotized plates of the vagina wall. According to our observations, spermatheca is divided into five parts. As described in other Fulgoromorpha (Bourgoin, 1993), sclerotized ornamentations are present on bursa copulatrix ; a glandular role of these ornamentations may be advanced, either as a trophic assistance for spermatozoa or as a destruction of spermatozoa which are in excess.

15-145

STUDIES ON THE OCCURRENCE AND PREDICTION OF *MYRMELEOTETTIX PALPALIS* (ZUBOVSKY)

C. Z. Liu, G. H. Feng
Department of Pratacultural Engineering, Department of Plant Protection, Gansu Agricultural University, Lanzhou, China

The life history, habits, and ecological factors affecting occurrence of *myrmeleotettix palpalis* were studied in Xiahe County, Gansu Province in 1989—1994. The results showed that the pest had only one generation a year. The development of the nymphs undergoes about 70 days, and the longevity of the adults lasts for 64 days. In the natural temperature, the developmental zero of the first instar was 4.17°C, the second instar 4.85°C, the third instar 7.98°C, the fourth instar 8.70°C, and the fifth instar 9.00°C, and the effective temperature summation was 24.66 day degrees in the first instar, 40.13 in the second instar, 23.84 in the third instar, 36.59 in the fourth instar and 59.12 in the fifth instar.
Two linear regression equations expressing the close relationships between the occurrence number in the second ten days of May and precipitation or thermo—precipitation coefficient in the first ten days of May were established. In addition, an equation expressing the relationship between the peak period and the mean temperature in the second ten days of May and winter lowest temperature was proposed.

15-147

BEHAVIOURAL ASPECTS OF A NEW SPECIES OF *HILDA* KIRKALDY (HEMIPTERA:TETTIGOMETRIDAE) FROM THE DRAKENSBERG MOUNTAINS OF SOUTH AFRICA

I.T.P. Pajor
Invertebrate Conservation Research Centre, Department of Zoology & Entomology, University of Natal, Pietermaritzburg, South Africa

This *Hilda* sp. nov., with the proposed name *proteacola* Bourgoin, is only the second recorded species within the subgenus *Prodhilda* Bourgoin 1988. It seems to be endemic to the central parts of the Drakensberg mountains in the province of KwaZulu-Natal, between 1480-1950 metres above sea level, on plants of the genus *Protea* L. (Proteales: Proteaceae). I found it regularly on both *Protea caffra* Meisn. subspecies *caffra* Chisumpa & Brummitt and *P. roupelliae* Meisn. subsp. *roupelliae*, but only occasionally on *P. dracomontana* Beard.
Up to four generations per year occurred on *P.r.roupelliae* (between September-June) and three on *P.c.caffra* (September-May). Generations were not strictly synchronized, with all three stages (egg-nymph-imago) co-occurring on the same part of a plant. They all preferred fresh-growing plant tissues. On *P.c.caffra* and *P. dracomontana*, eggs were deposited in batches of one to several dozens mostly on the outermost involucral bracts of the buds of inflorescences and the apical end of the adjoining flowering branches, but occasionally on young vegetative shoots. On *P.r.roupelliae*, egg batches were smaller and laid only on young leaves.
All 3 life stages were regularly attended by ants. An unidentified *Myrmecaria* sp. (Myrmecinae) was the most common one at all altitudes. *Anoplolepis custodiens* (F. Smith, 1858) (Formicinae) was dominant only between 1500 -1580 m a.s.l., while two further Myrmecinae species were sometimes seen together with *Hilda* (*Prodhilda*) *proteacola* Bourgoin: a *Pheidole* sp. (probably *megacephala*) and *Crematogaster* sp. A. The proportion of ants to plant-hoppers (nymphs and/or adults) was about 3 on *P.r.roupelliae* and 5 on *P.c.caffra*, with *A. custodiens* usually having higher densities.
No apparent damage to any of the affected parts of the proteas was noted. I did not observe any predation or parasitism in this *Hilda* species, however, the very alert imagines could successfully evade a number of likely predators or parasitoids.

15-148

LEAFHOPPERS, PLANTHOPPERS AND PHYTOPLASMAS
R.Sforza, D. Clair,X. Daire, J. Larrue, E. Boudon-Padieu
I.N.R.A, Laboratoire des mycoplasmes des plantes, Dijon, France

Knowledge on biodiversity among phytoplasmas detected either in Hemiptera or in plants are restricted to phytoplasmas causing damage to culture. Phytoplasmas are mainly transmitted by Hemiptera Cicadomorpha and Fulgoromorpha, except for some Sternorrhyncha Psyllidae. During 1995, the aim of our weekly trapping in french vineyards (Bourgogne and Rhône-Alpes) was to determine a vector of the french grapevine yellows, called « bois noir », whose pathogenic agent belongs to the stolbur group. 2400 Auchenorrhyncha specimens, classified into 45 species were tested using a molecular diagnosis, based on PCR amplification of phytoplasma rDNA ; less than ten species carried a pathogen, either a stolbur type or a clover phylloxy type (see Table). We obtained transmission of the stolbur type phytoplasma with the cixiid *Hyalesthes obsoletus* to grapevine, periwinkle and bindweed. It is likely that other hoppers are natural vectors of the pathogen.

DIABROTICA VIRGIFERA VIRGIFERA LE CONTE -
POTENTIAL RISK FOR EUROPE (GROWTH AND
HARMFULNESS IN YUGOSLAVIA)

S. Krnjajić, N. Dimić, P. Perić,M. Vukša, M. Cvetković
Institute for plant protection and environment, Belgrade,
Yugoslavia

Diabrotica virgifera Le Conte-western corn
rootworm will be new dangerous pest for more than
13 000 000 ha under maize in Europe.

Since 1992, when the first damages were
registered we have observed their biology and
harmfulness.

Due to similar climate conditions in Yugoslavia
and in American Corn Belt, *D. virgifera* adapted itself
and spread, with tendention of spreading over the other
countries in the following years.

In Yugoslavia *D. virgifera* has one generation per
year. It overwinters in the diapausing eggs which could
be found from mid July till the end of June of the
following year. Larval hatching started from mid May till
the end of June. Larvae could be found till the beginning
of August. The first imagoes could be detected from the
end of June till mid October. Egg laying began from mid
July with its maximum in August.

The larval stage makes a main damages on maiza
roots, and can destroy whole plant in severe attack.

The imagoes cause the secondary important
damages on leaf, then pollen and silk and at last on ear
tips. However, in the case of greater number of imagoes
the silk can be completely chewed and the pollination
disrupted.

15-149

SUMMARIZATION OF CHINESE ENTOMOLOGICAL LITERATURE
AND AGRICULTURAL CHEMICAL LITERATURE FROM ANCIENT
TIME TO 1995

Wang Hua-Fu
Jiamusi Agricultural College, Jiamusi City, China

This article was written on the basis of the wor-
ks entitled "THE INDEX OF CHINESE ENTOMOLOGICAL
LITERATURE", "THE INDEX OF CHINESE AGRICULTURAL
CHEMICAL LITERATURE",compiled by the author him-
self.

Entomological Literature:There are 113224 pieces
of records on insects liteature.There are 10,315
pieces of records on insects literature before
the foundation of P.R.China, after that there are
102,909 pieces of records on insects literature.
It is 10 times than the time before the founda-
tion of P.R.China. There are 293 regularly and
irregularly published journals and newspapers in
China. There are 82 sorts before foundation of
China, after that there are 211 sorts.

Agricultural Chemical Literature: There are113017
pieces of records on agricultural chemical liter-
ature. Of which, 36,115 are publicly published
papers from the Chinese journals, newspapers and
books; 20,150 are literature from restricted pub-
lications; 16,925 are translated papers; 39,651
are translated abstracts from foreign sources;174
are literature on agricultural chemicals in China
written inforeign languages either by Chinese sc-
holars or by foreign scholars. Among the total of
113,017 literature, 10,125 items were published
before the founding of P.R.China while the rest
102,892 items were published after the founding
of P.R.China in 1949,with the latter outnumbering
the former by more than 10 times.

15-151

PECULIARITIES OF TRITROPIC INTERACTIONS ON DIFFERENT
CABBAGE GENOTYPES

B.P.Asvakin & O.V.Ivanova
All-Russian Institute for Plant Protection, St.-Petersburg, Russia.

It is common knowledge that cabbage genotypes vary in terms and length of
some stages of plant development. These differences entail specific features of
interactions of cabbage with its main pest species at particular developmental
stages.

Delia brassicae and *Plutella maculipennis* are the main pests of cabbage at the
period from seeding to 11-14 leaf stage. No significant differencs have been
observed at that period in egg numbers of *D.brassicae* on different cabbage
genotypes. *P.maculipennis* has been found to prefer to oviposite on cabbage
plants damaged with *D.brassicae* and *Plasmodiophora brassicae* Wor.

At the second period of vegetation (from 11-14 leaf stage to head stage)
morphological differences of cabbage cultivars entail cultivar-specific
variations in root environmental conditions. These variations influence not
only behavior of the main pest species but the behavior of their
entomophagans as well. At that period *Delia floralis* F. and second generation
of *D.brassicae* place eggs on leafstalks of lower cover leaves and heads.
Cabbage root flies prefer therewith to oviposite on plants which were slightly
damaged previously by other injurious organisms. The extent of harmful
impact of phytophagans on the host plant has been observed to be
significantly lower on resistant cabbage cultivars as compared to susceptible
ones. Significant influence of characteristics of cabbage cultivars on the
percentage of root fly pupariums parasitized with specialist entomophagans
also has been revealed. In some cases the percentage of parasitised
pupariums was higher on resistant cultivars.

Intensification of activity of entomophagans and the use of particular
morphological and biochemical features of cabbage cultivars appear to be
effective tools for directional influence on biocenotic processes entailing
drastic decrease in pesticide application.

15-152

LIFE HISTORY, SEASONAL OCCURRENCE AND VARIETAL PREFERENCE of AZALEA LACE BUG *STEPHANITIS PYRIODES* SCOOT (HEMIPTERA: TINGIDAE)

C. Y. Hwang, S. W. Choi

Department of Agricultural Biology, College of Agriculture, Chonbuk National University, Chonju, Korea

Longevities of male and female were 50.5 and 51.6 days. Egg period was 13.4 days, and nymphal period was 15.3 days at 25°C. Nymphs ecdysed four times. One female laid 235.6 eggs on the average into the underside of leaf along the midribs and veinlets mainly.

S. pyrioides had four generations in Chonbuk, 1994 and peaks of adult population in each generation were showed by late May, mid-July, mid-August, and mid-October. *S. pyrioides* overwintered with eggs.

Sancheol, Hwaboso, and Seokam occurred less ovipositional preference than Guongzahong and Red hope. Nymph survival rates of Hwaboso and Seokam showed lower than those of Guongzahong and Sancheol.

It is supposed that optimal control time could be early May and less oviposition preferences in Hwaboso and Seokam will probably be useful for selection of non-preference varieties.

15-154

PATTERNS OF LIFE CYCLE IN *APHIS GOSSYPPI* (HEMIPTERA:APHIDIDAE)

Y. Narai, T. Murai

Shimane Agricultural Experiment Station, 2440 Ashiwata Izumo 693, Japan

A. gossypii has a characteristic polymorphism of life cycle pattern. We have investigated the life cycle patterns of 137 clones on the condition of short-day photoperiod at $16 \pm 1^\circ\text{C}$.

Percentage of holocyclic clone, anholocyclic clone and intermediate was 63.5%, 21.2% and 15.3%, respectively. Holocyclic clones have been divided into four types; a heteroecious type, an autoecious type, a GP1 type which has alate males and oviparae produced by a apterous female as well as a alate female and an androcyclic type which has only alate males produced by a apterous female. The heteroecious type has been found in 68 clones on 15 species of plant such as *Hibiscus syriacus*, *Celastrus orbiculatus*, *Cucumis melo* and *Solanum melongena*. The autoecious type has been found in one clone on *Rubia* sp.. GP1 type has been found in 15 clones on *Hibiscus syriacus*, *Fragaria grandiflora*, *Pyrus serotina*, *Chrysanthemum morifolium*, *Lilium* spp. and *Solanum melongena*. The androcyclic type has been found in 3 clones on *Cucumis sativus*, *Cucumis melo*, *Cucurbita* sp.. GP1 type clones could be distributed in whole Honshu Island of Japan. It may be possible to distinguish GP1 type from other types by their host plants.

15-153

BIOLOGICAL CYCLE AND DIAPAUSE IN *EUPHYLLURA OLIVINA* (COSTA) AND *EUPHYLLURA PHILLYREAE* FOERSTER (HOMOPTERA APHALARIDAE).
G. Del Bene, E. Gargani, S. Landi

Istituto Sperimentale per la Zoologia Agraria, Firenze, Italy

Research was carried out from 1993 to 1995 in order to verify which species of *Euphyllura* occur in Tuscany. While the presence of *E. straminea* Loginova is excluded, *E. olivina* (Costa) infests occasionally olive-trees and *E. phillyreae* (Foerster) is spread on spontaneous and cultivated phillyreas. The biology of the two species, on which various Authors report discordant data, was studied in the outskirts of Florence, at Pescia (Pistoia) and in the pine-wood of Cecina (Leghorn). All the sampled females were dissected and the ovaries examined in order to determine their development, which was classified by 5 stages to fix the state of diapause (1st and 2nd stage), reproductive quiescence (3rd and 4th stage) and maturity (5th stage).

E. olivina can complete 3 life-cycles on olive-trees (among which one is facultative) overwintering at every stage. Oviposition takes place in January-February (1st facultative generation), in March-April and in October. The embryonic development lasts 10-15 days, the larval one 40-50 days. The adults of the three generations are present continuously during the year. The ones of the springlike generation (2nd) spend the months from July to September in reproductive diapause. The 2nd generation whose nymphs develop at expense of the inflorescences, causing the wilting by sucking the sap, is the most dangerous as it can cause some losses of the crop.

E. phillyreae is monovoltine and overwinters as a quiescent adult. Oviposition begins in January and lasts until May. Adults appear in June and, after having spent an obliged period of summerlike diapause, they remain in quiescence from September until January-March. This species, because of the emission of waxy secretion and honeydew, can cause aesthetical damages on ornamental hedges.

Both species spend the summer in reproductive diapause, which is caused by mean temperatures higher than 20°C and terminates in September - October. On the contrary, *E. olivina* females of the overwintering generation and of the first facultative one reach their post-diapause quiescence in only two weeks. The diapause termination and the passage to the phases of reproductive quiescence and maturity, is synchronized with the phenologic stage of the host plant which is suitable for oviposition: blooming and emission of buds.

15-155

A NEW SERIOUS PEST OF CITRUS IN ALGERIA

Phyllocnistis citrella STANTON (LEPIDOPTERA: GRACILLARIIDAE)

Y. Guenaoui and A. Dehliz

Institut National de Formation Supérieure en Agronomie, Mostaganem - 2700- ALGERIE (213)

Phyllocnistis citrella is a new serious pest of citrus orchards in ALGERIA. This leafminer appeared during the early spring of 1994 and became the most injurious pest on citrus because it was abundant enough on young leaves to inflict serious damages to the algerian citriculture.

In order to know the incidence of this phytophagous in the citrus insect pest complex, observations were recorded during all the flush periods.

A seasonal fluctuation in the leafminer population is noted.

In a second set of observations we try to record indigenous parasitoids of *P. citrella* for evaluating the effectiveness.

We study a project of integrated control in which cultural practices biological and chemical controls will be combined.

15-156

EGG LAYING HABIT OF THE DIAMONDBACK MOTH, *PLUTELLA XYLOSTELLA* (L.) (LEPIDOPTERA: YPONOMEUTIDAE), AND DISTRIBUTION PATTERNS OF THE EGGS ON HOST PLANTS

H. Uematsu

Faculty of Agriculture, Miyazaki University, Miyazaki, Japan

Egg laying habits were studied in oviposition cages. Sixteen plants of cabbage or Japanese radish were arranged in 4 rows with 4 plants per row. A pair of diamondback moth was released in the cage for a period of four days. The numbers of eggs on plants were examined every 24 hours. The observations were made on 21 cage units (cabbage:9, radish:12).

Micro-distribution of eggs on the plant: A total of 1,512 eggs were recorded from cabbage. Of these, 43.4, 38.7 and 2.6 per cent were on the cotyledon, the stems, and the leaves, respectively. A total of 1,867 eggs were recorded from radish. Of these, 29.8, 1.4, and 67.4 per cent were on the cotyledon, the stems, and the leaves, respectively.

Distribution patterns of eggs on the 16 plants: A female laid 30 - 50 eggs on 5 - 10 plants in one night. Distribution patterns of eggs always showed marked departure from the Poisson in the direction of aggregation. Degree of the aggregate tendency in egg distribution was studied using the C_A index which is greater than zero for contagious distribution. Young females laid eggs more contagiously than aged females. The values of C_A index were 0.79 in cabbage and 0.73 in radish plants. These are slightly less than 0.995 estimated in the natural rape field, *Brassica napus*. The diamondback moth tended to lay several eggs in a single oviposition, when she arrived on a host plant. The contagious distribution pattern of eggs may be produced by this egg laying habit.

15-157

A MODIFIED CONTAINER FOR MASS REARING OF STINK BUG, *GLAUCIAS SUBPUNCTATUS* WALKER (HETEROPTERA: PENTATOMIDAE).

M. Yamanaka

Okitsu Branch, Fruit Tree Research Station, Shimizu, Shizuoka, Japan.

Rearing of stink bug, *Glucias subpunctatus*, had been currently done by placing its first instar nymphs in Petri dishes containing raw peanuts and wet cotton for food and water supply, respectively. However, under these conditions, the food supply easily got covered by mold, requiring constant renewal. Also, it was necessary to pour more water every 4 or 5 days. In order to avoid these inconveniences, a modified mass rearing container was designed. It was made up by two vinyl chloride cups (larger one: upper diam. of 130mm, depth of 100mm; smaller one: upper diam. of 100mm, depth of 50mm). The larger cup was placed above the smaller one, and they both were stuck together by glue. On the lid of the upper cup a hole (60mm in diam.) was opened and covered by a slightly depressed nylon gauze, on which the diet was placed. For connecting both cups, another central hole (8mm in diam.) was made on the stuck surfaces, and filled up with rolled filter paper (125mm long). Finally, distilled water was poured in the lower cup. Using this container, nymphs were able to feed the raw peanuts through gauze, and the filter paper roll was kept continuously, serving as water supply. Moreover, as the diet was placed outside the container, it did not mold. Thus, during whole rearing period, there was no need to renew neither food nor water supply. Rearing tests were started with first instar nymphs at densities of 28, 42, 56, 70 and 84 per container at 25 °C under 24L-0D, which emerged 21, 19, 18, 33 and 34 adults (i.e. 76, 46, 33, 47 and 40%), respectively. There was no prolongation on the developmental period of nymphs and no abnormally small adult has emerged in any of containers. This container may also prove efficient on rearing those other pentatomid species which are able to rear on raw peanuts.

15-158

DISTRIBUTION OF TWO EPILACHNA LADYBIRD BEETLES (COLEOPTERA: COCCINELIDAE) IN SOUTHWEST AREA OF KANAGAWA PREFECTURE, JAPAN

K. Sato, H. Ikemoto¹

Laboratory of Applied Entomology, Faculty of Agriculture, Tokyo University of Agriculture and Technology, Fuchu, Tokyo, Japan -1 Oofuna, Kamakura, Kanagawa prefecture, Japan

Epilachna vigintioctopunctata (henceforth: Evp) and the so-called "Western Tokyo form" of *E. vigintioctomaculata*-complex (WTF)* are pests of solanaceous crops, *Solanum tuberosum* (potato), *S. melongena* (eggplant), *Lycopersicon esculentum* (tomato), etc. There, however, are differences in habitats of the two species.

The geographic distribution of some *Epilachna* ladybird beetles is in the order of *E. vigintioctomaculata*, WTF and Evp from north to south in central Japan.

Distribution of Evp and WTF was investigated at 73 points in southwest Kanagawa prefecture, which is located 60-90km southwest of Tokyo.

Evp were observed at 54 points in the southern part of the survey region. *Epilachna* ladybird beetles were generally observed in slightly and shady wet environs of coppices or the edges of hills.

Both species were observed in 14 of the same points, where the regions of two habitats overlap.

There was a wide area in the central part of the Ashigara plain, where neither species has been discovered.

The southern boundary where WTF live is determined by the mean monthly air-temperature and the mean monthly minimum air-temperature at certain points during the winter season from November to February.

The northern boundary is not fine, but it is thought to be determined by land form, microclimate and the mean monthly maximum air-temperature in the summer season.

* Looking on WTF as having evolved from *E. yasutomii* feeding on *Caulophyllum robustum* Maxim. (blue cohosh), and thus a pest insect.

15-159

THE MOST FREQUENT SPECIES AND IMPORTANCE OF THE SENN PESTS OF THE GENUS *EURYGASTER* Lap. IN YUGOSLAVIA

S. Stamenković

Institute of Field and Vegetable Crops
Faculty of Agriculture, Novi Sad, Yugoslavia

The Senn pests or Wheat bugs (Heteroptera: Pentatomidae) are widely spread insects in all cereal-growing areas of Yugoslavia. However, they are most numerous in the northeastern parts of the country, especially in Vojvodina Province. The most representative species are *Eurygaster austriaca* Schrk. and *E. maura* L. with about 70% and 29% of the population, respectively. The other species, as *E. integriceps* Put. and *E. testudinaria* Geoffr. are less frequent. Species *E. integriceps* was found only in eastern parts of the country, close to the Bulgarian border, but not in Vojvodina Province where the populations of other species were most numerous.

Beginning with 1964, when the highest population of those insects was registered in Yugoslavia, the number of adults per square meter was checked in overwintering sites. The obtained data were useful to forecast the frequency of the pests in the next year. The bugs occurred in large numbers in 1964, 1968, 1969, and 1970. They had to be sprayed on large area in those years. More recently, their larger-scale occurrences were recorded in 1973, 1988, and particularly in 1993 and 1994, but without the necessity of controlling them.

15-160

OBSERVATIONS ON INSECTS VISITING FLOWERS OF CHERIMOYA AND ATEMOYA IN SICILY

V. Caleca, G. Lo Verde, S. Ragusa, A. Sinacori, H. Tsolakis
Istituto di Entomologia agraria, Università di Palermo, Italia

As an inadequate pollination is one of the factors limiting commercial production of *Annona* spp. in many countries, observations were carried out in Sicily at two different locations, Campobello di Mazara (Trapani) and Sciacca (Agrigento), where both Cherimoya (*Annona cherimola* Mill.) and Atemoya (*A. cherimola* X *A. squamosa*) were present. All the insects visiting flowers were surveyed and most of them identified. 48.9% (female flowers) and 36.6% (male flowers) were visited by insects. The staphylinid *Paraphloeostiba gayndahensis* (35.3%), the nitidulid *Carpophilus tersus* (32.9%), a species of Thysanoptera (22.8%) and the anthocorid *Orius laevigatus* (5.1%) were the most abundant species collected in Campobello, and *Orius laevigatus* (70.5%), a species of Thysanoptera (18.8%), a species of Heteroptera (5.5%) and *Paraphloeostiba gayndahensis* (2.4%) were the most abundant species collected in Sciacca.

15-161

A STUDY ON THE FAUNA OF CITRUS GROVES OF SOUTHERN ITALY.

D. Benfatto ¹, F. Di Franco ², P. Pantini ³, L. Rodolfi ³, M. Valle ³

¹ Istituto Sperimentale per l'Agricoltura, Acireale, Italy

² Dipartimento di Biologia Animale, Università di Catania, Italy

³ Museo Civico di Storia Naturale "E. Caffi", Bergamo, Italy

Within a research programme sponsored by the "Istituto di Agricoltura" of Acireale on the study of Arthropods of citrus groves; specimens living on the soil and tree foliage were sampled during the past years from several sites in Sicily and Calabria.

This report includes the data of the specimens caught in four sites by means of pitfall traps as well as the quantitative data on the more abundant orders of Insects and the references to the works that have already been published on this sample.

The most represented orders are Coleoptera (60%) Diptera (20%) and Hymenoptera (10%), for a total of about 60.000 specimens.

A further division of the Coleoptera has shown that the Carabidae is the most represented family (59% of the specimens). However Staphylinidae (21%) and Nitidulidae (16%) are also relatively abundant. From the study of more than 22.000 Carabidae it is possible to identify 28 species of which only 4 were found in all the sites.

The heterogeneity of the coenosis was calculated by the method of Sørensen and Renkonen and resulted statistically significant. The corological data are in agreement with similar studies on the ecology of citrus groves of Northern Italy that indicate the prevalence of widely distributed species.

However, in the case examined in this study it is worth mentioning the presence of three species of the Mediterranean area and one species endemic for Italy.

15-162

Investigation of Tobacco

Insects in Central Section of Yunnan Province

Xu Shuyun

(Tobacco Institute of Yunnan Province, Yuxi, Yunnan Province, P.C.653100, PRC)

Yan Yao Wan Yu

(Cigarette Branch Company of Yuxi, Yunnan, P.C.653100, PRC)

Central Section of Yunnan Province is one of principal tobacco producing Regions. For to prevent and control of tobacco pest, requested by Yuxi Cigarette Branch Company, Yunnan Insectology Society organized twenty experts to investigate the tobacco insects of Yuxi, Jiangchuan, Tonghai, Huaining, Chengjiang, Yimen and Xingping Counties. This investigation was carried by two steps, one was for economy loss from pest and another for insects investigation. After investigation, they carried out Specimens Classification and identification in line with the standards of the Institute of Zoology of CAS (Chinese Academy of Science).

They went through more than 60 villages and 30 communities which the distance was 4000 kilometers. They were across area of 17000 hectares and collected more 7300 specimens, which included 4500 specimens inserted needle and 2800 specimens immersed. After being identified, these specimens include Arthropoda and Arachnoidea of Insecta; Gastropoda and Lamellibrachia of Mollusca; Polychaeta, Oligochaeta and Hirudinea of Annelida. They are altogether more than 100 families, 19 Orders and 7 Classes of 3 Phyla.

This activity make a thorough investigation of principal sorts of tobacco pest in Central Section of Yunnan Province, and some sorts haven't been reported in the past time. In order to check up on the distributed sorts of tobacco pest in Central Section of Yunnan Province, the investigation of the infant insects and the area not investigated will be carry out next year. Some difficult and complicated specimens are being identified, nowadays.

This investigation provided scientific basis for prevention and control of tobacco pest.

15-163

PHYTOPHAGOUS AND BENEFICIAL ARTHROPODS FOUND IN WILD GRAPEVINE, *Vitis vinifera silvestris* (Gmelin) Hegi, POPULATIONS OF THE IBERIAN PENINSULA.

R. Ocete, R. del Tío & M.A. López

Laboratorio de Zoología Aplicada. Departamento de Fisiología y Biología Animal. Facultad de Biología. Universidad de Sevilla. Avda. Reina Mercedes, 6. 41012 SEVILLA. SPAIN.

Nowadays, the wild grapevine, *Vitis vinifera silvestris* (Gmelin) Hegi, is considered a very important phylogenetic resource available for plant breeding of cultivated varieties. In spite of its significance, there is not too much information about its pests. Due to this fact, a research program was initiated in 1990 in order to obtain a check list of phytophagous and beneficial arthropods found in several populations of that dioecious subspecies of *Vitis* growing all over the Iberian Peninsula. Some of the main species cited in the report are: *Colomerus vitis* (Pagenstecher) (Acari, Eriophyidae), *Tetranychus urticae* Koch (Acari, Tetranychidae), *Typhlodromus rhenanoides* Athias-Henriot (Acari, Phytoseiidae), *Jacobyasca lybica* (De Berg) (Homoptera, Jassidae), *Bemisia tabaci* Gennadius (Homoptera, Aleyrodidae), *Arthrocnodax vitis* Rübsaamen (Diptera, Cecidomyiidae) y *Chrysoperla carnea* (Stephens) (Neuroptera, Chrysopidae).

Some considerations about high levels of resistance detected against pests and the absence of symptoms caused by phylloxera, *Daktulosphaira vitifoliae* (Fitch) (Homoptera, Phylloxeridae) are included.

15-164

DISTRIBUTION OF *DIABROTICA VIRGIFERA VIRGIFERA* LE CONTE (COLEOPTERA: CHRYSOMELIDAE) IN YUGOSLAVIAR. Sekulić¹, T. Kerešić¹, D. Čamprag¹, I. Sivčev², B. Manojlović²¹ Faculty of Agriculture, Institute for Plant Protection, Novi Sad, Yugoslavia, - ² Institute for Plant Protection & Environment, Belgrade, Yugoslavia

Diabrotica virgifera virgifera Le Conte -Western Corn Rootworm (WCR), with other *Diabrotica* species is major problem on corn in monoculture in the USA. Estimate costs of rootworm damage and control measures range up to \$1 billion annually.

In July 1992., for the first time in Europe, damage from WCR larvae was registered in Yugoslavia, near-by Belgrade International airport. It means that pest might had been transported from America by airplane, probably in 1989-1990.

Main damages cause larvae, by feeding on roots and reducing the young corn plants' ability to take up nutrients and moisture so that plants become weakened, host to diseases, and ultimately fall over ("lodging"). In Yugoslavia, medium intensity to severe damages were recorded on 0.5, 6, 60 and 75 hectares from 1992-1995 respectively. In 1995, the frequent precipitation provided more intensive regeneration of damaged root.

The adult of WCR feeds on silks and blossoms. The result of uncontrolled beetle feeding is poor pollination, incomplete ear-fill, blank kernels, open target to diseases and finally reduced yield and quality. Searching for food, adults (mostly females) migrate by flying (supported by winds) to new maize fields and occupy new areas. In this way, during 1993 and 1994, *D.v.virgifera* expanded its range of distribution in Yugoslavia up to 40-50 km (20-25 per year). In 1995 the pest was found on 20 new localities, spreading in different directions, mostly to the North.

During the summer 1995, this corn pest, new for the Europe, already had been registered in south Hungary and east Croatia too (about 160 km north and 120 km west of Belgrade).

15-165

SPATIAL DISTRIBUTION OF THE CURCULIONIDAE COMPLEX ON CULTIVATED AMARANTHS IN SOUTH AFRICA.

W.J. Weeks, C.F. van Eeden, S.vd M. Louw¹

North West Agricultural Development Institute, Potchefstroom, South Africa - 1 Department of Zoology and Entomology, University of the Orange Free State, Bloemfontein, South Africa

Cultivation of vegetable amaranth, especially on small scale, is a common practice in Africa. In South Africa, however the cultivation of amaranth is still in its infancy. Although wild growing amaranths are widely utilized by the rural population as food source. Of the insect pest complex occurring on amaranths, the weevils (Curculionidae) constitutes the single largest group, comprising of eight species belonging to two subfamilies (Curculioninae and Ceutorhynchinae). The different species occur on different parts of the plant probably occupying different niches on the same plant. Overlaps in the spatial distribution of some of the species occur. Broadly speaking the plant can be divided into three parts. The top third is infested by six species, the middle third by two species and the bottom third by only one species. Two species viz. *Neocleonus sannio* (Herbst) and *Gasteroclisus cuneiformis* (Fahraeus) were found over the whole plant and probably were opportunistic leaf feeders. The most injurious weevils were *Hypolixus haerens* (Boheman), mostly occupying the bottom third and a *Baris* species-complex occupying the top third with overlaps occurring in the middle part of the plant.

15-166

SPATIAL DISTRIBUTION OF LARVAE AND DAMAGE OF THE OBLIQUE BANDED LEAFROLLER IN APPLE ORCHARDS

C. VINCENT¹ and Y. TESSIER²

1- Centre de Recherche et de Développement en Horticulture, Agriculture et Agro-Alimentaire Canada, 430 Boul. Gouin, Saint-Jean-sur-Richelieu, Qc. CANADA J3B 3E6. 2- Department of Physics, Rutherford Bldg, McGill University, 3600 University, Montreal, Que. CANADA H3A 2T8

The oblique-banded leafroller, *Choristoneura rosaceana* Harris (Tortricidae) has become resistant to organophosphorous insecticides in late '80s. Overwintered larvae resume feeding on shoots and foliage and summer generations feed on foliage and fruit. Because many cultivars are grown in a mixed fashion, commercial orchards are heterogenous environments.

The objectives of this project were to assess 1) if there is difference in larval abundance among apple tree cultivars 2) if there was a spatial pattern in the distribution of larvae in orchards.

Geostatistics were applied to detect spatial patterns. While there were differences in larval abundance and damage among cultivars, there were no differences in spatial distribution patterns of larvae.

15-167

REGISTRATION OF THE FLIGHT ACTIVITY OF APHIDS IN MIDDLE GERMANY DURING 1985 TO 1995 WITH A 40 FEET SUCTION TRAP

E. Schliephake, K. Geißler¹, E. Karl²

Institut für Epidemiologie und Resistenz, BAZ, Aschersleben, Germany - 1 Arbeitsgruppe Aschersleben, Martin-Luther-Universität Halle-Wittenberg, Germany - 2 Aschersleben, Germany

The suction trap in Aschersleben (Sachsen-Anhalt) was taken 1985 as first suction trap of Germany in operation. It has a limit of 12,2 m and a sucking performance of 2.400 m³ air per hour. Since November 1995 it is replaced by a newer model. Geographically it is localized in an area between the EURAPHID network in the western part and the suction traps of Poland, Czechia and Hungary in the eastern part of Europe.

Till now was caught with this suction trap more than 110 000 aphids. We could determine more than 80 species from 41 genera. The majority of the caught aphids was in the family of the Aphididae (91,8 %). The remaining individuals had assigned to the families of the Drepanosiphidae (1,97 %), Lachnidae (0,47 %), Pemphigidae (3,63 %), Anoeciidae (0,87 %), Thelaxidae (0,03 %), and Adelgidae (1,23 %). The absolute number of the aphids caught every year varies naturally from year to year in dependence of the weather conditions. The consequence of long bad weather periods during the mainly flight period is low numbers of captured aphids, e. g. within the years 1987 and 1991. In the year 1992 we caught till now the highest aphid number. This high number of aphids was mainly given by the summer flight of *Metopolophium dirhodum* (WALK.).

The most frequent species in the means of 1985 to 1994 were *Rhopalosiphum padi* (L.) (32,6 %), *Brevicoryne brassicae* (L.) (22,3 %), *Metopolophium dirhodum* (12,2 %), *Hyalopterus pruni* (GEOFF.) (3,8 %), *Pemphigus* spp. ((3,3 %), the *Aphis fabae*-group (2,5 %), *Brachycaudus helichrysi* (KALT.) (2,3 %), *Sitobion avenae* (F.) (2,1 %), *Cavariella aegopodii* (SCOP.) (1,8 %), and the *Myzus persicae*-group (1,5 %). All other species represents 15,5 % of the captured aphids.

An anholocyclic overwintering of the aphids in middle Germany is only possible within mild winters. A very early flight activity in the spring of the two most essential vectors of the barley yellow dwarf virus (BYDV), *R. padi* and *S. avenae*, we could observe with the suction trap after the very mild winters of the years 1989 and 1990.

ROUTINE MONITORING OF INSECT FLIGHT AT HIGHER ALTITUDES OVER FARMLAND.

J.R. Riley, A.D. Smith, D.R. Reynolds
Natural Resources Institute Radar Unit, Malvern, UK

A significant proportion of the insect fauna migrating over agricultural land does so at high altitude (above 100 metres). This overflying population is a potential source of insect immigrants into the farmland, and it therefore appears to be worthy of monitoring. In this poster we describe how routine monitoring of high-flying insects has become an economic and practicable possibility with the advent of automatically-operating, vertical-looking radar^{1,2}.

THE EFFECTS OF PESTICIDES ON NON-PEST INSECTS IN FARMLAND

T. Çilgi
Department of Biology, University of Southampton, Southampton, United Kingdom

Pesticides may cause side-effects on non-pest insects. These effects have been relatively well-researched in short-term studies in the United Kingdom and elsewhere. To investigate effects of pesticide use at larger spatial and longer temporal scales, the UK Government (MAFF) initiated the "Boxworth" (1981-1991) and "SCARAB" (1990-1997) projects in England. This was to study the consequences of pesticide applications under more agriculturally and ecologically realistic conditions. This paper presents trends and fluctuations in arthropod numbers under contrasting pesticide regimes in the SCARAB project fields, which indicate that there is no irreversible long-term adverse effect of current pesticide use on commonly monitored insect species (i.e. Carabidae and Staphylinidae). However, examination of the timing of applications in relation to the time taken for recovery of populations indicates that repeating applications of broad-spectrum insecticides in consecutive seasons might lead to more protracted adverse effects (as occurred in the Boxworth project). In addition, there is evidence from the SCARAB project that less commonly monitored insects are more sensitive to pesticides than routinely monitored species in western Europe. Therefore, this paper also examines the relevance of current approaches in investigating the impact of pesticides on non-target insects in the arable farmland in relation to current changes in agricultural practices in western Europe.

15-169

FLIGHT MUSCLE DIMORPHISM OF ANOMALA SCHOENFELDTI OHAUS (COLEOPTERA: SCARABAEIDAE)

J.Nishigaki, A.Iwata
Faculty of Agriculture, Shizuoka University, Ohyu, Shizuoka 422, Japan

In some scarab beetles, it is known that there are two kinds of adult females in field populations, one of which have normal flight muscles like adult males as well as other type without flight muscles. Physiological and ecological significance of such flight muscle dimorphism are not well known yet. To clarify them, we compared some characters such as the number of eggs in their ovaries, the influence of larval population densities and the flight habit between the adult females with flight muscles and without flight muscles. However, we could not find any obvious differences between them. Now we are seeking after the differences of other characters of them such as the size of their eggs and the adult life spans.

15-171

INSECTS IN FARMLAND: BIODIVERSITY AND BIOINDICATORS IN MONITORING TO DETERMINE ENVIRONMENTAL IMPACTS OF AGRICULTURAL CHANGE

G.K. Frampton
Department of Biology, University of Southampton, Bassett Crescent East, Southampton, United Kingdom.

It has been estimated that over 25 thousand species of terrestrial arthropod occur in arable land in the United Kingdom. Suction sampling alone (which is specific to epigeal species) revealed the presence of over 500 species of insects in cereal fields in southern England and long-term monitoring has shown that populations of some, including those of at least 65 species of Coleoptera, have declined significantly in abundance over the last two decades. These population changes have implications not only for trophic interactions (for example, populations of insect - feeding game birds have also declined significantly) but raise important questions about which species should be monitored for detecting effects of agricultural change, given that a relatively small proportion of all those present are ever encountered in any one study. This paper utilises empirical data from ongoing large-scale insect monitoring in UK farming systems to consider the pros and cons of selecting indicator species and monitoring insect biodiversity as two approaches for assessing environmental impacts of agricultural change. Pesticide usage is used here as an example of changing agricultural practice to address the question of whether routinely monitored indicator taxa such as Carabidae and Staphylinidae are the most appropriate insects for environmental impact assessments, or whether using other bioindicator taxa could be worthwhile.

15-172

EFFECT OF DAMAGE CAUSED BY CEREAL FLIES ON DISTRIBUTION OF *APHID SITOBION AVENAE* AMONG WHEAT PLANTS AND COMBINED INJURIOUS EFFECT OF THE PESTS.E.A.Sinelnikov¹ & A.P.Golovchenko²All-Russian Institut for Plant Protection, St.-Petersburg, Russia - 1
Povolzhsky Institut for Breeding and Seed Production, Kinel, Samara district, Russia - 2

The investigation has been carried out in Kinel (central Russia) under field trial conditions. Spring wheat plants (cv.Kinelskaya 59) with main stems damaged by fly larvae (*Phorbia securis* Tiensuu and *Oscinella pusilla* Meig. in the ratio of about 1:1) were labelled at early tillering stage. Undamaged plants (both adjacent to the damaged ones and standing apart of them) were labelled at the same time. Colonization of test plants by aphid *Sitobion avenae* F. and fly *Chlorops pumilionis* Bjerk was determined as well as grain yield per plant.

Only 37.5 % of the labelled damaged plants survived by the end of vegetation period. 85.4% of them were colonized by *S.avenae*. By this reason it was quite impossible to reveal an independent impact of the fly larvae on yield. Aphid colonization of initially intact wheat plants constituted 20.8% - 25.0%; no significant influence of vicinity to damaged ones was noted. Almost all wheat plants damaged by *Ch.pumilionis* at the heading stage also were colonized by the aphids. The share of wheat plants colonized by both these pest species constituted 8.0% in comparison with 2.2% which could be expected in the case of independent distribution. The grain yield was decreased by 90.8% for survived plants damaged by *Ph.securis/O.pusilla* and *S.avenae*; 36.9% for plants colonized only by the aphid and 56.6% for combination of *S.avenae* with *Ch.pumilionis*. Compensation of yield losses at the cost of plants adjacent to damaged ones has not been confirmed. It can be concluded that the fly larvae improve the suitability of wheat as host plant for the aphid. Their combined impact on yield have to be taken into consideration.

15-174

NEZARA VIRIDULA AND OTHER SAP-SUCKING INSECTS AND THEIR NATURAL ENEMIES ON CASTOR IN ITALY

E.Conti, F.Bin, E.Ciricofolo¹

Istituto di Entomologia Agraria, Facoltà di Agraria, Università di Perugia, Perugia, Italy - 1 Istituto di Agronomia Generale e Coltivazioni Erbacee, Facoltà di Agraria, Università di Perugia, Perugia, Italy.

Castor, *Ricinus communis* (Euphorbiaceae), has been introduced into some European Countries to produce oil for industrial purposes. In 1995 field observations were started on sap-sucking insects, mainly belonging to the families Cicadellidae (Homoptera), Miridae and Pentatomidae (Heteroptera), which attack this crop in Central Italy and other Mediterranean Countries.

Injuries to castor, caused by the cicadellids *Empoasca* spp. (leaf chlorosis and necrosis), the mirids *Lygus* spp. (apical meristem devitalization, leaf tattering) and the pentatomid *N. viridula* (flower and capsule shedding, seed piercing), were observed in several experimental fields, but percentages of damaged plants were generally low.

However, *N. viridula* seems to be a serious threat to the castor crop. Potential damage by this pentatomid was assessed in relation to crop stage and insect density by encaging the primary raceme of 2 castor varieties, with spined and spineless capsules respectively. Total shedding significantly increased (up to 100%) when *N. viridula* was introduced at flowering or at beginning of capsule development, while it was similar to the control (20-45%) when bugs were introduced at later stages of capsule development. As a consequence of shedding, the number of capsules and the seed weight per raceme decreased, although compensation occurred in one case, thus resulting in the production of heavier seeds. Feeding punctures by *N. viridula* were observed on seeds of both varieties, but percentages of pierced seeds were lower in spined capsules.

Natural control was exerted by several predators, adult parasitoids, and egg parasitoids. The most common and effective species were *Trissolcus basalis* (Scelionidae), reared from eggs of *N. viridula*, and *Anagrus atomus* (Mymaridae), from *Empoasca* spp.

15-173

TOBACCO FLEA BEETLE, *Epithrix hirtipennis* Melsh. (Coleoptera;Chrysomelidae), A NEW TOBACCO PEST IN TÜRKİYE F.TURANLI, Ş.KISMALI

Department of Entomology, Faculty of Agriculture, University of Ege, İzmir, Türkiye

The tobacco plants are attacked by so many pests in Türkiye. *Epithrix hirtipennis* was detected for the first time in tobacco growing areas of İzmir in 1993. In this year, an outbreak of this insect was observed. Due to the severe damage, some tobacco growers have left the damaged tobacco plants in the field. The distribution, host plants and population density of tobacco flea beetle were investigated in 1994-1995. It is a widespread species which occurs in all over the tobacco growing areas of İzmir. The adults feed on epidermis of leaves and make many holes. This damage decreases both quality and quantity of leaves. The adults and the holes on the leaves were regularly counted. It has been found that maximum 340 holes on a normal sized leaf and maximum 50 adult/per plant that has 9-10 leaves. It is observed that the bottom leaves more damaged than the upper ones.

15-175

HAZEL-NUTS "CIMICIATO" ANALYSIS AND POPULATION DYNAMICS OF THE HETEROPTERA AND RHYNCHOTA FAUNA IN HAZEL-GROVES IN THE VITERBO AREA (LAZIO, ITALY); RESULTS OF THE 1993-94 RESEARCH PERIOD.

B.Paparatti¹, L.Tanga², P.Girgenti³

- 1 Dipartimento di Protezione delle Piante, Università della Tuscia, Viterbo, Italy. - 2 Regione Lazio, Settore Decentrato Agricoltura, Viterbo, Italy. - 3 Regione Lazio, Sezione agricola zonale di Civita Castellana, Viterbo, Italy.

In this paper results are reported of a two-year research conducted to assess the "cimiciato" damage entity by some *Rhynchota Heteroptera* in hazel-groves of the Viterbo area.

Studies on the population dynamics showed that the following damaging species are present: *Gonocerus acuteangulatus* (Goeze), *Nezara viridula* L., *Piezodorus lituratus* (F.), *Palomena prasina* L. and *Raphigaster nebulosa* (Poda).

In both years, the most frequent species was *G. acuteangulatus*; in particular, in 1993 captures for this species accounted by 60.3% of the whole of damaging *Rhynchota Heteroptera* captured; in 1994, this percentage was of 85.9%.

Damage evaluation consisted of a visual and organoleptic examen of nuts, which showed that really damaged nuts were very few, maximum 2.4 % of total in 1993.

Our results lead to suggest that the frequency of chemical treatments, which are systematically applied in the area, could be consistently reduced.

15-176

SIGNIFICANCE OF THE CEREAL APHIDS SALIVA

A.Urbanska, B.Leszczynski
Department of Biochemistry, Agriculture & Pedagogic University,
ul. B.Prusa 12, Siedlce, Poland.

There was conclusively confirmed that both grain aphid, *Sitobion avenae* (Fabr.) and bird cherry-oat aphid *Rhopalosiphum padi* (L.) belong to serious cereal pests. Therefore multiple aspects of the natural aphid-host plant interactions were considered. In general the present study concerns the aphids salivary enzymes in the chemical interactions. The following aspects have been investigated: 1) presence of some enzymes in the grain aphid and bird cherry-oat aphid salivary secretions; 2) sequence of secretion of the gelling (stylet sheath) and watery saliva in plant tissues; 3) path of aphid stylet across plant tissues; 4) damages to the host-plants (tracks) caused by the aphids penetrations. The saliva of the studied aphids contains both middle lamella and cell walls - breakdowning enzymes (pectin hydrolases) and digesting enzymes (carbohydrases and proteinases). There were no qualitative differences between the enzymes of the studied aphids whereas the quantitative differences were recorded. *S. avenae* showed higher activity of α - amylase trypsin, carboxypeptidase A and leucine aminopeptidase; on the contrary *R. padi* had higher activity of polygalacturonase, pectinesterase, α -, β - glucosidase and invertase. The gelling saliva was secreted at first while the path of the stylets through the epidermis and intermediate tissues, instead the watery saliva was injected into sieve elements. *S. avenae* caused irregular local damages (interruption of cell walls and whole protoplasts) in the epidermis and in the parenchyma particularly; while *R. padi* hydrolysed also the thick cell walls of sclerenchyma in order to reach phloem. The prescnee of peroxidase and polyphenol oxidase in the saliva of the aphids proves their ability to defend themselves against wide range of cereal phenolies.

15-178

EFFECTS OF DUNG BURIAL ACTIVITY OF
(*DIGITONTHIOPHAGUS* *GAZELLA* (F.) (COLEOPTERA:
SCARABAEIDAE) ON NUTRIENT CYCLE

N.Yamashita, N.Yoshida
Department of Animal Production, Tohoku National Agricultural
Experiment Station, Morioka, Japan
To assess transportation of total carbon (C) and total nitrogen (N) from cow dung to the soil by the dung beetle, we introduced the beetles into containers with fresh cow dung on soil having a depth of 20cm. After the four weeks, we measured contents of C and N in residual dung, the soil (0-2cm and 18-20cm in depth) and dung balls. The balls were buried in the lower layer of soil by dung beetles. 33-61% of C and 31-76% of N contaient in the initial dung were transported to the dung balls with huriar activity of beetles, while C and N contained the dung did not moved into lower layer without theirs activity. To search transportation of dung material to plants bodies, we introduced the beetles into containers with fresh dung marked by RbCl on the soil having a depth of 20cm and planted orchardgrass seedlings in them. After six months of planting, we measured the biomass of orchardgrass and the concentration of Rb in bodies of orchardgrass, residual dung, soil and dung balls by atomic absorption spectrophotometer. The biomass and the concentration of Rb in bodies of orchardgrass with burial activity of beetles were significantly higher than those without the burial activity. These results suggested that the dung burial activity of the beetles promoted the nutrient cycle occurring among dung, soil and orchardgrass.

15-177

DENSITY YIELD RELATIONSHIPS FOR
COLORADO POTATO BEETLE, *Leptinotarsa*
decemlineata (SAY), (COLEOPTERA,
CHRYSEMELIDAE) ADULTS AND LARVAE ON
POTATOES

N.J. Bostanian & G. Mailloux¹
Agriculture & Agri-Food Canada, Horticultural Research
& Development Centre, St-Jean-sur-Richelieu, Quebec,
Canada 1) Ministère de l'Agriculture, des Pêcheries et de
l'Alimentation, Service de Phytotechnie de St-Bruno, St-
Bruno de Montarville, Québec, Canada

A three year study showed that the relationship between the density of Colorado potato beetle overwintering spring adults and spring larvae vis-à-vis potato yield can be described by 2 straight lines. A damage boundary of 5.8 spring adults per plant was established. There was not appreciable seasonal overlapping between adults and young larvae in the field. For summer adults, an action threshold of 10 beetles per plant is proposed. Regarding spring larvae, a damage boundary of 12 larvae per stalk was established. Depending on growing conditions, action thresholds of 4, 6 and 8 larvae per stalk are proposed.

15-179

THE EFFECT OF SIMULATED RAINFALL ON
PSEUDOCOCCUS CITRICULUS GREEN (HOMOPTERA:
PSEUDOCOCCIDAE)

Tomonori Arai
Okitsu Branch, Fruit Tree Research Station, Okitsu, Shimizu,
Shizuoka, Japan
Pseudococcus citriculus is a pest of citrus in Japan. It does not usually cause serious problems in citrus orchard, but often occurs in greenhouses, reducing the value of the fruits by excreting honeydew, in which the sooty mold fungi grows. At the experimental orchards, the first generation of this pest occurred from late May to June, rainy season in Japan, and it was observed that the rainfall decreased this generation's survival rate. Potted satsuma mandarin trees infested with *P. citriculus* were exposed to simulated rainfalls delivered at rates of 5, 10, 20 and 40mm/h with and without wind at a rate of 2m/s for 30, 60, 90 and 120 minutes. Rainfalls with wind tended to wash out more *P. citriculus* individuals from the plants than those rainfalls without wind. Rainfalls of longer durations also tended to be more efficient on washing them out. Furthermore, first instar was more vulnerable to simulated rainfall than the other developmental stages. From these result, rainfall in the orchard consists in an important mortality factor to *P. citriculus*.

15-180

RESISTANCE TO BIRD CHERRY-OAT APHID AND CEREAL LEAF BEETLE IN WINTER WHEAT

M. Papp

Cereal Research Institute, Szeged, Hungary

Resistance tests based on infestation by bird cherry-oat aphid (*Rhopalosiphum padi* L.) and estimation of leaf-feeding damage by cereal leaf beetle (*Oulema melanopus* L.) were conducted on 18 and 26 winter wheat varieties, respectively, in 1987-1995.

Grain yield and thousand-kernel mass were measured in infested and non-infested control plots in cages covered by insect nets. Highly significant differences were found between genotypes in infestation by bird cherry-oat aphid and feeding damage by cereal leaf beetle. Infestation by bird cherry-oat aphid varied between 20% ('GK Zombor') and 63% ('GK Lili'). The most resistant variety, 'Downy' had 20% leaf-feeding damage by cereal leaf beetle and most susceptible, 'GK Kincső' 72%. Complex effect of bird cherry-oat aphid and cereal leaf beetle was observed in 1987-1990. Yield of the most tolerant genotype ('GK Korány') was reduced by 33%, while the thousand-kernel mass was reduced only 27%. The maximum losses were 67% in yield and 54% in thousand-kernel mass. A close correlation was found between infestation severity by bird cherry-oat aphid and yield reduction ($r = 0.78$, $P < 0.001$). Principal components and multiple regression analyses were performed to determine the relationships among tested characteristics and to quantify the effect of some of them.

In 1991-1995, when cereal leaf beetle attacked alone, the most sensitive genotype, 'Mv 13' suffered 41% loss in yield, while the most resistant one, 'Downy' 18%. The correlation between feeding damage by cereal leaf beetle and yield reduction was medium ($r = 0.66$, $P < 0.001$).

Trichome length of the flag leaf exhibited a significant correlation with feeding damage by cereal leaf beetle ($r = -0.80$, $P < 0.001$).

This work was supported by OTKA grant No. T6045.

15-182

EFFECT OF LEAF PUBESCENCE IN RESISTANCE OF SOYBEAN TO THE FALSE MELON BEETLE, *ATRACHYA MENETRIESI* FALDERMANN.

Hiroo Kanno

Tohoku National Agricultural Experiment Station, Yotsuya, Omagari, Akita 014-01, Japan

The effect of pubescence in resistance of soybean to the false melon beetle (FMB), *Atrachya menetriesi* Faldermann, was investigated in the field and laboratory using genotypes of soybean with varying levels of pubescence of leaves. There was a negative co-relationship between trichome density on leaves and levels of leaf damage caused by feeding of FMB adult. Most of the genotypes which exhibited high level of resistance to FMB were highly pubescent. There was clear difference on damage level of leaves between high pubescent variety, T-207, and glabrous variety, Mumoh-hadaka, by adult feeding in dual-choice assays. The differences of damage level of leaves between T-207 and Mumoh-hadaka did not change even after reciprocal application of methanol extracts and squeezed plant sap of both varieties on the leaf surface. It might indicate that this phenomenon does not concern with chemicals. Furthermore, the beetles attacked intensively to half parts of leaf which were removed trichomes in pubescent variety, T-207. The normal type of trichome only confirmed on soybean leaf by SEM observation. There was no glandular trichome which produce some kinds of substance. According to these results, trichomes might act as mechanical barrier to feeding behavior of the beetles. The pubescence therefore indicates to be an important factor associated with resistance of soybean to FMB.

15-181

INITIATIVES TO MANAGE THE WESTERN CORN ROOTWORM

(*CLEOPTERA:CHRYSMELIDAE*): AN OLD PEST FOR AMERICA BUT A NEW PEST FOR EUROPE

B.D. Barry, B.E. Hibbard

United States Department of Agriculture, Agricultural Research Service and Department of Entomology, University of Missouri, Columbia, Missouri 65211

The western corn rootworm, *Diabrotica virgifera virgifera* LeConte, is an economic pest of maize, *Zea mays*, in the United States and annually is responsible for over one billion dollars in loss and management costs. This insect is relatively new in Europe, and it is a potential pest there. Our research is focused on insect plant resistance. We have identified antibiosis in exotic maize germplasm from Mexico and South America. Other sources of resistance have been identified in germplasm of relatives of maize: *Tripsacum*, teosinte, *Zea perennis*, and *Z. diploperennis*. The level of resistance and cultivar adaptability in the various germplasms is currently being enhanced by back crossing and recurrent selection.

15-183

INTENSITY ATTACK OF EUROPEAN CORN BORER (*PYRALIDAE: OSTRINIA NUBILALIS* Hübner) ON CORN IN SLAVONIA (CROATIA)

M. Ivezić, E. Raspudić, D. Horvat

University of J. J. Strossmayer in Osijek, Faculty of Agriculture, POB 117, 31000 Osijek, Trg Sv. Trojstva 3, Croatia

European corn borer (*Ostrinia nubilalis* Hübner) is a very important economic pest on corn in northerneast part of Croatia. The intensity attack is very high but its control is very poor.

In Slavonia region, appearance of European corn borer on corn was being investigated from 1985 to 1995. Every year about 50 hybrids of corn, FAO groups 100 to 700 were investigated. The dissection of plants was done during the autumn prior the harvest. Measured factors were as follows: number of holes, number of caterpillars and their position as: in ear, above the ear and below the ear, per plant.

All hybrids are attacked by this pest every year, and the highest intensity was at FAO groups 400, 500 and 600. The lowest attack was 17,05% and the highest was 98,44% (average 56,61%). The highest number of holes and caterpillars was below the ear (45,30%, 61,62%), above the ear (28,91%, 26,26%), and in the ear (25,78%, 12,12%).

Only agrotechnical measures are provided among integrated pest management. The last few years we tried to control European corn borer by biological insecticides on the base of *Bacillus thuringiensis* Berlinier. The attack has been reduced from 9 to 42%. The investigation is very important and indicates the possibilities of biological control as one measure of integrated pest management in corn production.

15-184

ENHANCING OVERWINTERING MORTALITY OF COLORADO POTATO BEETLE *LEPTINOTARSA DECEMLINEATA*

A. Mateeva

Department of Entomology, Higher Institute of Agriculture, Plovdiv, Bulgaria.

Colorado potato beetle *Leptinotarsa decemlineata* is one of the most important pest by different kinds of fam. Solanacea. Parallel with the chemical means for insect pest control alternative plant protection solution have been proposed in our country—biopreparats, bioagents, plant extracts and different agroecological activities. The possibility for utilization the agroecological activities related to diapause ecological nature has been investigated as phenomenon by Colorado potato beetle.

The investigations have been carried out in four potato field with natural barriers from bushes, rocks and fodder agro.

In all investigated field except those of the control, potato enticing strips have been planted later and in some of them a has been used. On the basis of the so carried out investigation it has been established that the enticing strips planted with subsequent potatoes on the potato fields and fodder agro can attract the larger part of the population. The complementary food quantity makes longer the beetles' active life and it leads to discordance between the photoperiod and the related with him mechanism of the specimen endocrine system. As a result from all agricultural activities the hibernate mortality rate reach to 86% in separate fields.

15-186

NATURAL REGULATION THE INSECT-PESTS OF SPRING-RAPE IN NORD-WEST RUSSIA

Malyshev D.S., Chukov S.N.

Biological Research Institute of St.-Petersburg University, Russia

One of the question in the history of agriculture is high crops rape (*Brassica oleifera*) in Russia of the second half XIX of a century - from 16 up to 32 centners on hectare on the significant area (350 thousand of hectares). Presently 80-e years on these soils crop has lower on the order below. Partly it was called soil degradation, but one of reasons is losses of a crop from more than 100 species insect-pests. Therefore, in modern technology rape culture it is provided up to 5 - 7 insecticide treatment. Our researches have revealed two peculiarities, which enable rape cultivation without application insecticides. This promoted first of all late autumn seeding for 5-7 days before occurrence heavy snow. Due to natural seeds vernalized and plant growth in conditions extended day the crop was formed in super early terms. Thus the mass exit of main crop destroying insects occurred late formation the most favourable for their stage of development rape. In this case the term mature growth of rape appears shorter, than term of development it pests. In XX a century because of refusal from grass-arable rotation the favourable conditions for distribution crucifer weeds were created. With it dynamics of the rape pests insects is closely connected. Besides at present time the late autumn seeding is impossible, because sharp reception of long-term forecast of the occurrence steady snow cower now is practically absent.

15-185

THE ROLE OF JAPANESE BEETLES IN THE BIRD STRIKE HAZARD AT AN AIRPORT IN EASTERN UNITED STATES

D. F. Caccamise, and L. M. Reed

Department of Entomology, Rutgers University, New Brunswick, N.J. 08903, USA

Damage related to the feeding habits of Japanese Beetles (*Popillia japonica*) is well known, yet serious problems also occur when adult beetles attract insectivorous birds to airport habitats. Many coastal airports are periodically invaded by large numbers of Laughing Gulls resulting in severe bird strike hazards that can seriously endanger aircraft and personnel. At times the problems are so severe that air operations must be curtailed resulting in significant economic and social costs. We studied the relationships between Japanese beetle populations and Laughing Gulls to develop management strategies compatible with the unique requirements of an airport environment. We worked at Atlantic City International Airport (ACY), a large (2,225 ha) urban airport serving the needs of commercial, government and private air traffic. It is situated 8 k from the Atlantic coast on the interface between an urban zone and pine-oak forests. We monitored populations of adult Japanese beetles and Laughing Gulls over four seasons. Each year the increase in gulls closely followed the increases in adult beetles. Gull numbers peaked at ACY when gulls were feeding young in colonies located 10 k away in coastal salt marshes. Diets of gulls showed heavy reliance on Japanese beetles as food for developing young in colonies. Since gulls came to ACY to obtain food for their young, we undertook management of the gull problem by controlling the adult Japanese beetles. Our management strategy was based on removal of the vegetation used as food by adult beetles (airport regulations precluded use of chemical agents). Pilot studies conducted over 3 years showed significantly lower numbers of beetles in treated areas. Determination of whether fewer beetles reduces gull numbers awaits implementation of our experimental approach over the entire airport.

15-187

ACTIVE SPACE OF A HIGH DOSE PHEROMONE POINT SOURCE MEASURED BY FIELD ELECTROANTENNOGRAM AND DISRUPTION OF TRAPPING IN AN APPLE ORCHARD

D.M. Suckling and G. Karg

HortResearch, Lincoln, New Zealand,

The active space of a single pheromone point source designed for mating disruption was measured by pheromone trapping and electroantennogram recordings in an apple orchard. One hundred polyethylene dispensers were applied to a single central tree, and pheromone traps baited with high dose lures (1 mg) were placed in four radiating transects along or across rows. Catches were compared with a similar layout in an untreated block.

The prevailing northeasterly wind distorted the active space. The single point source prevented any trap catch up to 13.5 m downwind, compared to 4.5 m upwind, or to either side. The electroantennogram recordings, made at distances of 5, 10, 20, 30 and 40 m downwind indicated that pheromone bursts were sometimes detectable 40 m downwind.

This experiment suggests that deployment of dispensers may need to take distortions in the active space from a prevailing wind into account. Less distance between dispensers may be required parallel to the wind direction, compared with deployment orthogonal to the wind.

15-188

MULTI-BAITED SEX PHEROMONE TRAPS FOR *COSSUS COSSUS* AND *ZEUZERA PYRINA* MALESS. Maini, P. Riolo, R. Ferrari¹, F. Galgano¹, S. Nardi², F. Rama³

Dipartimento di Biotecnologie Agrarie ed Ambientali, Università di Ancona, Italy - 1 Centro Agricoltura Ambiente, Crevalcore, Bologna, Italy - 2 ESAM, Ancona, Italy - 3 Isagro Ricerche s.r.l., Novara, Italy

In Italy, the two species of Lepidoptera Cossidae - European goat moth (EGM) *Cossus cossus* (L.) and Leopard moth (LM) *Zeuzera pyrina* (L.) - can infest both fruit orchards as well as other trees. EGM and LM larvae can live together on the same tree plant, burrowing galleries in trunks and branches. The chemical control is difficult and, in case of insecticide sprays, the ecological impact could be very high, especially in reforestation areas. Recently, several trials demonstrated the success of the mass trapping of EGM and LM males. Experiments were conducted to evaluate capture efficiency in relation to: 1) different types of traps (funnel with or without different kinds of baffles); 2) position of traps in the tree canopy; 3) effect of multi-baited traps *i.e.*: EGM sex pheromone dispenser added to LM dispenser in one trap compared to single-baited sex pheromone trap (standard trap). The EGM sex pheromone dispenser was a bimatrix loaded with 8 mg Z512Ac (outer rubber caps) + 4 mg Z310Ac (inner rubber septum protected by a nylon sheath) and the LM dispenser was a polyethylene cap with 9.5 mg E2Z13-18Ac + 0.5 mg E3Z13-18Ac + 0.5 mg Z2Z13-18Ac. Multifactorial analysis demonstrated that: 1) there was no difference in male captures of both species related to type of trap; 2) traps located over the tree canopy were the most efficient for EGM and LM male captures; 3) the number of males of the two Cossidae species trapped in multi-traps was not different with respect to standard traps. To our best knowledge, this is the first report showing that two moth species can be attracted simultaneously in open field at the same trap with no reduction in efficiency. Multi-baited traps are also used to monitor stored-product Phycitinae moths. However, in other Lepidoptera species, multi-baiting is usually less attractive as compared to a normal, selective and specific lure. Multi-baiting traps can be recommended either for mass trapping or survey applications for EGM and LM.

15-190

NOCTUA PRONUBA AND SPILOSOMA LUTEUM MALES ATTRACTION TO VIRGIN FEMALES AND SYNTHETIC SEX PHEROMONE OF HYPHANTRIA CUNEA

S. Maini, D. Belfiori

Dipartimento di Biotecnologie Agrarie ed Ambientali, Università di Ancona, Italy

The Fall web-worm moth (FWW) *Hyphantria cunea* Drury (Lepidoptera Arctiidae), was introduced into Italy in 1977. Studies of FWW sex pheromone trapping demonstrate the possibility of surveying its spread in our country. In 1993, '94 and '95, sticky traps baited either with synthetic sex pheromone (polyethylene cap loaded with 1 mg of: Z9, Z12, Z15 - Octadecatrienal; Z3, Z6 - 9S, 10R - Epoxyheneicosadien; 1, Z3, Z6 - 9S, 10R - Epoxyheneicosatrien) or 2-3 FWW virgin females were attractive not only to FWW males but also to the Buffer ermine (BE) *Spilosoma luteum* Hufn. (Lepidoptera Arctiidae) and the Large or European yellow underwing (EYU) *Noctua pronuba* L. (Lepidoptera Noctuidae) males. These moths are not yet included in the Am *et al.* pherolist updated to Nov. 17/1995. In unbaited traps, no males were caught. The lack of selectivity generally occurs when the bait is a blend of synthetic chemical components rather than natural bait: *i.e.* virgin females and/or sex pheromone extracted from females. This phenomenon might be explained by the fact that FWW represent an exotic species. Both BE and EYU males were caught by either natural or synthetic baits. The average number of males caught per season in each trap was about 20 for BE and EYU. *S. luteum* is a bivoltine polyphagous species harmless to crops while *N. pronuba* is a pest in several cultivated plants. The life cycle of EYU may be mono or bivoltine. In 1979, *N. pronuba* from Europe was introduced into Canada and in 1985 in USA. Therefore, a survey using traps baited with FWW sex pheromones can be helpful in detecting the spread of EYU to new areas. Further efforts are needed in order to know more about the chemical communication system of these moth species such as the cross attraction and the chemical identification of the sex pheromone components.

15-189

THE ROLE OF PHEROMONES AND AN INSECT GROWTH REGULANT IN THE MANAGEMENT OF *SYNANTHEDON TIPULIFORMIS* (CLERK) (LEPIDOPTERA: AGERIIDAE).

R J Hardy

Specialist Agricultural Services Pty Ltd
Sorell, Tasmania, Australia

A large scale, replicated field trial investigated the value of pheromones to disrupt the mating of the *Synanthedon tipuliformis* (Clerk). It involved seven blackcurrant plantations, covering 80 hectares divided into twenty two plots. It established the superior efficacy of (E,Z)-2, 13 octadecadien-1-ol acetate (known as E, Z2, 13-18:OAc), and referred to as the "Australian blend", over the binary mixture of (E,Z)-2, 13 octadecadien-1-ol acetate (known as E, Z2, 13-18:OAc) and (E,Z)-3, 13 octadecadien-1-ol acetate (known as E, Z3, 13-18:OAc), and known as the "New Zealand blend". The trial demonstrated an optimum pheromone straw density of 250 straws per hectare except where the pest population exceeded 1 larvae per metre of stem (in mid winter) and 500 straws per hectare were required. Straws were placed evenly except for concentrations at the upwind side of the plantations, assuming the prevailing north westerly winds would have greatest impact on mating disruption, but it was found the impact of sea breezes late on hot days was more important. The insect growth regulant fenoxycarb was found to be efficacious in the control of the pest and could be used to complement the impact of pheromones where the pest population was high. It also offers an alternative means of control where pheromones cannot be used and prospects for the control of other *Synanthedon* species.

15-191

FIELD OBSERVATIONS ON SEXUAL ATTRACTANT OF *PHYLLOCNISTIS CITRELLA* STANTON: (7Z,11Z)-7,11-HEXADECADIAL

S. Ortu

Istituto di Entomologia agraria, Università di Sassari, Italy

Considering the importance that pheromone traps can have in integrated control of *Phyllocnistis citrella* Stainton specific observations were carried out in the field using traps baited with 1 mg of sexual attractant (7Z,11Z)-7,11-Hexadecadienal contained in rubber capsules or in small polyethylene vials. Pheromone trap captures were compared to those of the chromotropic traps in lemon-yellow plexiglas. The pheromone baited traps captured a greater number of individuals than the chromotropic traps (14.0 adults/trap/week in traps baited with pheromone in rubber capsules and 10.7 in those baited with pheromone in plexiglas vials against 5.8 in the chromotropic traps).

The adults captured in the pheromone traps were observed under the microscope in order to determine the sex by observing the genitalia. Only 45.3% of the captured individuals were male. The attraction of both sexes to the same substance raises serious doubts as to whether it is the sexual pheromone.

15-192

IDENTIFICATION OF THE SEX PHEROMONE
OF THE LOOPER MOTH *Ctenoplosia albostrata*
(Lepidoptera: Noctuidae)

T. Hata^{*1}, H. Sugie^{*2}

*1 National Institute of Sericultural
and Entomological Science
1-2 Owashi Tsukuba, Ibaraki 305, JAPAN

*2 National Institute of
Agro-Environmental Sciences
3-1-1 Kannon-dai Tsukuba, Ibaraki 305, JAPAN

The looper moth *Ctenoplosia albostrata* is one of the pests of chrysanthemum in Japan. To control this insect, we investigated the sex pheromone. Larvae were collected from October to December in Tsukuba and reared on leaves and an artificial diet for successive generations under 16L-8D. To isolate and identify the female sex pheromone, their abdominal tips were collected at different times of day and extracted with hexane for 30 min. The extracts were analyzed by GC-MS and GC-EAD. Then it is shown that the amount of the pheromone had a maximum peak at 3 hours after light-off and the main component is (Z)-7-dodecenyl acetate which is known as a common sex pheromone component in PLUSIINAE.

15-194

APPLICATION OF MATING DISRUPTION TECHNIQUE TO CONTROL THE
GRAPE MOTH *LOBESIA BOTRANA* (DEN. AND SCHIFF.) IN TUSCANY

B. Bagnoli, D. Goggioli

Istituto Sperimentale per la Zoologia Agraria, Firenze, Italy

Between 1991 and 1994 the mating disruption technique (MDT) was applied to control *Lobesia botrana* (Den. and Schiff.) (Tortricidae) on a typical Sangiovese cv vineyard in the Chianti region (Tuscany). A 4 ha area was treated in 1991, which was extended to 8 in 1992, to 10 in 1993 and to 12 in 1994. Double-bulb shaped BASF dispensers containing 495 mg (1991), 240 mg (1992), 220 mg (1993) and 240 mg (1994) of the main component of the sexual pheromone of *L. botrana*, E7,Z9-12:Ac, were distributed in the vineyard at a density of 500-600/ha, before the beginning of the second flight to control both carpophagous generations. In 1991 and 1992 chemical insecticide treatments were applied to limit the first generation in order to reduce the density of the adult population.

Effectiveness of the MDT was evaluated by comparing the number of male captures per pheromone trap, the number of larvae per bunch and the number of damaged grapes per bunch recorded in four situations: the central areas of the pheromone treated vineyard (CPTV), the border areas of the pheromone treated vineyard (BPTV), the insecticide treated vineyard (ITV) and the untreated vineyard (UV).

In the pheromone treated vineyard the male captures were always highly limited; however, these were totally absent during the second and third flight only in CPTV in 1992 and 1993. In each of the four years in CPTV the mean number of larvae per bunch was 0.06, 0.17, 0.05, 0.17 for the second generation and 0.52, 0.24, 0.00, 0.69 for the third. In UV the corresponding values were 2.40, 1.37, 0.23, 0.66 for the second generation and 5.48, 3.12, 0.04, 3.18 for the third. From statistical analysis larval infestation in CPTV was always significantly lower than in UV except for the third generation in 1993 when the population density of *L. botrana* reached extremely low levels everywhere. The percentage effectiveness of MDT varied between 74.2% and 97.5%.

In 1991, 1992 and 1993 larval infestation in CPTV was statistically not different from or inferior to the one in ITV. The same result was obtained in 1994 second generation, while in the third the mean number of larvae per bunch was much higher in CPTV (0.69 vs. 0.24). Larval infestation in BPTV was always and in some cases significantly higher than in CPTV.

On the whole the MDT showed positive results when considering percentage effectiveness in comparison with the untreated control. However, this technique was not able to limit larval infestation sufficiently, particularly in the case of the third generation; consequently it is not yet suitable for vineyards in the Chianti region.

15-193

EUROPEAN CORN BORER MONITORING IN SWEET CORN:
SEX PHEROMONE AND PHENYLACETALDEHYDE MULTI-
BAITED TRAPS

S. Maini, G. Burgio¹

Dipartimento di Biotecnologie Agrarie ed Ambientali, Università di
Aucona, Italy - I Istituto di Entomologia 'G. Grandi', Università di
Bologna, Italy

Ostrinia nubilalis (Hb.) (Lepidoptera Pyralidae) the European corn borer (ECB) can be monitored using different sampling techniques: sweeping net, egg masses scouting, light and sex pheromone traps, etc. However, some of these samplings are either time-consuming or not really related to the subsequent larval damage. Intraspecific pheromonal variability in ECB may produce low correlation between the number of males caught and corn infestation. In protected sweet pepper, the possibility of monitoring ECB infestation has already been investigated using cone traps baited with sex pheromone and Phenylacetaldehyde (PAA) (multi-baited traps). PAA is a semiochemical that attracts ECB males and females. In trials carried out in sweet pepper, the average number of females caught showed a significant correlation with fruit damage. In sweet corn, trapping experiments were conducted over a two year period with two kinds of cone traps (XLa, XLb) set up at the borders of corn fields. ECB attacks of first and second generation larvae were evaluated in the corn ears using a damage index (DI). The sex pheromone bait was a rubber stopper with 0.1 mg of a blend of: (97:3) E:Z-11-14Ac. In conjunction, the PAA bait (100 mg in a felt fibre dispenser) was added to the rubber stopper. A correlation was found between the number of females caught per trap and DI ($r=0.70$ for XLa and $r=0.60$ for XLb trap). On the contrary, the number of males caught per trap, either with XLa or XLb, were not correlated to DI. A linear model of multiple correlation fitted to the data of simultaneous captures of males and females showed that the coefficients were not as high as compared to the simple correlation. The correlation coefficients obtained by fitting a curvilinear response surface were higher (i.e. $r=0.76$ in case of XLb trap) thus indicating that the simultaneous counting of males and females in cone traps can be an efficient monitoring tool.

15-195

MONITORING THE LEAF ROLLER, *Phtheochroa cranaodes* (M.)
(LEPIDOPTERA: TORTRICIDAE) BY NATURAL AND SYNTHETIC
SEX PHEROMONE.

A.E. Eiras¹, P. Witzgall², C.R. Unelius³, A. Kovaleski⁴, E.F. Vilela⁵

¹Universidade Estadual do Norte Fluminense, Campos, Brazil; ²Swedish
University of Agricultural Sciences, Alnarp, Sweden, ³Royal Institute of
Technology, Stockholm, Sweden; ⁴CNPV/EMBRAPA, Vacaria, Brazil;

⁵Universidade Federal de Viçosa, Viçosa, Brazil

The leaf roller, *Phtheochroa cranaodes* (Meyrick), is the most important lepidopteran pest of apple orchards in southern of Brazil. The damage occurs when the larvae feed on the fruit skin, reducing its commercial value. Larvae shelter in the leaves and fruits thus their control by most insecticides become very difficult. A monitoring system by natural sex pheromone (virgin caged females) has been used with some limitations, a problem that could be eliminated through its replacement by a synthetic sex pheromone. The main component of the sex pheromone produced by *P. cranaodes* female was isolated and identified as dodecadienyl acetate, based on chemical analysis and eletroantennogram assays. Field trapping revealed that the synthetic sex pheromone was as efficient as caged virgin female and it lasted for more than 9 weeks. Therefore, the results suggest that synthetic sex pheromone can replace the caged virgin female for monitoring *P. cranaodes* population in apple orchards.

15-196

TRITERPEN, AMYRIN AND AMYRIN ACETATES IN MULBERRY TREE AS FEEDING STIMULANTS OF THE YELLOW-SPOTTED LONGICORN BEETLE, *PSACOTHEA HILARIS* (PASCOE)(CERAMBYCIDAE: COLEOPTERA)

H. Honda, M. Miyazawa¹, K. Sugino and T. Yoneda¹
Institute of Agriculture and Forestry, University of Tsukuba, Tsukuba, Ibaraki 305, Japan, 1- Faculty of Science & Engineering, Kinki University, Higashiosaka 877, Japan

The yellow-spotted longicorn beetles are a serious pest of Moraceae trees including *Morus* spp. and *Ficus* spp. in Japan. Recently, an infectious *Beauveria brongniartii* is developing as a biological control agent of this pest, and some semiochemicals, feeding stimulants or attractants from their host plants are requested for enhancing infection by this fungus. *n*-Hexane extracts of mulberry bark showed strong stimulation of feeding activity in the beetles. The active extracts were further fractionated and purified with silicagel CC, TLC and HPLC. By GC-MS, ¹³C-NMR analyses, four triterpens, α -amyrin, β -amyrin, α -amyrin acetate and β -amyrin acetate were identified as main components of active fractions. The fractions including these triterpens also served as a swallowing factor in feeding. Ursonic acid and oleanolic acid also induced significant feeding responses of the beetles.

15-198

Difference in host preference of *Epilachna admirabilis* (Coleoptera: Coccinellidae) among certain Cucurbitaceae

M. Abe, K. Matsuda, Y. Tamaki

Faculty of Agriculture, Tohoku University, Aoba-ku, Sendai, 981 Japan

Epilachna admirabilis Crotch is a phytophagous lady beetle which feeds on cucurbitaceous plants such as the genera *Trichosanthes*, *Melothria* and *Gynostemma*. *Gynostemma pentaphylla*, one of the host plants, was classified as strain 1 to 3 based on collected areas and was used for feeding and rearing tests.

In feeding and rearing tests, the strain 3 was less preferred to others, and the larvae died at first instar. In this results, it was thought that strain 3 may contain antifeedant(s) to *E. admirabilis*.

Fresh leaves of *G. pentaphylla* strain 1 to 3 were extracted with MeOH and partitioned successively with CHCl₃, EtOAc, BuOH and water.

Each fraction obtained was used for leaf disk bioassay. The results of bioassay showed that CHCl₃ fractions of each strain and BuOH fraction of strain 3 had antifeedant activity. As a result, BuOH fraction of strain 3 was suggested to play an important role in antifeedant activity.

15-197

THE INSECTICIDOUS INFLUENCE OF TOMATINE ON THE GERMAL CELLS OF THE COLORADO BEETLE *LEPTINOTARSA DECEMLINEATA* SAY.

Z. Čudare

Department of Experimental Entomology, Institute of Biology, Latvian Academy of Sciences, Salaspils, Latvia

Necrosis process caused by tomatine in the cells of the Colorado beetle is similar to that caused by chemical insecticides. Necrosis takes place in a part of the male and female germ cells during the last stages of their development. The dissolution of the oogoniums and spermatogoniums has not been observed. Regarding ovocytes, the structure of the nucleus changes at first. In the pycnotical nucleus nucleoli remain out of the compact structures of chromatin. The mass of the pycnotical nuclei often flows out the cytoplasm through a breach in the nuclear membrane. The dissolution of the cytoplasm of ovocytes begins in the external part fitting to the epithelial follicular cells. Usually the epithelial follicular cells, which embracing the ovocyte, touched by the necrotical changes remain still after the disappearing of the ovocyte's nucleus and cytoplasm.

The process of necrosis touches also male germ cells - spermatides, spermatozooids. In the follicle of spermary it has been observed that the sheaves of spermatides' and spermatozooids' nuclei flow together in a dense mass. As a result of the disintegration of the ovules the amount of the Colorado beetles' eggs diminishes.

15-199

THE MYSTERY OF METHYL EUGENOL: I. WHY METHYL EUGENOL IS SO EFFECTIVE FOR CONTROLLING FRUIT FLIES

O. Iwahashi and T.S. Subahar¹

Department of Entomology, University of the Ryukyus, Senbara Okinawa 903-01, Japan - 1 Department of Biology, Institute Technology Bandung, Ganesa Bandung, Indonesia

The Oriental fruit fly, *Bactrocera dorsalis*, was eradicated from the Ryukyu Islands, Japan, using methyl eugenol (ME) and the male annihilation technique. The fly population on each island was nearly or completely eradicated within 1 year after fiber blocks (4.5 X 4.5 cm) saturated with 10 g of poisoned ME were distributed at a rate of 2 - 4 per hectare/month. Considering the notion that eradication of a pest population from an isolated area is unlikely because pest control using chemicals such as insecticides or attractants become less efficient as the population density decreases, the success of the male annihilation technique using ME is a mystery.

Many naturally occurring plants emit some natural analog of ME and many *Bactrocera* fruit fly species are strongly attracted to these plants, indicating that there is a special biological significance for the flies. Although some authors have proposed ideas to explain the biological significance of ME, the reason why eradication of *B. dorsalis* was achieved so easily remains a mystery.

Based on the results of our outdoor screen cage experiments on the attractiveness of ME to the carambola fruit fly, *Bactrocera carambolae*, and some published data, we discuss why ME is so effective in controlling fruit fly species.

15-200

GROWTH INHIBITION IN THE MILKWEED BUG, *ONCOPELTUS FASCIATUS* DALLAS BY PLUMBAGINOIDS

G.T. Gujar* and A. Dorn, Institute for Zoology, Johannes Gutenberg University, Saarstrasse 21, D-55099, Mainz, Germany, * present address : Division of Entomology, Indian Agricultural Research Institute, New Delhi, India

Effect of 6 closely related plumbaginoids on the growth and mortality of the last instar nymphs of the milkweed bug, *Oncopeltus fasciatus* Dallas were studied by topical treatment. Plumbagin (2-methyl, 5-hydroxy, 1,4-naphthoquinone) showed high toxicity to the day 0 last instar nymphs than at any other age at 10 µg/20 mg body weight dose. The lethal dose of plumbagin for 50 % nymphal mortality was 2.75 µg/insect for day 0 last instar nymph. Plumbagin at 2 and 4 µg/insect caused growth inhibition and delayed moulting by more than 2 days as compared to control. The higher doses of plumbagin caused more mortality of nymphs. At a discriminating dose of 4 µg of plumbaginoid/insect, plumbaginoids like menadione, 1,4-naphthoquinone and plumbagin significantly inhibited growth of the last instar nymphs over the others viz., juglone, lawsone, and lapachol, besides control. Starvation also caused significant growth inhibition. The structure-activity relationship of plumbaginoids is discussed in relation to the mode of action.

15-202

THE USE OF NEEMAZAL-T/S TO CONTROL MUSEUM PESTS, FOR EXAMPLE WITH *TINEOLA BISSELLIELLA* (HUM.) (LEPIDOPTERA: TINEIDAE)

A.Wudtke, Ch. Reichmuth

Federal Biological Research Centre for Agriculture and Forestry, Institute for Stored Product Protection

Earlier successful studies with neem in plant protection suggested that in museums and other cultural institutions this agent may be suitable for use against museum pests too. Because of possible damages of the color pigments from exhibits it is necessary to replace chemicals like camphor or naphthalene with harmless alternatives like neem.

For the tests with woolen pieces the same dose of NeemAzal T/S was used and applied in the weight ratio 1 : 1 onto the woolen.

At 25°C and 65% r. h. 10 larvae were placed on woolen pieces of equal size. After 3 weeks, the rest surface of the woolen was digitized by use of a scanner and was evaluated with a pixel-count program. For the first time it was possible to prove the applicability of this method for objective assessment of frass damage.

The tested concentrations of neem led to a significant less frass damage.

The 2 %-solution was able to reduce the destruction by 76 % of the tested surface.

15-201

EFFECT OF SOME PLANT WATER EXTRACTS ON *PIERIS BRASSICAE* L. (LEPIDOPTERA : PIERIDAE)

A.Luik., A. Ploomi, A. Pettai

Institute of Plant Protection, Estonian Agricultural University, Estonia

The influence of crude water extracts of *Rheum rhaponticum* L., *Matricaria inodora* L., *Artemisia absinthum* L., *Artemisia vulgaris* L., *Tanacetum vulgare* L., *Achillea millefolium* L., *Ledum palustre* L., *Sambucus racemosa* L. in different concentrations on cabbage butterfly oviposition and larval mortality was investigated.

The extract influence depended on the concentration and larval instar. Most effective were 20% extracts. Higher (25-30%) concentrations did not have significantly more effect on caterpillars. Middle instars larvae were more susceptible to extracts than young or last instars caterpillars. The high larval mortality (80% and more) was caused by extracts revealed on the third day after treatment.

All extracts had influenced on oviposition behaviour of butterflies which laid smaller number of eggs on treated plants than untreated. The treatment cabbages with extract of *T. vulgare* totally prevented butterflies eggs laying on cabbage.

Extract of *L. palustre* effected also as growth regulator - the normal pupation was interrupted in many treated last instar caterpillars.

15-203

FEEDING PREFERENCE AND EVALUATION OF THE ANTIFEEDANT ACTIVITY OF CRUDE EXTRACTS FROM *Melia azedarach* L. (MELIACEAE) AND *Chrysanthemum coronarium* L. (ASTERACEAE) ON *Lobesia botrana* Den. & Schiff. (LEPIDOPTERA: TORTRICIDAE).

R. del Tío, R. Ocete & M.E. Ocete.

Laboratorio de Zoología Aplicada. Departamento de Fisiología y Biología Animal. Facultad de Biología. Universidad de Sevilla. Avda. Reina Mercedes, 6. 41012 SEVILLA. SPAIN.

The feeding preference of the 4th larval instar of *Lobesia botrana* Den. & Schiff. (LEPIDOPTERA: TORTRICIDAE) has been stated by using the dry weight consumption of leaves of several grapevine varieties as an index. The experience was performed for two days with leaves from Palomino Fino, Sultanina, Pedro Ximénez, Cardinal varieties and wild grapevine, *Vitis vinifera silvestris* (Gmelin) Hegi. The statistical analysis of data indicated that the average consumption of leave disks from Palomino Fino was significantly the lowest.

The same procedure was used in order to evaluate the antifeedant activity of crude extracts from berries of *Melia azedarach* L. (MELIACEAE) and leaves and flowers of *Chrysanthemum coronarium* L. (ASTERACEAE). All the tests were carried out at a concentration of 40 µg/cm² of each extract. The analysis of results showed that there was a statistical significance among samples treated with *Ch. coronarium* and the control ones.

15-204

ANTIFEEDANT, FUMIGATORY AND CONTACT TOXICITY
EFFECTS OF ESSENTIAL OILS AGAINST *EPIPHYAS*
POSTVITTANA (LEPIDOPTERA: TORTRICIDAE) IN NEW
ZEALAND

B.H. Rohitha, R.A. Hill, J.T. Taylor, F.J. Parry.

Natural Products and Ecological Production Group, The Horticulture and Food Research Institute of New Zealand Limited. Ruakura Research Centre, Hamilton, New Zealand.

Twenty essential oils including the oils of cinnamon, chamomile, pepper, juniper, cypress, cedarwood, clove, and eucalyptus were examined for their antifeedant and fumigatory properties against *Epiphyas postvittana* (light brown apple moth). Oils of pepper, cajuput and juniper showed significant fumigatory activity against the light brown apple moth. Oil of cinnamon and pepper had highly significant antifeedant effects. Feeding toxicity was observed with two essential oils namely thyme oil, and pepper oil. The significance of the active ingredients for the observed biological activity in the oils is discussed.

15-206

PHYSIOLOGICALLY ACTIVE PLANT COMPOUNDS AS
STRESS FACTORS FOR INSECT PESTS

L.S. Ivashchenko & N.A. Vilkova

All-Russian Institute for Plant Protection, St.-Petersburg, Russia

The system of plant immunity to harmful organisms is based on plant properties functioning as barriers for attack. Atreptic, morphological, growth, ontogenetic and physiological barriers are recognized according to classification by Vilkova (1972) as well as a number of induced resistance barriers.

Antibiotic impact of host plants on their insect consumers is performed through combination of both rather local and general morphophysiological and biochemical alterations in organisms of the insects. These alterations entail deterioration of the physiological state of consumers resulting in their death or in a decline in their biotic potential. Eventually the reduction of numbers of phytophagous insects is achieved. Both the basal plant compounds (carbohydrates, proteins and lipids) and secondary metabolites - xenobiotics are of decisive importance in plant antibiotic influence on insect pests.

The main types of insect physiological reactivity to plant antibiotic influence expressing in terms of specific metabolic processes have been revealed by the example of a number of pest species such as colorado potato beetle, european corn borer, cotton cutworm and some others. Metabolic disruptions entail functional alterations in individual insect organs and systems. These alterations give rise to stresses of different depth depending on an extent of antibiotic influence of a resistant plant.

15-205

INSECTICIDE EFFECTS OF PLANT'S CHAPERONES

F. Kocourek¹, T. Jaliashvili², V. Táborský³

- 1 - Research Institute of Plant Production, Praha, Czech Republic,
- 2 - Georgian Academy Agritechnological Science, Tbilisi, Georgia,
- 3 - Czech Agriculture University, Praha, Czech Republic.

Chaperones enriched fractions were prepared from plant biomass of the *Viciaceae* family by a new, patented in Czech agri-biotechnology. The enhanced synthesis of chaperones in the plants were induced by temperature stress (-2°C). The enriched fractions of chaperones used for experiments contained thermally stable cold-shock proteins 25-10 kDa.

The insecticide effect of the chaperone enriched fractions has been confirmed on model insect pests: *Leptinotarsa decemlineata*, *Oulema melanopus*, *Lymantria dispar*, and *Pieris brassicae*. The greatest insecticide effect of cold-shock proteins were found against early development stage of those insect which require large amounts of food. The intake, of cold-shock protein sprayed plants by the insect larvae is reduced (antifeedants), and the weight of the larvae is lower than that of the controls. The mortality of larvae were about 50-70 % during experiment. Remaining larvae of lowest weight just were dying later. The cold shock proteins influence on insect species is selective.

The insecticide results of investigated cold-shock proteins is similar with the natural, self-defense mechanism of the plants.

15-207

BIOLOGICAL ACTIVITY OF ESSENTIAL OILS AND ITS
APPLICATIONS IN ECOLOGICAL AGRICULTURE

A. Mateeva

Department of Entomology, Higher Institute of Agriculture, Plovdiv, Bulgaria.

It is clear today more than any time that the ecological agriculture is the unique chance for soil's survival and preservation. The conception the soil is a living organism, a living system in which all must be balanced takes a central place in it.

The aim of the present investigation is to establish the essential oil's role in the ecological agriculture's context. A number of observations is carried out about the direct toxic effect of a set of essential oils active substances on economically important diseases and enemies.

On the base of the investigations it has been fixed that some of the essential oils grown in Bulgaria can be used successfully as:

- a predecessor culture acting an important role in the density reduction and mortality *Myzodes persicae* Sulz, *Aphis fabae* Scop., *Leptinotarsa decemlineata* Say, *Phytonomus variabilis* Hrbst.
- a means of acaricide toward *Tetranychus urticae* and *Schizotetranychus viticola*.
- producing a high economical effect when used in the ecological farm's crop-rotation.

15-208

USE/RISK REDUCTION PRACTICES FOR IMIDACLOPRID IN COLORADO POTATO BEETLE (COLEOPTERA: CHRYSOMELIDAE) MANAGEMENT

J. J. Linduska¹, G. P. Dively

Department of Entomology, University of Maryland, College Park, MD USA

The systemic/contact insecticide, imidacloprid (Admire 240FS, Bayer Corp.), can be applied as a soil treatment in many ways - one of which is a transplant drench to control Colorado potato beetle, *Leptinotarsa decemlineata* (Say) (CPB) in tomato and eggplant. Many growers prefer this preventative approach but it is costly and may result in pest resistance, as it has for other systemic insecticides. The labeled doses are 279 to 419 grams a.i. per hectare depending on row spacing. Field studies have shown that drenches at doses as low as 46 grams a.i. per hectare applied directly to plant bedding trays prior to transplanting afforded effective protection against post-diapause adults and first generation larvae. The optimum dose may depend on the crop, cell size of the bedding tray, and time of the drench treatment. Other advantages besides cost savings included reduced handling and exposure risks associated with delivering the insecticide via the transplant water and elimination of the 12-month plant-back restriction which creates a rotational problem for many growers. Also, adjustments of the drench dose and effective protection period so that the systemic action of imidacloprid becomes ineffective between CPB generations may create a temporal refuge for susceptible individuals to reduce the risks of pest resistance.

15-209

PLANT-DERIVED SEMIOCHEMICAL BAITS: A METHOD FOR POPULATION MONITORING AND SUPPRESSION OF INSECT PESTS

T.M.R. Bucci, J.M. Gaggero¹ & T.E. Anderson

BASF Corporation, Research Products Center, 26 Davis Drive, Research Triangle Park, North Carolina, USA

¹Micro Flo Corporation, 7525 Auburn Blvd., Suite 1D, Citrus Heights, California, USA

Secondary plant compounds have previously been shown by many researchers to have pronounced effects on the behavior of various insect species. Because many of these plant compounds serve as attractants or gustatory stimulants, a reasonable assumption has been that these compounds may be useful as insect baits. Baits can be used for both monitoring insect populations and suppressing pest populations. With regard to pest suppression, a bait, which may include a phagostimulant alone or a stimulant in combination with an attractant, could allow for decreased amount of toxicant relative to many standard insecticides currently on the market. SlamTM and AdiosTM (Micro Flo Company, BASF Corporation, USA) are foliar insecticides used for controlling adult *Diabrotica* pest species. These insecticides provide a model system for demonstrating the efficacy of an insect bait for suppressing an insect population. Data indicate that SlamTM and AdiosTM, which contain a floral attractant, a feeding stimulant (cucurbitacin) and carbaryl, is highly effective in luring Diabrotic beetle pest species to treated corn, cucumbers, melons and vegetables. Upon contact with the insecticidal material on the treated plants, the insects begin feeding compulsively. Ingestion of the bait in combination with the toxicant has been shown to give up to 99% mortality when applying a use rate of only 0.56 kg/ha. Because of the reduced amount of active ingredient (up to 97% reduction relative to many registered products) and high level of species specificity, natural enemies are not adversely affected. These novel insecticides show promise for safe, effective control of Diabrotic pests by using semiochemical bait technology.

15-210

EFFICACY OF EMAMECTIN BENZOATE (MK244), AC303630 (A PYRROLE), AZADIRACTIN, AFMNPV, AND *BACILLUS THURINGIENSIS* AT CONTROLLING LEPIDOPTEROUS PESTS OF CABBAGE IN CENTRAL FLORIDA WITH OBSERVATIONS ON INSECTICIDE RESISTANCE AND SAMPLING

G. L. Leibe, K. E. Savage

Central Florida Research and Education Center, Institute of Food and Agricultural Sciences, University of Florida, Sanford, Florida, USA

Emamectin benzoate (MK244), AC303630 (a pyrrole), azadirachtin, AfMNPV (a celery looper, *Anagrapha falcifera* (Kirby), multicapsid nuclear polyhedrosis virus), and *Bacillus thuringiensis* (BT) were among insecticides evaluated since 1992 for control of lepidopterous pests of head cabbage in central Florida. The percentage of plants with the bud (or head) and next four youngest leaves infested with larvae and/or pupae was used to measure insect activity. Level of infestation and damage were determined weekly. Marketability was determined at harvest. In general, level of damage at harvest was correlated with the level of diamondback moth (DBM), *Plutella xylostella* (L.), infestation beginning about halfway through crop development. Emamectin benzoate and AC303630 were effective at controlling DBM. A rotation of emamectin benzoate and BT was less effective than emamectin benzoate alone. Results with azadirachtin were varied. AfMNPV was effective on cabbage looper, *Trichoplusia ni* (Hübner), and cabbage webworm, *Hellula rogatalis* (Hulst), but not on DBM. Differences in efficacy among the BT-products were consistent with the types of insecticidal protein toxin contained in the products and toxin activity associated with BT-resistant DBM.

15-211

EFFICACY OF SELECTED INSECTICIDES AGAINST *PHYLLONISTIS CITRELLA* (Stainton) (LEPIDOPTERA: GRACILLARIDAE), THE CITRUS LEAFMINER.

E. M. Abou Fakhr and N. Antar.

Department of Crop Production & Protection, Faculty of Agricultural & Food Sciences, American University of Beirut, Lebanon.

Field applications of six insecticides belonging to different chemical groups were performed against *Phyllocnistis citrella*, the citrus leafminer (CLM) in summer 1995. Fertilization effect as a factor in enhancing CLM infestation was also studied. Comparative laboratory bioassays with different immature stages of the insect were performed using the six insecticides. The efficacy of the insecticides was determined by changes in the population of the insect throughout sampling during the summer. Results have indicated significant differences between the control and other treatments. Differences in efficacy of the tested insecticides were correlated with their mode of action.

15-212

MANAGEMENT OF *EUXOA AUXILIARIS* (GROTE) AND *AGROTIS ORTHOGONIA MORRISON* IN SOUTH DAKOTA WINTER WHEAT (LEPIDOPTERA: NOCTUIDAE).

M. A. Boetel & B. W. Fuller.

Department of Plant Science, South Dakota State University, Brookings, South Dakota, USA.

In the absence of United States Environmental Protection Agency registered products for protection of winter wheat, field studies were initiated in 1990 to evaluate several organophosphate and pyrethroid insecticides for control of the army cutworm, *Euxoa auxiliaris* (Grote) and pale western cutworm, *Agrotis orthogonia* Morrison infestations. Sub-soil burrowing behavior (up to 10 cm below soil surface) of these pests decreased the likelihood of direct contact with applied insecticides. Thus, residual control was important in our evaluations. Naturally-infested winter wheat fields were selected for our experiment at Murdo (1990, 1993), and Wall (1992). Artificial infestation of *A. orthogonia* was carried out in studies at the Bruce (1995).

All insecticides and respective application rates provided significant ($P < 0.05$) cutworm reductions in comparison to untreated control plots. However, no significant differences were detected between either rates or compounds with naturally-infested studies. However, microencapsulated methyl parathion (PennCap-M 2FM, Elf Atochem) provided significantly superior *A. orthogonia* control at 0.84 kg (AI)/ha to that of either 0.56 and 0.28 kg rates. Additionally, our data was instrumental in supporting the registration of chlorpyrifos (Lorsban 4E, Dow Elanco) which provided growers with an efficacious method of managing these important winter wheat pests.

15-214

EFFECTS OF TRIFLUMURON ON THE EGGS AND LARVAE OF EUROPEAN GRAPEVINE MOTH, *Lobesia botrana* DEN.-SCHIFF. (LEPIDOPTERA; TORTRICIDAE) .

Ş.KISMALI, F.Ü.ALTINDIŞLI¹

Department Of Plant Protection, Faculty of Agriculture, University Of Ege, İzmir, Türkiye-1 Entomology Laboratory, Plant Protection Research Institute, İzmir, Türkiye

In the laboratory tests triflumuron 25 WP(IGR) at the dose of 40 g/100 l water was applied topically to the different hour-old eggs and larvae of *Lobesia botrana* to search the egg development and hatch rate and the larval abnormalities and mortality rates. The effects of this compound on the egg hatch in all groups were different from control treatment, the average effect rates were calculated to be 44.21% for 24-48 hour-old eggs that were the most sensitive group.

It is observed that the treatment against the larvae caused several morphological abnormalities both the first and second instar larvae of 0-24 or 24-48 hour-old ones. Compound was also effective on the mortality rates of larvae 24-28 hour-old larvae of both first and second instars were the most sensitive group. In the field the most sensitive group to the compound was the 24-48 hour-old eggs.

15-213

THE STRATEGY OF STRUGGLE WITH GRASS MOTH (*LOXOSTEGE STRICALIS* L.) ON THE MODERN STAGE.

I.B.Knorr

Institute for Systematics and ecology of animals, Siberian Branch of the Russian Academy of Sciences, Novosibirsk, Russia.

An enormous extent of outbreaks of reproduction of grass moth on the Euroasian continent dictates a close collaboration of the experts from different countries for monitoring of long-term dynamics of this species, including that of the storage of diapausing pronymphs. Since the search for the ground cocoons of grass moth is rather a complicated task we can see the solution of the problem in the carrying out yearly regional inspections of the key-roots by high-mobile teams formed of the most qualified specialists.

The experience of applying the chemical means against the adult moths, which are much more sustainable to insecticide than the caterpillar, allows a highly optimistic evaluation of the idea of preventive treatments of moth congregations in the places of a mass hatching from the pupae, where the moths stay until maturity and spreading to the reproductive sites. This measure allows to decrease essentially the probability of appearance on the crops of numerous egg layings and caterpillar hearths.

Moreover, while planning and conducting the complex of protective measures against grass moth it is important to take into account a successive nature of appearing of the caterpillar hearths in accordance with the passing of migrational waves of the pest imagines. This means that within a large region suffering from the pest there is a possibility of manoeuvring with the struggle means being in disposal.

15-215

DISCUSSION ON PESTS AND DISEASE CONTROL OF RATOONING RICE IN CHONGQING

Liu Jiaqi, Zhou Tianyun

Chongqing Plant Protection Station, Chongqing, China

The paper gives an introduction on investigation of pests and disease of semilate rice —ratoon rice sprouting from semilate rice stubble and research of pesticides selection from 1988 to 1994 in Chongqing, China. Damages of major pests and disease occurring in ear stage of semilate rice, such as rice plant hopper, rice borer, rice leaf roller and sheath and calm blight of rice on yields of semilate rice and ratoon rice were evaluated, and relation of yield losses between semilate rice and ratoon rice affected by these pests and disease was discussed. Analysis showed that the relativity of yield losses between semilate rice and ratoon rice was quite evident. Based on evaluation, 5~10% yield loss of semilate rice in ordinary year in Chongqing on an average was from damages of pests and disease mentioned above, and then, related to a yield loss of ratoon rice of 9~10%. In year of outbreaks of pests and disease, yield loss of semilate rice reached to 11~38%, and resulted in a yield loss of ratoon rice of 11~100%. It was concluded that effective pest and disease control in ear stage of semilate rice was important for culture of ratoon rice.

Two pesticides i.e. 50% wettable powder of Puminisi which is a complex of Shachongdan (

) and Buprofezin, and 5% granule of Shachongdan were recommended. Field tests showed they were quite effective in controlling while applied with validamycin A.

15-216

BIOLOGICAL STUDIES ON OSTRINIA FURNACALIS SPECIES GROUP OF JAPAN (LEPIDOPTERA: PYRALIDAE)

Y. Yoshiyasu & M. Yazaki

Laboratory of Entomology, Faculty of Agriculture, Kyoto Prefectural University, Shimogamo, Kyoto, Japan

Nine species of the genus Ostrinia have been recorded in Japan. Among them 5 species including O. furnacalis are much close to each other (furnacalis species group). The species of this group are distinguished by slight morphological differences, and the biological information is relatively limited except for O. furnacalis due to the difficulty for identification.

The biological studies, i. e., larval development, post-diapause development, host plant preference, and so on, revealed that these species were confirmed to be distinct from each other. And one species related to O. zagliaevi was newly recognized from a southern island of Japan. Some new morphological characters for identifying these species are also discussed.

EXTERNAL THREATS: PROCESSES FOR DETERMINING THE RISKS TO BRITISH FORESTS FROM EXOTIC INSECT PESTS

H.F. Evans

Forestry Commission Research Division, Alice Holt Lodge, Wrecclesham, Farnham, Surrey, GU10 4LH, UK

Britain's island status has a number of consequences for its flora and fauna. Following the last ice age, the number of tree species and their associated insects have been impoverished relative to mainland Europe. Forestry, as a component of the landscape and, particularly, commercially, is dominated by exotic tree species. For example, Sitka spruce (*Picea sitchensis*), Norway spruce (*Picea abies*), Corsican pine (*Pinus nigra* var. *maritima*) and lodgepole pine (*Pinus contorta*) are the main commercial conifer species.

The expansion of forestry from the early 1950s has been accompanied by an increase in the number of exotic insect pests that have established in Britain. Notable among these have been the bark beetles (Coleoptera: Scolytidae) *Ips cembrae*, *Ips sexdentatus* and *Dendroctonus micans*, the latter having been discovered only in 1982.

Recent interest has focused on the so-called Asian strain of the gypsy moth, *Lymantria dispar* (Lepidoptera: Lymantriidae) which has been causing major problems in Germany and was found for the first time in Britain during 1995.

These, and other examples, will be discussed within the context of Pest Risk Analysis (PRA) with particular reference to Britain. This will concentrate on the processes of identification of potential pests in other countries, the likelihood of those pests being transported to Britain and the potential for establishment and damage should the pests get through plant health barriers. Consideration will be given to the risk factors arising from the increase in forestry in Britain and on the absence of natural enemies of most exotic potential pests, even those that are present in neighbouring countries on mainland Europe. Risk mitigation measures will then be assessed in relation to the key potential pests identified in the PRA process. These will be discussed and evaluated in relation to their success and how they might be improved to ensure future freedom from exotic pests.

16-003

FOREST PEST RISK ANALYSIS AND ESTABLISHED FOREST AND TIMBER INSECTS IN NEW ZEALAND.

John Bain

New Zealand Forest Research Institute, Rotorua, New Zealand.

Since the early days of European colonisation New Zealand has been a trading nation and as a consequence has acquired many insect species from overseas. Approximately 170 overseas forest and timber insects are established in NZ and over 600 species of wood- and bark-boring insects have been intercepted at ports. Most of the establishments have been relatively innocuous but a few have had a major effect and some have influenced the choice of tree species in commercial plantations. No overseas insects have had an serious effect on indigenous forests.

NZ has very strict quarantine regulations that are strictly enforced; this combined with the country's remote location means that quarantine procedures are more likely to be effective than in continental countries. During the past 20 years active and passive (desk) pest risk analyses of both commodities and pest species have played a major part in influencing quarantine regulations and procedures. Examples of this, including the way New Zealand has dealt with the threats posed by pine wilt nematode (*Bursaphelenchus xylophilus*) and Asian gypsy moth (*Lymantria dispar*), are discussed.

16-002

ASSESSING THE RISK POSED BY SOME FOREST INSECT PESTS TO THE UNITED KINGDOM

R.H.A. Baker, D.R. Gray¹, K.F.A. Walters

Central Science Laboratory, MAFF, Hatching Green, Harpenden, Herts, United Kingdom - ¹ Department of Entomology, Price Hall, Virginia Polytechnic Institute and State University, Blacksburg, Virginia, USA

Lymantria dispar is an important Lepidopteran pest of forestry and amenity woodland in continental Europe. However, from 1907, when *L. dispar* became extinct in the United Kingdom, until June 1995, when a breeding colony was found in North London, only migrant males of this species have been found naturally in the UK. This paper explores some of the methods which can be used to assess and manage the risks posed by *L. dispar* to the UK in the light of the new outbreak.

Particular emphasis will be given to the role of climate in determining the potential for establishment of this species in the deciduous woodland of southern Britain. An egg phenology model will be employed to predict egg hatch dates at the outbreak site to assist eradication measures and development will be predicted at other key UK locations. Climatic comparisons will also be made between the UK and other areas in Europe which are subject to severe outbreaks of *L. dispar* to determine whether sufficient temperature accumulates during the summer to enable the life cycle to be completed.

The implications of these analyses will be taken into account in a review of the risks posed by *Hyphantria cunea*, another Lepidopteran tree pest in continental Europe, to UK forestry and horticulture.

16-004

THE ROLE OF CLIMEX IN PEST RISK ANALYSIS

R. W. Sutherst, G. F. Maywald and D.B. Skarratt
Co-operative Research Centre for Tropical Pest Management, Gehrmann
Labs, University of Queensland, Brisbane 4072, Australia

The volume of international trade poses escalating threats to the integrity of many natural and human-modified systems around the world by spreading exotic species of pests, diseases and weeds. Meanwhile the World Trade Organisation and the FAO have called for harmonisation of quarantine procedures. Given the great disparity between the capacities of developed and developing countries to undertake pest risk assessments, and the global value of all pest related information, there will be major benefits in the adoption of some common tools and languages to exchange information. CLIMEX is one such tool. It uses a simple file of parameter values to describe the key climatic requirements of species, without the need for detailed knowledge of their lifecycles. CLIMEX makes risk assessments, in relation to climate and hence geographical locations, transparent and so CLIMEX files can be used as an international medium for the exchange of pest risk information. At the time of writing, CLIMEX is being used in about 120 laboratories world wide, and it has been applied to over 100 species of insects, fungi and plants with equal success. It is being considered for linking with the CABI entomology database and offers great opportunities for expanding the options available for quarantine pest risk analyses, with significant new insights being gained into each new species that it is applied to.

16-006

RISK MANAGEMENT OF PINE WOOD NEMATODE
INVASION AND THE BARRIER ZONE DEFENSE
PROJECT IN JAPAN

N. Kamata
Forestry and Forest Products Research Institute, Tohoku Research Center,
Morioka, Japan

The pine wood nematode (PWN), *Bursaphelenchus xylophilus* (Nematode: Aphelenchoididae), which causes pine wilt disease (PWD), is believed to be native in North America and is thought to have been introduced to Japan in logs imported in the early 1900s. By 1984 approximately 25% of pine forests in Japan were infested. Although the Japanese pine sawyer, *Monochamus alternatus* (Coleoptera: Cerambycidae), is the most important insect vector of PWN in Japan, human transportation has been more closely related to the spread of PWN. The PWN has been expanding its range by both neighborhood diffusion and long-distance dispersal. The long-distance dispersal was sometimes over 100 km, which is obviously caused not by the beetles but by humans. In northern Japan, the PWN was first found in 1975 over 200 km away from the edge of the nearest population front. Introduction is thought to have begun with the most aggressive forms of PWN transported by ship to the paper factory. Because low temperatures cause a delay in host symptom development and a slower rate of nematode population increase, the spread of the PWN and the number of infested pine trees have been slowed down in N Japan. This fact means that the control efforts and the intrinsic rate of increase of PWD are balanced in these regions. It is speculated that the PWN will expand slowly in N Japan by the repeating processes of 'spread and establishment into uninfested areas in hot dry summers' and 'keeping the status quo in cool summers'. To stop the new invasion in the hot dry summer is the key to the control strategy in the northern extremes of the nematode's range. A risk of establishing the PWN population in uninfested areas was assessed by a thermal constant above developmental threshold of *M. alternatus*. I will also introduce the barrier zone defense project in the expanding front of Japan.

16-005

CURRENT AND POSSIBLE FUTURE EXOTIC FOREST INSECTS
IN NORTH AMERICA: THE NORTH AMERICAN EXOTIC FOREST
PEST LIST PROJECT

Robert A. Haack
US Department of Agriculture, Forest Service, North Central Forest
Experiment Station, East Lansing, Michigan, USA

More than 370 exotic forest insects are now established in North America, many of which have greatly altered forest ecosystem diversity, function, and productivity. These exotics represent 10 insect orders, being mostly Homoptera (31%), Coleoptera (28%), Lepidoptera (22%), and Hymenoptera (10%). The scolytid *Tomicus piniperda* is one of the most recent exotics to become established in North America, being first detected in 1992 in Ohio. Of the exotic forest insects now in North America, 78% came from Europe, 20% from Asia, 1% from Africa, and 1% from Australia. Some of the North American tree genera that support the most exotic insect species are, in decreasing order, *Prunus*, *Pinus*, *Salix*, *Malus*, *Populus*, *Quercus*, *Betula*, *Acer*, *Picea*, *Alnus*, *Ulmus*, *Crataegus*, and *Abies*. Most of these exotic insects arrived during the past 100 years. Future introductions of new forest pests are likely due to increasing world trade, shipments of equipment and vehicles from overseas military bases back to North America, and importation of whole logs from other countries.

The North American Forestry Commission, Forest Insect & Disease Working Group has recently initiated an effort to create a list of exotic forest insects (and other pests) to exclude from North America. Most members of this working group represent federal forestry and quarantine agencies in Canada, Mexico, and the United States. It is hoped that this list will allow quarantine efforts to be focused on those pests that pose the greatest risk to North American forest ecosystems. This talk will present an overview of the project, including its goals, criteria, and progress to date.

16-007

INTRODUCTION AND SPREAD OF EXOTIC TREE SEED PESTS IN
EUROPE vs. COLONIZATION OF EXOTIC TREES BY NATIVE
EUROPEAN SEED PESTS: ARE THE PROCESSES SIMILAR ?

A. Roques, G. Roux
INRA-CRF, Zoologie Forestière, Ardon 45160 Olivet, France
Worldwide development of tree-improvement programs, especially establishment of seed orchards, has renewed attention to insects infesting tree seeds. The more as the development of international seed trading includes the potential introduction of exotic pests with seed lots, when ineffective phytosanitary measures are applied at borders. A European survey of the *Megastigmus* spp. (Hymenoptera: Torymidae) attacking tree seeds showed a total of 19 species, of which 7 were introduced to Europe. Among them, at least 3 species have been introduced from North America during the recent years. Most of these insects seemed capable of developing in unfertilized seeds as a survival adaptation compensating for pollination problems.
The potential host ranges of the introduced chalcids were surveyed and compared to those of native seed insects. The establishment and spread of exotic seed pests in the area of introduction appeared to depend on the presence of native tree species congeneric to the original host. When such species existed (e.g., firs), the exotic chalcids were observed to shift on them but the competition with native pests for seed exploitation limited their impact. By contrast, the exotic pests did not attack any native species when none of them were congeneric to the original host (e.g., Douglas-fir). In that case, the seed chalcid introduced along with the host tended to occupy the entire niche because of the absence of competitors, and parasites as well. For example, the Douglas-fir seed chalcid now occurs at high densities throughout Europe, including remote southern areas, and patterns of seed exploitation largely differ from those observed in the native areas. Introduction of seed chalcids of *Chamaecyparis*, or *Cryptomeria* from Asia to Europe is expected to result in a similar situation.
The process of colonization of exotic trees by native seed insects seemed somewhat similar. Most exotic trees introduced to Europe showed a large colonization by native insects specialized in exploiting the seed resource of congeneric native species, e.g. spruces. When no native congeneric tree species existed, colonization by native insects remained limited, and only proceeded from species poorly specialized in seed exploitation.

16-008

EPIDEMIOLOGICAL ASPECTS OF GEOGRAPHIC WITHIN - RANGE TRANSLOCATION OF *PITYOGENES CHALCOGRAPHUS* LINNÉ POPULATIONS (COLEOPTERA: SCOLYTIDAE)

E. Führer

Institut für Forstentomologie, Forstpathologie und Forstschutz, BOKU Wien, Austria

Populations of the spruce bark beetle, *Pityogenes chalcographus* L., in Europe show genetic variation, partially due to their phylogeographic position. Its biological manifestation was experimentally tested, considering parameters which could be relevant for the epidemic potential of the insects. The results indicate that *P. chalcographus* populations indeed can differ in respect of such traits, e.g. host tree specificity, speed of development etc.. Cross-breeding of beetles from distinct populations caused various effects between the parental partners as well as in the F1 progeny, depending on the origin of parents. Between partners partial incompatibility on the ethological, physiological and cytological level could be ascertained. In some F1 crossings heterosis effects in terms of vigour, fecundity and aggressiveness became visible.

It is concluded that (1) differences in the epidemic potential between distinct populations of *P. chalcographus* may be based on the phylogeographic and ecogeographic differentiation of its genetical structures; (2) the diversity of environments, where *P. chalcographus* can exist and where it is specifically adapted to in the form of local non-epidemic populations, demonstrates its ecological adaptability; (3) this implies the risk of coincidence of ecologically over-adapted alien genotypes with conditions epidemiologically most appropriate for them, when being transferred by timber trade within the geographic range of the beetle; (4) within - range translocation of beetles may also result in genetically new types of populations, in which heterosis effects raise the inclination to epidemics.

16-010

INSECT VECTORS OF PINWOOD NEMATODE: CONSEQUENCES OF INTERNATIONAL MOVEMENT OF *MONOCHAMUS* SPP.

M. Linit, W.T. Stamps, X. Zhang, S. Necibi

Department of Entomology, University of Missouri, Columbia, MO USA

The pinewood nematode, *Bursaphelenchus xylophilus* (Steiner and Buhner) Nickle, has been collected from over 20 species of *Pinus* in North America. The nematode is dependent upon adult beetles in the genus *Monochamus* (Coleoptera: Cerambycidae) for transport from infected to non-infected pines. In North America, the nematode is a common secondary pathogen of dying trees but only rarely causes pine wilt, usually on susceptible species of exotic pines. The nematode was introduced into northeastern Asia early in this century and has devastated pine forests in throughout Japan and in parts of China, Taiwan and South Korea. The nematode is not known to exist in Europe, however, suitable insect vectors do exist. Europe faces the threat, therefore, that the nematode could become established and spread if it were introduced. Such introduction could come in the form of infected wood or through the introduction of nematode infested beetles. Comparative studies of two species of vectors, *M. carolinensis* from the midwestern United States, and *M. alternatus* from northeastern Asia suggest that the reproductive and transmission efficiency does not differ greatly between the species. Adult, nematode-infested, *Monochamus* females do have the ability to transmit the nematode to new host material. This suggests that the introduction of a single, unmated adult female could introduce the nematode to new geographical locations where it could form an association with potential native vectors.

16-009

A PHYLOGEOGRAPHIC ANALYSIS OF EUROPEAN *IPS TYPOGRAPHUS* (L.) (COLEOPTERA, SCOLYTIDAE) POPULATIONSCh. Stauffer^{1,2}, F. Lakatos^{1,3}, R. Blecha¹, G.M. Hewitt²¹ Institut f. Forstentomologie, Univ. f. Bodenkultur, 1190 Vienna² School of Biological Sciences, UEA Norwich NR4 7TJ³ Department of Forest Entomology, H-9400 Sopron

Ips typographus (L.) is an important pest in the European spruce forests. The European *I. typographus* populations vary in many aspects like aggressiveness or reaction towards synthetic pheromones. These phenotypic-behavioural differences suggest that the populations are genetically distinct. There is little knowledge about the genetic variability of the populations within Europe. Population genetics can provide information on the origin of established populations, gene flow among populations and sometimes also anthropogenic influences. Here 21 European populations collected from logs were investigated by screening isozymes and sequencing three regions of the mitochondrial genome.

The northern populations had in average less alleles than the other populations and the genetic variation was lower. The northern populations as well as the populations from border zones (non-autochthonous spruce stands) had less gene flow. Although the estimation of the gene flow was high among the populations a geographic isolation with distance was detected. The sequence results (892 bp) revealed very low variation with eight mitotypes detected over all populations. The populations from Italy and Croatia were variable having most mitotypes. Most populations had only one to two mitotypes.

The geographic pattern of the geno- mitotypes might have evolved by postglacial processes of colonisation and migration. We suggest that in the last glacial periods the refugial zones were in the south (e.g. Dinaric Alps and Apennine), where most geno- mitotypes still inhabit the spruce stands. From these areas beetles re migrated to central and northern Europe. Some of the geno- mitotypes colonized successfully, some did not. This would explain the North South cline concerning the variability. Consequences of the results will be discussed: significance of the source of introduced populations for its epidemic potential; effects of wood transports; selection of geno- mitotypes might be responsible for the different reaction of the European *I. typographus* populations towards the synthetic pheromones.

16-011

A COMPARISON OF THE PEST STATUS OF AUSTRALIAN INSECTS FEEDING ON *EUCALYPTUS* SPP IN AUSTRALIA AND OTHER COUNTRIES.

R.B. Floyd

CSIRO Division of Entomology, GPO Box 1700, Canberra ACT 2601, Australia

Eucalyptus spp, which are largely endemic to Australia, have been introduced to many countries and grown in plantations for hardwood production. There are a number of records of Australian insects, including *Phoracantha semipunctata*, *Gonipterus* spp. and *Paropsis charybdis* becoming pests of *Eucalyptus* in other countries yet not attaining pest status in Australia. The most obvious explanation for this phenomena is release from natural enemies in the introduced range. However, the differences in pest status and biology of the insects in exotic locations cannot be fully explained by a lack of natural enemies. Other aspects such as host range and geographic distribution in Australia, competing species and differences in silvicultural practices will be discussed.

16-012

SYSTEMATICS AND BIOLOGY OF PARASITOIDS OF EUCALYPT PESTS IN AUSTRALIA - THE PROBLEM "DOWN UNDER"

A.D. Austin
Department of Crop Protection, Waite Campus, The University of Adelaide, Glen Osmond, S.A. 5064 Australia.

The complex of hymenopteran and dipteran parasitoids associated with various defoliating and wood-boring insects of eucalypts in Australia can include 20 species or more. These complexes comprise an array of function types, e.g. primary and hyperparasitoids, idiobionts and koinobionts, solitary and gregarious species, mostly belonging to the Ichneumonoidea and Chalcidoidea. They provide the source of potential biocontrol agents of eucalypt pests outside Australia, but in this respect several problems are evident. Of prime importance is that serious eucalypt pests overseas are not necessarily critical pests in Australia, and therefore their biology and taxonomy is often poorly known. This was the case for the parasitoids of the cerambycid *Phoracantha semipunctata* and the pergid sawfly *Phylacteophaga froggatti*. In these cases, a large proportion of their parasitoids represented new or ill-defined species and, for *P. froggatti*, biological studies showed that two species being considered for introduction into New Zealand were facultative hyperparasitoids of the most common primary parasitoids, *Bracon* spp., and therefore potentially damaging to any biocontrol efforts.

Not only are there taxonomic problems with parasitoid complexes but also with some pest groups themselves, as shown by recent studies on *Phoracantha* and *Phylacteophaga*. Further, the rate at which taxonomic and biological knowledge is accumulating on parasitoids of eucalypt-feeding insects is low because of the paucity of research staff in Australia. Currently, there are only four parasitoid taxonomists in Australia, two of which are part-time.

Although such drawbacks exist, the chances for success of biocontrol of eucalypt pests outside of Australia is high. Eucalypt-feeding insects and their parasitoids are relatively specific and are therefore unlikely to move onto other plants and insect hosts, respectively. Further, taxonomic problems can be overcome through collaboration with overseas workers and by focusing research more narrowly. These aspects will be discussed using the above species and others as case study examples.

16-014

INSECTS AND THEIR POTENTIAL DAMAGE IN EUCALYPT PLANTATIONS OF EASTERN TAIWAN

J. T. Chao, Y. B. Fan, S. S. Lu, C.S. Chen¹

Division of Forest Protection, Taiwan Forestry Research Institute, 53 Nanhai Road, Taiwan, R.O.C. -1
Department of Biology, Fu Jen Catholic University, Taipei, Taiwan, R.O.C.

One light trap was set at each of two eucalypt plantations (one mainly composed of *E. grandis* and the other *E. grandis* and *E. camaldulensis*) in Eastern Taiwan. Insects were light trapped from 1830 to 2200 once or 2 consecutive nights each month. A total of 34,912 insects of 15 orders were light trapped during the period from December 1993 to November 1994. Significant differences were found among the number of insects caught monthly and among the number of trapped orders of insects. Lepidoptera were the most abundant insects, representing a about 1/3 of the total insects collected. At least 469 species belonging to 22 families could be identified from the trapped moths. No significant difference was found between the number of moth species collected from 2 plantations. Most of the important pest species damaging eucalypt plantations before 1992 (e.g., hepialid *Endoclyta sinensis*) were either not trapped or trapped with low numbers. The dynamics of trapped insects through the year is described. Implication of the results from this study to forest management is discussed.

16-013

BIOLOGY AND MANAGEMENT OF INTRODUCED ARTHROPOD PESTS OF EUCALYPTUS: SITUATION IN SOUTH AMERICA

E.Berti-Filho

Depto.de Entomologia-ESALQ/USP - Piracicaba, SP Brazil

Most of the South American forest plantation areas are covered with *Eucalyptus* species. The largest areas are located in Brazil (3,600,000 ha), Argentina (231,000 ha), and Chile (207,000 ha). Large areas are located in Colombia and Peru, and median or minor areas in Paraguay, Bolivia, Suriname, Ecuador, French Guyana, and Guyana. Since its introduction *Eucalyptus* spp. have been attacked by a high number of native insect pests of the Orders: Lepidoptera (defoliating caterpillars), Coleoptera (borers or defoliators), Hymenoptera (leaf-cutting ants), and Isoptera (root or trunk termites). The introduced species such as the eucalypt snout beetle, *Gonipterus* spp. (Curculionidae), and the eucalypt borer, *Phoracantha semipunctata* (Cerambycidae), both native from Australia, are not really a problem at present. The overall breadth of insects on *Eucalyptus* spp. in South America and the damage caused by the most serious native pests are presented.

16-015

ECOLOGY OF THE EUCALYPTUS LONGHORNED BORER (COLEOPTERA: CERAMBYCIDAE) IN CALIFORNIA

L.M. Hanks, T.D. Paine, J.G. Millar

Department of Entomology, University of California, Riverside, California, USA

The eucalyptus longhorned borer, *Phoracantha semipunctata* F., was first discovered in Southern California in 1984 and continues to expand its distribution. The adult beetles are attracted to fallen eucalyptus branches, freshly cut wood, and even living trees. On these hosts the males compete aggressively for mates, and larger males have a reproductive advantage. Females deposit eggs under loose bark and the larvae mine along the cambium.

Eucalyptus species vary greatly in their resistance to borer attack, and adult *P. semipunctata* show an oviposition preference for species that are the highest quality hosts for their larvae. Resistance of living trees is strongly affected by environmental factors. In particular, moisture availability influences host resistance; turgid bark of healthy trees presents a physical barrier to colonization by borer larvae. Trees under water deficit are attractive to the adult beetles and vulnerable to attack by the larvae. Because eucalyptus in California are commonly of susceptible species and occur in poor growing conditions, the borer is a serious and economically important pest.

16-016

INTRODUCTION OF NATURAL ENEMIES FOR
BIOLOGICAL CONTROL OF THE EUCALYPTUS
LONGHORNED BORER (COLEOPTERA:
CERAMBYCIDAE) IN CALIFORNIA

T. D. Paine, J. G. Millar, L. M. Hanks, Q. Wang
Department of Entomology, University of California,
Riverside, CA USA

An encyrtid egg parasitoid, *Avetianella longoi*, and four braconid larval parasitoids, *Syngaster lepidus*, *Callibracon limbatus*, *Jarra phoracantha*, and *Jarra maculipennis*, have been imported into California from Australia and established in rearing colonies for mass production and release. Releases of *A. longoi* and *S. lepidus* have been conducted in coastal and inland areas and it appears that *A. longoi* has become established in several sites. This parasitoid can be reared in large numbers in laboratory colonies; female fecundity is ca. 200 eggs and development from egg to adult takes < 17 days at 25 °C. Females are very efficient at finding suitable beetle egg masses in the field with a mean parasitism rate of >90%. There are indications that *S. lepidus* has also established in at least one site but research releases of the larval parasitoids will continue to be made. Progress is slower with the larval parasitoids than with *A. longoi* because of more labor-intensive rearing procedures, longer developmental times, and more difficult field detection and evaluation methods. Once the natural enemies are established, the combined effect of improved cultural management of established trees, planting of more resistant *Eucalyptus* species, and biological control should reduce the amount of tree mortality caused by the beetle.

16-018

PESTS AND DISEASES IN PLANTATION *EUCALYPTUS*:
A GLOBAL PERSPECTIVE

Michael J. Wingfield
Tree Pathology Cooperative Programme, Department of Microbiology
and Biochemistry, University of the Orange Free State, P.O. Box 339,
Bloemfontein 9300. South Africa

The intensive propagation of various *Eucalyptus* species as exotics in plantations is a growing trend in many parts of the world. Currently, in excess of 8 million hectares have been planted to these trees outside their native range. These plantations have thus become a major source of timber and particularly pulpwood, internationally. Numerous insect pests and diseases have resulted in serious losses to these plantings in many parts of the world. These include both pests that are known to occur on eucalypts where they are native, and others that are endemic to areas where these trees are being planted as exotics.

All indications are that losses due to pests and diseases in plantation eucalypts will continue to increase substantially in the future. Many factors will contribute to this situation which, in the longer term, will significantly complicate the propagation of these trees. New introductions of pests and pathogens are being recorded regularly. This trend will most likely continue due to increased international trade and tourism and the difficulties associated with the application of effective quarantine. Fascinating examples are also beginning to emerge, where relatively host specific pathogens of other myrtaceous genera have apparently adapted to virulence on *Eucalyptus*. These "new" pathogens not only threaten exotic plantation trees, but also *Eucalyptus* species in their native range. In this presentation, I will outline examples of these emerging trends that, in my view, not only threaten commercial forestry, but also global forest biodiversity.

16-017

CONTROL OF THE EUCALYPTUS SNOOT BEETLE
GONIPTERUS SCUTELLATUS GYLLENHAL IN
CALIFORNIA BY THE EGG PARASITOID *ANAPHES*
NITENS (GIRAULT) (COLEOPTERA:
CURCULIONIDAE - HYMENOPTERA: MYMARIDAE).
J.G. Millar, L.M. Hanks, and T.D. Paine.
Department of Entomology, University of California,
Riverside, California, U.S.A.

The Eucalyptus snout beetle *Gonipterus scutellatus* Gyllenhal is a serious pest of Eucalyptus in many areas of the world. It was first detected in California in spring of 1994, and, as in other countries, it spread quickly from the original site of infestation. A biological control program was rapidly developed, using the egg parasitoid *Anaphes nitens* (Girault), with the first parasitoid releases occurring in early fall of 1994. One year later, densities of all life stages of the beetle at release sites had decreased dramatically, to the extent that beetles were difficult or impossible to find. Furthermore, defoliation levels had decreased from greater than 80% before releases to less than 10%, and are still dropping. Further work in 1996 will concentrate on releasing parasitoids at new sites of infestation. The high efficiency of the parasitoid and its rapid deployment once beetle populations were detected may prevent the beetle from becoming a serious pest in California.

16-019

POTENTIAL ROLE OF ENTOMOPATHOGENS IN THE
CONTROL OF EUCALYPT DEFOLIATORS.

J. Madden, and V. Patel.
Cooperative Research Centre for Temperate Hardwood Forestry,
Hobart, Tasmania, Australia

Commercial utilization of *Eucalyptus* spp. is a major component of the Australian rural economy. Historically, commercial eucalypts have been defoliated by a complex of leaf feeding beetles and moths which results in reduced growth and yields and delayed harvest.

Current control relies on the use of insecticides which, though effective, destroy natural enemies and other biota. Furthermore, aerial spraying of forests adds to public concerns about human health and the environment.

We report on the natural occurrence of entomopathogenic nematodes and fungi as components in the natural biocontrol of paropsine chrysomelids and the potential deployment of strains of local *Beauveria* and exotic *Metarrhizium* as biocides for the control of adults and larvae of a major pest, *Chrysophtharta bimaculata*.

16-020

CONTROL OPTIONS FOR THE LEAF BEETLE, *CHRYSOPHTHARTA BIMACULATA* (OLIVIER) (COLEOPTERA: CHRYSOMELIDAE) IN EUCALYPT PLANTATIONS IN TASMANIA

H.J. Elliott, J.A. Elek, R. Bashford
Forestry Tasmania, Hobart, Australia

The leaf beetle, *Chrysophtharta bimaculata* is a major defoliator of eucalypts in Tasmania causing significant reduction in growth rates and poor tree form. The current control strategy relies on monitoring of pest populations, predation by a suite of natural enemies and aerial spraying of synthetic pyrethroids to keep larval populations below an economic threshold. Biological, silvicultural and genetic options are being investigated in order to achieve more effective and environmentally benign control of this pest.

Microbial agents, particularly *Bacillus thuringiensis* var. *tenebrionis* (*B.t.t.*) have some potential for replacing synthetic pyrethroids in control programmes. *B.t.t.* is effective against eggs and young larvae and prescriptions for aerial spraying operations have been developed. However, *B.t.t.* has no effect on adult *C. bimaculata* which account for considerable defoliation. Investigations into the use of *Eucalyptus regnans* and *E. delegatensis* as trap trees within plantations of the more commercially favoured *E. nitens* have shown that populations of *C. bimaculata* can be concentrated on the trap species. Some provenances and families of *E. nitens* have been found to be less susceptible to defoliation and appropriate genetic selections may reduce the impact of this pest in the longer term.

The integration of these control options into an improved management strategy for *C. bimaculata* is discussed.

16-022

EXPANSION OF THE RANGE OF *LYMANTRIA DISPAR* IN NORTH AMERICA: ECOLOGY AND MANAGEMENT

A.M. Liebhold, A.A. Sharov¹

Northeastern Forest Experiment Station, USDA Forest Service, Morgantown, WV USA - ¹ Department of Entomology, Virginia Polytechnic Institute and State University, Blacksburg, VA USA
The gypsy moth was accidentally introduced near Boston in 1869 and since then has been expanding its range through much of northeastern North America. Because the gypsy moth is highly polyphagous, it is likely to become established in nearly all forested portions of North America but outbreaks will likely occur in less than half of these areas. The expansion of the gypsy moth's range can be attributed to three population processes: reproduction, short distance dispersal by 1st instars, and long-range dispersal of various life stages caused by humans. Analyses of historical data indicate that the rate of gypsy moth spread in North America has increased over the last 100 years; spread is currently occurring at about 20 km/yr. A large program designed to evaluate the feasibility of slowing the spread of this insect using a barrier zone is currently being tested. Results to date indicate that this program has been at least partially successful in slowing gypsy moth spread.

16-021

GENETIC VARIATION OF THE GYPSY MOTH, *LYMANTRIA DISPAR* COMPLEX (LEPIDOPTERA: LYMANTRIIDAE)

P. Arduino, L. Bullini, R. Prota¹, M. Verdinelli²

Dipartimento di Genetica e Biologia Molecolare, Università di Roma "La Sapienza", via Lancisi 29, I-00161 Roma, Italy - ¹ Istituto di Entomologia Agraria, Università di Sassari, via E. de Nicola 1, I-07100 Sassari, Italy - ² Istituto di Ricerca sul Controllo Biologico dell'Ambiente, C.N.R., I-07100 Sassari, Italy.

Isozyme variation and genetic relationships among populations of the *Lymantria dispar* complex, having different geographic origin, were electrophoretically analyzed on the basis of 32 loci. Samples from Japan were found to be genetically more variable (average $H_c=0.13$) than those from Europe (average $H_c=0.09$) and North America (average $H_c=0.04$). The low values of Nearctic populations reflect founder effects involved in their origin. Populations from Europe and North America (*L. dispar dispar*) were genetically homogeneous (average Nei's $D=0.01$). The Japanese samples from Hokkaido (*L. dispar hokkaidoensis*) and northern Honshu Island (*L. dispar* subsp.) were more differentiated showing a D from *L. dispar dispar* of 0.09 and 0.10 respectively. A high genetic distance ($D=0.25$) was estimated between *L. japonica* (from central Honshu) and all the *L. dispar* samples tested. Lab crosses between these two taxa showed that their reproductive isolation is only partial; therefore *L. dispar* and *L. japonica* should be considered as semispecies. The evolutionary relationships among the members of the *Lymantria dispar* complex are analyzed and discussed.

16-023

ADULT REPRODUCTIVE BEHAVIOR OF ASIAN GYPSY MOTHS, *LYMANTRIA DISPAR* L. (LEPIDOPTERA: LYMANTRIIDAE)

R.T. Cardé, R.E. Charlton¹, W.E. Wallner²

Department of Entomology, University of California, Riverside CA USA - ¹ Department of Entomology, Kansas State University, Manhattan KS USA - ² Northeastern Forest Experiment Station, USDA Forest Service, Hamden CT USA

The reproductive activities of the Asian gypsy moth were studied in the Russian Far East, Central Siberia and Germany, where this strain has recently been detected. The timing of male Asian gypsy moth attraction to synthetic pheromone has a bimodal pattern: most males are attracted in the afternoon, but a second, smaller peak of activity occurs after sunset. Daytime temperature modulated the timing of daytime attraction but did not alter the timing of the onset of attraction following sunset. Female eclosion and mating also followed a bimodal pattern: a midmorning to midday peak followed by a smaller afternoon peak. These bimodal patterns allow temporal coordination of the male's ranging flight and the availability of emerging and pheromone-emitting females. These patterns of attraction and the similarity of mating behaviors suggest that the Asian, European and North American strains should interbreed freely in areas of contact or new sympatry.

Following daytime mating and before egg deposition, females usually flew from their mating site at dusk when the light level fell to ca. 1 lux. A few females, however, delayed their departure to the dusk of the second night following mating.

16-024

ECOLOGICAL EFFECTS OF *LYMANTRIA DISPAR* IN NORTH AMERICA

R.M. Muzika, Northeastern Forest Experiment Station, USDA Forest Service, Morgantown, WV USA

Forests in eastern North America have been highly disturbed for over two centuries. In addition to anthropomorphic related disturbance, major catastrophic events like chestnut blight (*Cryphonectria parasitica*) have changed the composition and structure of the hardwood forest. The introduction of *Lymantria dispar* over a century ago has also resulted in pronounced changes in these forests. The genus *Quercus* dominates many forests in eastern North America, and as the preferred host of *Lymantria dispar*, a possible loss of dominance could be possible. However, data suggest that *Quercus* still maintains a presence in much of the forests of eastern North American, although at smaller scales, such as stand level, *Quercus* may disappear entirely. Generally, the changes caused by *Lymantria dispar* have more to do with affecting successional rate than species shifts. In three example areas: New England, the mid-Appalachians, and Michigan, *Lymantria dispar* appears to increase the rate of succession, accelerating species replacement processes, competitive relationships, and altering the relative species contribution, but having a minor effect on the overall species composition.

16-025

LYMANTRIA DISPAR : REGULATORY CONCERNS AND RESEARCH NEEDS
D.G. McNamara,
EPPO, 1 rue Le Nôtre, 75016 Paris, France

For more than one hundred years, *Lymantria dispar* has been spreading and causing serious forest damage in north-eastern United States. During that period, the species has been of minor concern throughout its natural range in Europe, only causing local and occasional damage at the southern extremes of oak forests. In recent years, there have been increasing reports from the USA and Canada about a possible "Asian strain" of *L. dispar* being introduced from the Russian far east, with a wider host range, more aggressive behaviour and, most obviously, females capable of sustained flight. These reports have stimulated European countries to enquire whether such a strain might present a risk to European forests and to ask whether it has already been introduced to Central Europe.

A study of European literature on *L. dispar* indicates that the characteristics of the so-called "Asian strain" have long been known to occur in European populations, and recent RAPD-PCR analyses of European and Asian populations suggest that no new introductions have taken place. For the moment, therefore, the situation regarding *L. dispar* in the palaearctic regions appears to be unchanged and European countries do not see the need to adopt new quarantine measures. However, there is an urgent need to understand the characteristics of different populations and their geographic distribution in both the palaearctic and nearctic regions.

16-026

MANAGEMENT OF FOREST INSECTS IN PORTUGAL

Maria Rosa Paiva

New University of Lisbon (UNL), Faculty of Sciences and Technology (FCT),
P - 2825 Monte de Caparica, Portugal

In Portugal forest ecosystems extend over 1/3 of the country and forestal industries make a significant contribute to the GNP. The main trees present are the cork oak, *Quercus suber*, the holm oak *Q. rotundifolia*, pines mainly *Pinus pinaster* and *P. pinea*, and eucalyptus, particularly *E. globulus*. Frequent insects to be found on oaks are, among others, the lepidopters *Lymantria dispar*, *Tortrix viridana*, *Malacosoma neustria*, *Eruproctis chrysorrhoea* and the buprestid *Coroebus bifasciatus*. Due to causes which are briefly analysed, insect population management is not intensively undertaken. In pine stands the processionary moth *Thaumetopoea pityocampa* is endemic, and outbreaks occur frequently. "Secondary" bark beetles, mainly *Tomicus piniperda*, *Ips sexdentatus* and *Orthotomicus erosus*, are sometimes recorded attacking standing trees, particularly in the vicinity of areas struck by fire. Cultural practices are normally undertaken, while pheromone baited traps have been used for research purposes only. Economic damage is caused to eucalyptus plantations by the borer *Phoracantha semipunctata*, against which control measures rely upon the use of trap trees. In 1991, a new species of an Encyrtid was discovered in Portugal. This rather efficient egg parasite has been cultered and small scale releases conducted. Another exotic pest, the curculionid *Gonipterus scutellatus*, has recently entered the country. In general, only small scale management of forest insect pests is practised. Although biological and biotechnological control methods look promising, in most cases the knowledge required for its implementation is still found in an incipient stage. To a certain extent, natural control by parasites and predators is in operation, probably as a result of a parsimonious use of insecticides so far made in forestry in Portugal.

16-027

A STRATEGY FOR FOREST HEALTH: ECOSYSTEM-BASED PREVENTIVE PEST MANAGEMENT

E. Führer

Institut für Forstentomologie, Forstpathologie & Forstschutz, BOKU Wien, Austria

In countries, where organized forest management systems have a long tradition, also knowledge of the sources of pest problems in manmade forests has early developed. Nevertheless, forestry concepts frequently neglected the principles of safety for economical reasons, thus being forced to apply pest control methods by which rather the symptoms of instability were suppressed than were its roots eliminated. The strategy of modern forest protection should be directed to a general prevention against the risks of pest epidemics. Therefore, detailed guidelines for a forest management aimed at risk reduction must be established, based on a profound knowledge of insect epidemiology.

It seems there to be a crucial prerequisite to thoroughly understand the causative principle of predisposing / eliciting factors. This would us enable to identify and localize risky situations in advance. Pest monitoring could then be focussed to such areas and forest management could specifically take care of concepts directed to damage prevention. The limitation of forest economy by ecological facts could be more precisely determined, quantified and from a longterm perspective considered in the planning procedures of forestry.

Assessment and manipulation of the epidemic-related predisposition of forests require intensified studies into the host plant / herbivore / antagonist tritrophic interactions as well as research into the ecosystemic processes by which they are determined. Thus, forest entomology should not only concentrate its interest on this topic; it also should link itself closer to forest ecosystem research. This could considerably contribute to a better understanding and counteracting of pest problems in forests under changing environmental and economical conditions.

16-028

FOREST PEST MANAGEMENT IN THE UK

D. Wainhouse
Forestry Commission Research Station, Farnham, UK.

Commercial forestry in the UK is dominated by non-native conifers, plantations which contribute only 24% of our annual softwood timber requirements. Minimising the risk of pest introduction on imported timber and studying the ecology of native insects on non-native trees have therefore been important themes in the ecology and management of forest insects in the UK.

Current issues in Plant Health will be discussed in relation to Pest Risk Analysis using *Ips typographus* and *Lymantria dispar* as examples.

The management of an introduced pest will be illustrated by *Dendroctonus micans*, emphasising the importance of internal quarantine, surveys, tree resistance and biological control by an introduced predatory beetle. The possible use of kairomones to monitor for the establishment and distribution of the predator will be discussed.

Defoliating Lepidoptera will be used to illustrate the problem of managing native pests that have adopted non-native plantation trees as hosts. The role of site and stress factors in affecting tree susceptibility and the significance of variability within insect populations will be considered.

16-030

MANAGING FOREST INSECT PESTS IN THE UNITED STATES:
CHANGING ATTITUDES AND PRIORITIES

M.L. McManus, D.B. Twardus¹

USDA-Forest Service, Northeastern Center for Forest Health Research, Hamden, Connecticut USA - 1 USDA-Forest Service, Forest Health Protection, Morgantown, West Virginia USA

Although the complex of bark beetles and defoliators that affect U.S. forests has not changed substantially, there has been a significant shift in how these pests are perceived and what actions should be taken to mitigate their impact. More emphasis is being directed at managing forest ecosystems rather than specific forest pests, recognizing that the disturbance caused by insects, diseases, and their interactions with environmental factors affects the health and stability of forests. There is much concern about the introduction of exotic pests and how increased international trade and travel might exacerbate this threat.

In the 1990s, the southern pine beetle, *Dendroctonus frontalis* Zimmerman (Coleoptera: Scolytidae), and the gypsy moth, *Lymantria dispar* L. (Lepidoptera: Lymantriidae) continue to challenge forest managers and property owners and are the subject of suppression and/or eradication projects on state and federal lands. The status and impact of these pests, and current approach to their management will be discussed in detail.

16-029

INTEGRATED CONTROL OF THE SPRUCE WEB-SPINNING SAWFLY, *CEPHALCIA ARVENSIS* PANZER IN ITALY, WITH PARTICULAR REFERENCE TO THE SILVICULTURAL ASPECTS (HYMENOPTERA: PAMPHILIIDAE)

A. Battisti, L. Masutti

Istituto di Entomologia agraria, Università di Padova, Italy

The spruce web-spinning sawfly *Cephalcia arvensis* caused a large outbreak in the period 1985-1992 in two areas of the Venetian Prealps (N-E Italy), concerning about 1,200 ha of 70 to 80-year-old plantations of Norway spruce (*Picea abies*).

Climatic, pedological, and silvicultural factors seem to be predominant among the possible causes of the outbreaks. In fact it has been possible to point out that: 1) the period 1983-1986 was in both areas unusually hot and dry, especially during the developmental time of the pest (June-July); 2) a strong water stress occurred in the three years preceding the outbreaks; 3) inside each area, the distribution of the insect attack was not uniform, reflecting the variability in soil conditions and in stand density.

The relationships between these factors and the insect attack may be interpreted in two complementary ways: 1) lower mortality and faster development of the insect induced by favourable climatic conditions (high summer temperatures and lack of precipitations); 2) variation in food quality as a consequence of the water stress suffered by the trees, according to the soil features and the stand density.

The IPM program applied against the pest was based on the following steps: 1) monitoring of adults, especially males, with visual traps and sampling of prepupae in the soil, 2) set-up of life tables and identification of key-factors of mortality, 3) definition of tolerance level of the pest according to the number of expected adult emergences, 4) direct control on the whole attacked area by preventing adult females to climb the trees by means of sticky bands put around the trunk of every tree. This control method allowed to reduce from 54 to 71% the number of eggs laid on treated trees with respect untreated ones. Two additional experiments were conducted on small plots using an insect growth regulator insecticide against larvae in the foliage and four strains of entomogenous nematodes against the prepupae in the soil. Two nematode strains gave mortality percentages around 50% and look promising for future applications.

16-031

FOREST INSECT PEST MANAGEMENT IN CANADA: PAST, PRESENT AND FUTURE

I.S. Otvoš and L. Safranyik

Natural Resources Canada, Canadian Forest Service, Victoria, B.C., Canada

There are about 119 million hectares of forest land in Canada managed for timber production. Most of the stands are in the Boreal Forest zone. The recognition of insect problems, and how these problems were addressed, is generally reflected in the intensity of forest management practiced. The native and introduced insect pest species were treated differently. Specific examples are given for the past and current insect management methods, and general trends are described for the future.

Up to the middle of this century no control measures were attempted unless the insect outbreaks covered extensive areas. This meant that the main focus of the earliest control measures were aimed at highly damaging bark beetles and defoliators. The methods used were suppression techniques, mainly the use of hard chemicals for defoliators, and burning and salvage logging for bark beetle-infested stands.

Classical biological control was, and still is, used against pests of foreign origin which were introduced into Canada without their natural enemies. Inspection and eradication are used to prevent or delay establishment of exotic pests.

At present, with the forest landbase and timber supply shrinking, there is a shift towards more intensive forest management. This change is reflected in methods of control - attempts are made to manage insect pest problems before drastic measures are required to control them. This change is also noticeable in the way insect problems are addressed. Besides defoliators and bark beetles in mature stands, insects attacking regeneration and affecting cone and seed production are also of concern. It is recognized that insect damage and its impacts should be minimized in an ecologically sound and environmentally friendly manner. Insects are managed instead of being suppressed, and whenever possible an integrated approach is taken. Broad spectrum chemicals have been replaced by the more selective microbial insecticide for defoliators. Silvicultural manipulation and pheromone-based management are currently being investigated as a means to minimize the impact of bark beetles.

In the future, attempts will be made to prevent insect problems before they have a chance to develop. The approach will be more holistic and ecologically based, taking into account other interactions besides those between the host tree and insect species. The control agents used to manage forest insects are likely to have narrow activity ranges - a requirement likely to be demanded by the environmentalists and general public. This will increase the pressure on scientists to develop novel control agents (such as genetically engineered microbes or introducing insect pathogenic microbes into host trees). However, some of these novel approaches are not likely to gain general acceptance, and the trend may be to manage forest insects through increasing the health of the forest.

16-032

MANAGING ATTACK BY BARK AND AMBROSIA BEETLES (COLEOPTERA: SCOLYTIDAE) IN FIRE-DAMAGED *PINUS* PLANTATIONS AND SALVAGED LOGS IN SOUTH-EAST QUEENSLAND

F.R. Wylie, M. DeBaar, J. King, C. Fitzgerald, B. Peters
Department of Primary Industries Forestry, Brisbane, Australia

In late 1994, bushfires in the Beerburrum area north of Brisbane damaged 8688 hectares of pine plantations (mostly *Pinus elliottii*, *P. caribaea* and *P. taeda*). A volume of 660,000 m³ of timber was considered salvagable. Large scale salvage operations were commenced quickly in order to minimise damage by the established exotic bark beetle *Ips grandicollis* Eichhoff and associated sapstaining fungi. The bark beetle began attacking fire-damaged trees 6 weeks after the fire and was significant in most areas at 10 weeks. Sapstain caused by *Ips* became significant at the completion of a life cycle of the insect (about 4 weeks in summer). Losses caused by *Ips* and sapstain during this phase were estimated at several million dollars Australian, most of this in privately-owned plantations where salvage was delayed for several months.

Salvaged timber is stored on a 34 hectare site at Beerburrum under water spray to inhibit degrade of logs by insect and fungi. Serious attack of the logs by the ambrosia beetle *Xyleborus perforans* (Wollaston) and decay fungi has occurred one year after the storage commenced. The circumstances associated with the insect attack and management options are discussed in this paper.

16-034

INSECTS AND MITES CAUSING GALLS ON THE LEAVES OF MAPLE *ACER PSEUDOPLATANUS* L. IN POLAND

M. Skrzypczyńska

Department of Forest Entomology, Academy of Agriculture, Kraków, Poland

In the years 1994-1995 studies were conducted on the leaves of *Acer pseudoplatanus* L. in the Ojców National Park in Poland. Studies included a total of 4000 leaves randomly collected from 40 trees /100 leaves from each tree/. The species composition of galls was similar in both years. *Aceria pseudoplatani* /Corti//Acar., Eriophyidae/ turned out to be the most numerous species in both years, namely 2637 individuals and 3659 indiv. respectively. Index of occurrence frequency /F/ for the two years reached the highest value in *A. pseudoplatani*, namely 1.252 and 1.829 respectively, and the lowest in *Dasineura vitrina* /Kieffer/ /Dipt., Cecidomyiidae/ 0.013 in 1994. On the basis of Agrell's index of species coexistence it was shown that the strongest bond existed between *Driscina glutinosa* Giard /Dipt., Cecidomyiidae/ and *A. pseudoplatani*.

16-033

THE IMPROVED MANAGEMENT OF FOREST INSECT PESTS IN POLAND

B. Glowacka

Forest Protection Department, Forest Research Institute, Warsaw, Poland

Pest insects are one of the major threats to the forests in Poland. They occur at various intensity in all stand age classes. Seedlings are attacked by *Melolonthinae* especially in plantations established at former agricultural lands. *Curculionidae* is the other group of pest in plantations and *Hylobius abietis* is the most common species. In mature stands *Hymenoptera* and *Lepidoptera* larvae as well as secondary pests mainly *Ips typographus*, *Tomicus piniperda* and *Phaenops cyanea* occur in the outbreaks.

Until recently pyrethroids have been used on a large scale in pest management. At present the quantity of pyrethroids is greatly reduced. Pheromone traps are applied as a protective measure against *H. abietis*. Recent research has shown that the application of the fungus *Phlebiopsis gigantea* to the stumps at clear-cuttings does not only protect trees against root rot but also inhibits the development of the *H. abietis* larvae in the stumps.

In the control of defoliators the *B.t.* products are used against the *Lepidoptera* and diflubenzuron against *Hymenoptera* pests. Secondary pest are reduced mainly by the removal of colonized trees and by the captures of *I. typographus* and *T. piniperda* beetles in feromone traps. Chemical insecticides are still applied to soil against white grubs and studies are carried out to develop biological methods for the control of that group of pests.

16-035

DESCRIBING THE NATURAL HISTORY AND ASPECTS OF THE ECOLOGY OF *CINARA CUNEOMACULATA* (APHIDINA; STERNORRHYNCHA)

J. Dagg & St. Scheurer

Institute of Environmental Analysis and Human Toxicology, Berlin, Germany

Cinara cuneomaculata (DELGUERCIO) is a lachnid tended by ants. It colonizes young shoots of the larch (*Larix decidua*). In 1995 the population-maximum was in August/September as typical for this species. It derived from annual sequence of generations and coherent fluctuations of abundance. The annual growth pattern of the host plant correlated with this late population-maximum.

A preview is given setting the results in relation to climatic change, year-ring structure of the host plant and larch-honeydew honey yields.

16-036

MORPHOLOGICAL DIAGNOSIS, DISPERSAL AND SEASONAL DYNAMIC OF *CINARA PRUINOSA* HARTIG (APHIDINA (LACHNIDAE)) SUCKING ON *PICEA SP.* IN BERLIN - BRANDENBURG DURING 1992 - 1995

K. Bauer-Dubau¹, St. Scheurer²

- 1) Stadtmuseum Berlin, Abteilung Naturwissenschaft, Germany
- 2) Institut of Environmentanalytic and Humantoxicology, Berlin, Germany

Cinara pruinosa lives throughout the year on different spruce trees (*Picea abies*, *P. bicolor*, *P. excelsa*, *P. pungens*, *P. schrenkiana*, *P. smithiana*, *P. sylvestris*) in Berlin - Brandenburg and reaches high density levels (600 - 1100 individuals on trees up to 2 m height). New results will be introduced about the morphological characteristics, the preferred sucking-places and the seasonal dynamic of *C. pruinosa* living on different species of *Picea*. Observations of direct visit of *Apis mellifera*, *Bombus hortorum*, *B. pratorum*, *B. terrestris* and *Paravespula germanica* indicate that *C. pruinosa* becomes more significant as a possible supplier of honeydew for Hymenoptera as assumed till now. Furthermore experiments with rings of glue demonstrate that the dependance of ants (*Lasius niger*, *L. fuliginosus*) of *C. pruinosa* is more important as assumed up to now.

16-038

Bark and ambrosia beetles of Costa Rica, density and occurrence with respect to distribution of major host trees in the La Selva Biological Station reserve.

Karl H. Thunes and Lawrence R. Kirkendall

Institute of Zoology, University of Bergen, Norway

In conjunction with a major rain forest inventory projecy being conducted in northeast Costa Rica, we are carrying out a finer scale studies of the relationship of resource quality (host species) and resource abundance to the community structure of wood-boring beetles (Scolytidae, Platypodidae). In 1994 and 1995, trunk sections (baits) of totally eight species were placed out in primary and secondary rainforest, an abandoned cocoa plantation and a managed polyculture of native trees (replicates of each set of baits). After 25 days on the forest floor, they were mounted in rearing bags for approx. four months to collect the offspring beetles. More than 40,000 specimens of Scolytidae and Platypodidae emerged from the baits. There were considerable differences in emergence patterns, both within each habitat and between forest types. Fine-scale distribution of the species shows that most species aggregate substantially, with five species making about 90% of the total. The numbers are related to resource input as estimated by density/area of host trees.

16-037

THE IMPACT OF APHIDS ON THE GROWTH OF SITKA SPRUCE (*PICEA SITCHENSIS* (BONG.) CARR.) IN UPLAND BRITAIN.

N.A. Straw, N.F. Fielding, G. Green, A. Waters

Entomology Branch, Forestry Commission Research Division, Alice Holt Lodge, Wrecclesham, Farnham, UK

Sitka spruce is the most important timber producing tree in north and west Britain and over 530 000 ha have been planted with this species in upland areas. These plantations are prone, however, to defoliation by green spruce aphid (*Elatobium abietinum* Walker) (Homoptera; Aphididae) and infestation by root-aphids (*Pachypappa* and *Pachypappella* spp.) (Homoptera; Pemphigidae), and both types of aphid have the potential to reduce spruce productivity.

In 1992, the UK Forestry Commission started a long-term, manipulative field experiment in a recently re-planted area of Hafren Forest, Wales, to obtain quantitative information on the impact of aphids on spruce growth and to assess the economic consequences of damage. The experiment comprises four treatments in which insecticides are used to exclude *E. abietinum* or root-aphids separately or in combination, and a fifth treatment where *E. abietinum* populations are raised artificially. The influence of aphids on tree increment is estimated by comparing the performance of infested and uninfested trees.

Natural aphid populations have been low since 1992 and have had no significant effect on tree growth (n=180 trees), but *E. abietinum* on trees inoculated artificially in April 1994 (n=45 trees) attained densities 33 times higher, reaching, on average, 19 aphids.100 needles⁻¹ by June. This caused 41% of the 1991-1993 needles to fall prematurely, and led to a 22% reduction in leader shoot growth (p<0.001) and a 10% reduction in shoot growth on the upper whorl (p=0.013) by the end of the year. Total tree height was 12% shorter at the end of 1994 compared with naturally infested and sprayed trees (p<0.001). Results from 1995 indicate similar growth losses in the second year after defoliation.

16-039

STUDIES OF THE INTRASPECIFIC VAFIATIONS IN *TRICHOGRAMMA DENDROLIMI*, A MAJOR BIOLOGICAL CONTROL AFENT AGAINST THE PINE MOTHS IN CHINA

LIU Shu-sheng, SHI Zu-hua, HE Jun-hua

Department of Plant Protection, Zhejiang Agricultural University, Hangzhou, China

Trichogramma dendrolimi is a widely distributed and the most frequently utilized parasitoid against forestry insect pests in China. Intraspecific variations of the parasitoid have long been speculated as one of the major factors responsible for its variations in control efficacy. In this study, 12 stocks of the parasitoid, collected from five species of *Dendrolimus* and 12 localities from 22°N to 43°N in China, were established. Comparative experiments of the following aspects were conducted between the stocks to reveal possible intraspecific variations: (1) 72 different combinations of cross trials between the stocks were conducted and revealed no evidence of reproductive isolation among the stocks. (2) Comparison of performance under a wide range of climatic conditions showed all the stocks responding similarly to favorable and high temperatures. However, the northern stocks performed better than the southern ones after cold storage. (3) Under some diapause induction conditions, the rates of diapause were significantly higher in the northern stocks than in the southern ones. (4) No significant differences were detected in the ability of host discrimination among the stocks. (5) When eggs of 6 host species were arranged into various host combinations and exposed to 11 of the stocks, no significant differences, either in host preference or host suitability, could be detected between the stocks. These results as a whole suggest that the populations of *T. dendrolimi* across China still remain one well defined species, but some intraspecific variations have occurred. Howcver, the observed variations were generally low and sometimes unstable, it is as yet difficult to take them into practical considerations in the utilization of this parasitoid.

16-040

THE INTRODUCTION OF *PAUESIA JUNIPERORUM* (STARY) (HYMENOPTERA: BRACONIDAE) INTO MALAWI FOR THE BIOLOGICAL CONTROL OF *CINARA CUPRESSI* (BUCKTON) (HOMOPTERA: APHIDIDAE)

C.Z. Chilima¹, S.T. Murphy², G.S. Meke¹

1 Forestry Research Institute of Malawi, Zomba, Malawi - 2 International Institute of Biological Control, Ascot, Berkshire, UK.

From 1986, the cypress aphid, *Cinara cupressi* (Buckton) was reported causing extensive damage to exotic and native cypress stands in Malawi. Since 1991, the Forestry Research Institute of Malawi (FRIM), with technical support from the International Institute of Biological Control (IIBC), has been undertaking a classical biological control project against the pest; this project forms part of a wider integrated pest management project funded by the British Overseas Development Administration.

In 1994 and 1995, the parasitoid *Pauesia juniperorum* Stary, collected from western Europe and screened at IIBC, UK, was shipped to Malawi for rearing and direct field release. The field releases were made in cages containing aphid ingested branches during the months August to early October. Parasitoids released in 1994 did not establish. However, in 1995, females released in cages provided a large number of progeny with an evenly balanced sex ratio. These were allowed to disperse naturally from the cages. Regular branch samples taken later in the year indicated that the parasitoid had dispersed several hundred meters from the cages. Mean parasitism on branches was 48 per cent.

16-042

THE IMPACT OF *PHYTOLMYA LATA* INJURY ON GROWTH AND BIOMASS ACCUMULATION OF IROKO (*MILICIA EXCELSA*)

J.R. Cobbinah and J. Appiah-Kwarteng

Forestry Research Institute of Ghana

Kumasi, Ghana.

The Iroko gall fly, *Phytolmya lata* is the most important limiting factor to the establishment of Iroko plantations in Subsaharan Africa. We studied the effect of *P. lata* injury during Iroko early development on dry matter accumulation and partitioning. Losses in components of growth and dry matter accumulations were measured monthly and at the end of 18 months.

Overall, compared with control plots, growth of infested plots were significantly reduced. Plants infested were significantly shorter, had smaller number and smaller sized leaves. Average height and girth of the infested plots were reduced by 52% and 30% respectively. Dry weights of stem, branches and leaves were significantly greater in uninfested plots than in infested plots. Reductions in dry matter accumulations and partitioning at 18 months were 68.93% for stem, 48.32% for branches and 64% for leaves. Foliage of infested plants were highly chlorotic. We conclude that *P. lata* injury has significant effect on growth and biomass accumulation in the early development of Iroko plants.

16-041

ECOLOGICAL VARIABILITY IN THE POPULATION OF CURCULIONID PESTS OF FOREST PLANTATION (CURCULIONIDAE: COLEOPTERA)

D. KUMAR

Department of Zoology, Govt. College for Girls, Sector 42, Chandigarh, India.

The curculionids form an important part of the phytophagous beetles and are associated with a variety of flora. A large number of curculionids are pest of forest trees of economic importance like *Tectona*, *Dalbergia*, *Eugenia*, *Pinus*, *Mangifera*, *Quercus*, *Shorea*, *Bombax*, *Ficus*, *Acacia*, *Tamarix*, *Cassia*, etc. The study has been made by observing the type of flora, of different regions for working out the possible co-relation of the concerned species with biotic and abiotic factors. Sympatric and Allopatric occurrence of the species has shown promising relationships which are likely to be proved extremely useful in establishing ecological patterns of distribution.

The various aspects which were studied to correlate their ecological characteristics with behavioural patterns pertaining to the amount of host plant range, seasonal prevalence, fecundity, development and population structure will be highlighted.

16-043

WOODWASP NATIONAL CONTROL PROGRAM IN BRAZIL

E. T. Iede

EMBRAPA - Empresa Brasileira de Pesquisa Agropecuária

CNPq - Centro Nacional de Pesquisa de Florestas

Colombo, Brazil

Brazil has about 6 million ha of forest plantations of which 2 million ha consist of *Pinus* spp. Most of these stands were planted with a small number of species at high density and inadequate forest management. In 1988 an outbreak of *Sirex noctilio* Fabricius was recorded in Rio Grande do Sul State. It is present in 200,000ha, and is also advancing on Santa Catarina and Paraná States. The use of biological control is the best measure to control *S. noctilio*. The most effective agent is *Deladenus siricidicola* Bedding, a nematode that sterilizes the females. In 1989, it was bred by the PROGRAMA NACIONAL DE CONTROLE A VESPA-DA-MADEIRA (PNCVM). This programme is broad in scope and also includes: the early detection and monitoring of the spread through the use of trap trees and ground inspections, and the adoption of preventative measures, through adequate forest management. Plans for the future include the introduction of the parasitoid wasps *Rhyssa persuasoria* (L.) and *Megarhyssa nortoni* (Cresson) to compliment the nematode and the parasitoid *Ibalia leucospoides* (Hochenworth).

16-044

THE ROLE OF AIR AND SOIL POLLUTION IN THE DEVELOPMENT OF INSECT OUTBREAKS IN FORESTS

P e k k a N u o r t e v a
Environmental Protection, Helsinki University,
Finland

Forest declines of a new type have occurred in many countries in Europe and Northern America. It has been debated, whether these are caused by pests or by pollution. In practically all cases insect pests or fungal diseases have been dominantly present and give sufficient reason for forest decline. The pollutant levels have only rarely reached such a degree, where trees have been damaged in experimental exposition. The conclusion has been drawn that pests are killing the forests, not the pollutants.

This conclusion may, however, be an oversimplification. The damage is clearly worst in the nearest vicinity of polluting industries and intensity of forest damage is regionally in clear positive correlation to pollution. Historically, forest declines have increased simultaneously with human population and industrialization.

It is possible to assimilate the contradictory thinking of forest entomologists and environmentalists. It is only necessary to accept the fact that pollutants and strong silvicultural measures may diminish the pest resistance of trees to a degree where a pest outbreak is released. In fact this has been known by forest entomologists for several decades. It is important to realize that insect outbreaks represent only the final phase of a multistress syndrome.

16-046

DEFOLIATION-INDUCED INCREASE IN WILLOW LEAF FLUCTUATING ASYMMETRY REFLECTS LOW FOLIAGE QUALITY FOR *MELASOMA LAPPONICA* (CHRYSOMELIDAE)

E.L. Zvereva, M.V. Kozlov, E. Haukioja
Laboratory of Ecological Zoology, University of Turku, Turku, Finland

We studied the interaction between the leaf beetle, *Melasoma lapponica*, and willow, *Salix borealis*, in the surroundings of the large nickel-copper smelter in NW Russia. Although foliar Ni reached 250 µg/g and ambient SO₂ - 250 µg/m³ near the smelter in 1994, growth, reproduction and leaf fluctuating asymmetry (FA) of willow did not indicate pollution-induced stress. However, moderate pollution ameliorated foliage quality in 1993, as indicated by higher survival of larvae fed with leaves from moderately polluted plots. This alteration of host-plant quality contributed to an outbreak of *M. lapponica* in moderately polluted sites, whereas in both heavily and slightly polluted habitats, beetle density was consistently lower. By the end of the growing season of 1993, *S. borealis* was almost completely defoliated in moderately polluted sites for the first time since we started our observations in 1989. During the following year, we recorded increases in leaf FA of *S. borealis* in the outbreak plots. Since FA in these plots was at the background level in 1992, before an increase in beetle density was observed, we considered the increase in FA as a response to defoliation. Willow leaf quality in the outbreak sites was lower in 1994 than in 1993, as indicated by higher mortality of beetle larvae, lower fecundity of adults and lower fertility of eggs. This decrease in host-plant quality was correlated with an increase in leaf FA. Accordingly, changes in plant quality caused by severe herbivore damage (a biotic stress) could be assessed by measuring FA, a non-specific stress indicator. We conclude, that our insect-plant system fits the Plant Vigour Hypothesis and possesses self-regulatory mechanisms based on negative feedbacks: plants stressed by herbivory are poorer quality hosts for the next generations of herbivores.

16-045

EFFECTS OF AIR POLLUTION IMPACT ON THE POPULATION DYNAMICS OF THE LESSER SPRUCE SAWFLY, *PRISTIPHORA ABIETINA* CHRIST (HYMENOPTERA: TENTHREDINIDAE)

E. Führer, R. Berger, Ch. Schafellner, A. Schmied, A. Xandner

Institut für Forstentomologie, Forstpathologie & Forstschutz, BOKU Wien, Austria

Pristiphora abietina is a severe pest of Norway spruce in plantations situated outside the natural range of the host tree. Causes of its outbreaks are mainly sought with faults of forest management, but also air pollution impact is suspected of triggering its epidemics. Theoretically, food chain balance at various points is vulnerable by pollutants. The results of field and laboratory studies strongly support the hypothesis that air pollution impact ranks with the factors which influence the population dynamics or even potentially provoke epidemics of this insect.

There is good evidence of food quality improvement by increased nitrogen supply to the host plant, partially by shifting the protein / phenolics ratio in the young needles, thus influencing larval growth. Sulfur concentration in the foliage obviously affects the mortality of the early larval instars, which - apart from the coincidence of bud break with oviposition - is in line with the degree of damage on the trees. Acidification of the soil contributing to the development of lots of needle litter, improves the resting conditions for the cocoons in the ground, thus reducing nymph mortality. Significant mortality factors attacking the resting nymphs in their cocoons are pathogenic fungi. Their efficiency is affected by the traits of soil litter and by the effects of heavy metals accumulated in the fungi. Finally, the deposition of sulfate and ammonium ions to the ground cover may be toxic for cocoon parasitoids.

In the light of these findings the persisting epidemics of *P. abietina* in spruce plantations appear as the result of combined environmental effects, the both being anthropogenic: forest management and air pollution.

16-047

DISAPPEARANCE OF MASS APPEARING PHYTOPHAGOUS INSECTS ON THE EXAMPLE OF PINE MOTH *Dendrolimus pini* L. (Lepidoptera, Lasiocampidae)

Malyshev D.S.
Biological Research Institute of St.-Petersburg University, Russia

At present a number of mass phytophagous insects become rare and disappearing. One of them Pine moth. Its vast outbreaks in Western Europe were stopped in the beginning of a current century, in East Europe - in a middle of a current century, in Siberia tend cessation at present. The displacement of outbreaks for east and their termination is connected to loss of the primary stands Scotch pine, having by a maximum stock of the needles. As have shown our researches, its complete disappearance connected with anticipatory fall of the needles called acid deposits. At loss more than 10 % falling Pine moth is absence. It is saved in the primary stands in common with enthomophages (Malyshev, 1994). The complete absence of a mass phytophagous species conceals in self the following dangerous phenomena. Clearing of a ecological niche of the consumers of the needles; ii Increase of threat of outbreaks as insects, as other organisms; iii Infringement forest successions. Thus, the complete absence of mass appearing phytophagous insects is result further disintegration of forest ecosystems. The prevention it can be served by measures on reduction anthropogenous press and preservation species diversity of forest ecosystems.

16-048

ACCUMULATION OF METAL POLLUTANTS IN RED WOOD ANTS, THEIR INFLUENCE ON THE COLONY DEVELOPMENT AND USING OF ANTS IN THE BIOINDICATION

A. - J. Martin, P. Nuorteva¹

Institute of Plant Protection, Estonian Agricultural University, Tartu, Estonia

¹ Department of Limnology and Environmental Protection, University of Helsinki, Helsinki, Finland

Considering environmental conservation and biomonitoring, it is important to note that some functional groups of red wood ant workers are loaded with the highest content of metal pollutants found among boreal forest animals (Nuorteva, 1990). The highest content of metal pollutants was recorded in all studies among foragers (outside workers) in the red wood ant colony. In artificial feeding experiments of ant colonies with metal contaminated honey (500 mg CdCl₂ per 1 kg honey) showed the rise of metal content of foragers up to 75 mg/kg Cd/dry wt. Extremely high metal content (up to 73.4 mg/kg Cd) was recorded also in foragers in a polluted industrial and mining areas of Europe (Stary, Kubiznakova, 1987). For comparison, in unpolluted Estonia and Finland regions this parameter was only 7,1 mg/kg, still lower Cd content was determined in reserve ants. Negligible amounts were found in females, males and in the brood, 0,1 - 0,25 mg/kg both in unpolluted and in polluted areas and in artificial fed colonies. Detail analyse of artificial fed ant colonies showed that Cd and Hg compounds inhibit the activity of enzymes participating in ATP synthesis (Migula et al., 1993) on which the formation of energy stores and the development of newly emerged workers into reserve ants is directly based. Therefore the lack of reserve ants in observed nests was to be expected. Particularly low level of metal compounds in brood and in sexuals gives evidence of the ability of the ant colony to protect their offspring through filtering poisons in the sociobiological food chain. Ants possess systems of physiological and sociobiological poison tolerance. This is one of the features offering singular possibilities of better survival for social insects, especially in the conditions of the superstructures like supercolonies.

The highest content of pollutants in foragers is very important appearance for using of red wood ants in the bioindication of environment pollution level especially in forest biocoenoses, whereas a red wood ant colony collect a lot of aphid honeydew and prey food during summer period (active season). **Through colony food chain also pollutants from vegetable and prey food accumulate during lifetime mainly in the foragers as eldest polyethic group of ants.** It is relatively easy to estimate by the help of foragers the pollution level of forest biocoenoses. It would be cheap express method for estimation of environment pollution situation

16-050

MOLECULAR AND PHYSIOLOGICAL BIOMARKERS IN INSECTS AS THE TOOLS IN ENVIRONMENTAL HAZARD ASSESSMENT

P. Migula

Department of Animal and Human Physiology, University of Silesia, Katowice, Poland

The use of biomarkers in environmental pollution enables monitoring of stress responses, ranging from biochemical to community levels. The biomarker is defined as a biological response to chemical(s) that allows to measure its exposure and toxic effects. A good bioindicator system should be based on well recognised and combined methods developed in laboratory and later validated in the fields. Among biochemical biomarkers inducible detoxification enzymes with a low level of specificity (MFO, glutathion S-transferases) are good measures of specific stress factors. The use of patterns of enzymes involved in energetic transformations, metallothioneins or lipid peroxidation are better for evaluating pollution hazards from heavy metals. On the organism level changes in energy-yielding substrates and in the adenine nucleotide pool, with the adenylate energy charge are useful indicators of sublethal stress.

Weak and target points in the functioning of the temperate zone forest ecosystems under multistress from industrial pollution are well recognised. Among them small soil-dwelling arthropods, ants, carnivorous insects or spiders are of a special importance. Since measures on a molecular level are useful in monitoring for effects or exposure before alterations in the population or community level are recognised, their validity in environmental assessment are undoubted. Advantages and disadvantages as well as constraints in the use of biomarkers exemplified on social insects, herbivorous insects and spiders will be presented in details. Data obtained in laboratory conditions on insects exposed to controlled stressing factors could not be easily transferred to the field conditions. Biomarkers studied in ants receiving controlled excess of metals in natural conditions provided more information on that matter and made easier the extrapolation of individual biomarkers to the field monitoring at a community level.

16-049

DENDROCHRONOLOGICAL INDICATION OF RESISTANCE OF PINUS ELДАРICA MEDW. TO DIORICTRYA SPLENDIDELLA H-S (LEPIDOPTERA, TORTRICIDAE) IN GEORGIA

K. Sarajishvili

The Georgian National Committee of Unesco program "Man and the Biosphere" (MAB), Academy of Sciences, Tbilisi, Republic of Georgia

It was made comparative dendrochronological study of two adjacent pine stands plots damaged and undamaged by *D. splendidella*. As a rule the separate trees and the damaged stands are forming wide year tree rings and containing the more resin canals in the one tree ring. The plants of rapidly growing stimulation by watering or planting on rich moisture soil cause the formation of the wide year rings and damage such trees by *D. splendidella* on 80-90%. After stopping the watering or when the main root run through the rich stratum soil deeply, the tree year rings become narrower and the pest starts gradually leave such trees and plots, and already don't settle on them.

Putting forward the conception of *P. eldarica* resistance depending on annual growth as a genetic property.

16-051

THE ROLE OF FOREST ENTOMOLOGY IN THE PROTECTION OF THE GLOBAL ENVIRONMENT

Pekka Nuorteva

Environmental Protection, Helsinki University, Finland

Environmentalists have the task to protect the life supporting machinery of nature. Forests play an essential role in the functions of that machinery. The task of the forest entomologists is to prevent such human activities, which reduce the resistance of trees against their arthropod pests.

Forest insect calamities, promoted by environmental pollution and overdimensioned silvicultural practices, have caused forest deaths and decline on a local and regional scale. A danger of even more extensive damage is possible, because insects represent in nature a really mighty force. Their species diversity and biomass are superior to all other systematical categories of animals. If the damaging potential of insects is released in full, the result may be really horrible.

It is not safe nor rational to try to control insect calamities when they have already broken out. Prevention of such human activities, which have the capacity to promote outbreaks of pests, is a much safer method. Prevention needs, of course, a much deeper knowledge than the control of outbroken calamities. Here, in this congress, we have arranged two sessions in order to clear up the basis for the anthropogenic promotion of insect population outbreaks.

16-052

EDGE EFFECT IN THE DISTRIBUTION OF FOREST INSECTS AND ITS SIGNIFICANCE IN MONITORING AND SAMPLING

A. Gourov, V. Tagliapietra¹, A. Battisti¹
V. N. Sukachev Institute of Forest, Siberian Branch of the Russian Academy of Sciences, Krasnoyarsk, Russia - ¹ Istituto di Entomologia Agraria, Università di Padova, Padova, Italy
Edge effect in the distribution of some gall-forming, phyllophagous, xylophagous and conophagous insects was studied across the larch forest/alpine meadow ecotone (Monte Bondone, Trentino, Northern Italy) and spruce forest/calcareous meadow ecotone (Bosco del Cansiglio, Veneto, Northern Italy) in 1993-1995. The occurrence of concrete species and ecological groups of dendrophagous insects was recognized by the numbers of damaged "food units" (1-year shoots, buds, cones, percentage of grazed and sucked needles) or by the numbers of "nests" (for *Epinotia tedella*, *Cephalcia arvensis*, and *Laspeyresia pactolana*) and galls (for *Sacchyphantes abietis* and *Laspeyresia zebeana*). It was shown that the damage by nonspecialized phytophagous insects was concentrated on young trees in meadow positions not far from the forest border, while specialized pests damaged the inner forest trees in near-border positions more intensively. In many cases, higher damage was not registered on the border-line trees exactly but into the limits of a more or less wide transition zone between forest and meadow. In this zone, all the types of damage occurred, although some of them were absent on core forest trees or on the isolated trees in meadow positions. Some insect species were probably attracted to border conditions (e.g. *D. abietella*, *L. zebeana*), while others avoided border trees and increased their abundance in core habitats (*S. abietis*, *C. arvensis*), or did not show noticeable preference (*E. tedella*, *L. pactolana*). During the period of observations, the last two species were characterized by relatively high population density. A practical conclusion is that both monitoring and sampling of forest pests at low population density have to take into account the general pattern of insect abundance across the forest border.

16-054

BLUE-STAIN FUNGI VECTORED BY AGGRESSIVE AND NON-AGGRESSIVE BARK BEETLES (COLEOPTERA: SCOLYTIDAE)

P. Krokene, H. Solheim
Norwegian Forest Research Institute, Ås, Norway
Bark beetles are generally regarded as forest pests, but only a very small proportion of the 5,800 species in the world are aggressive and can kill healthy trees. Most species are non-aggressive, and colonize dead trees (saprophagic species) or severely stressed or dying trees (facultatively parasitic species). We have studied the blue-stain flora of several Eurasian bark beetles that colonize Norway spruce, including the aggressive *Ips typographus* L., the facultatively parasitic *I. duplicatus* Sahlb., *Pityogenes chalcographus* L. and *Polygraphus poligraphus* L. and the saprophytic *Hyurgops palliatus* Gyll.
I. typographus and *I. duplicatus* carried very high frequencies of the phytopathogenic fungus *Ceratocystis polonica* (Siem.) C. Moreau. The other bark beetles carried no known pathogens. We mass-inoculated Norway spruce with the fungi most frequently isolated from the beetles (*C. polonica*, *Ophiostoma piceae* (Münch) P. Sydow, cfr. *Ambrosiella* sp. and Dark sterile sp.A). *C. polonica* was the only fungus that stained the sapwood 15 weeks after inoculation (56% of cross-sectional sapwood area). It induced five times longer phloem necroses, 21 times more necrotic cambium and 11 times more necrotic phloem than any other fungus. These results are consistent with the hypothesis that aggressive bark beetles are associated with more phytopathogenic fungi than other bark beetles.

16-053

INVESTIGATIONS ON THE LIFE HISTORY OF *NEMOSOMA ELONGATUM* L. (COLEOPTERA: OSTOMIDAE), A BARK BEETLE PREDATOR

C. Dippel
Freie Universität Berlin, Institut für Zoologie, Angewandte Zoologie/Ökologie der Tiere, Berlin, Germany
The ostomid beetle *Nemosoma elongatum* is a common and widely distributed predator of bark beetles. The larval and adult stages prey on various scolytid species. In Central Europe the main prey species are the coniferous bark beetle *Pityogenes chalcographus* and the beech bark beetle *Taphrorychus bicolor*. *N. elongatum* uses the aggregation pheromones of the scolytids to locate prey. Therefore this antagonist was found in high numbers in bark beetle pheromone traps, especially in Chalcoprax baited traps. Detailed investigations on life history were initiated as a preliminary step in determining the role of this species in natural bark beetle regulation. In laboratory embryonic and postembryonic development depended on temperature and averaged 70 days at 25/15°C. Prey consumption of the *N. elongatum* larvae was approximately 30 bark beetles per individual. The adult longevity averaged 3 to 5 months and mean fecundity was 64 eggs per female at 20/10°C. At this temperature one *N. elongatum* individual consumed one bark beetle adult per day on average. Due to these data this predator species must be considered as an important and effective antagonist of bark beetles. The suitability of *N. elongatum* for biocontrol of bark beetles is discussed.

16-055

IPS TYPOGRAPHUS : EVIDENCE OF PASSIVE MOVEMENT TOWARDS OVERWINTERING SITES

J.-C. Grégoire, A. Drumont, N. De Windt
Laboratoire de Biologie animale et cellulaire, Université Libre de Bruxelles, Belgium
A proportion of the populations of *Ips typographus* overwinters into the bark of attacked trees, whilst the remaining part overwinters in the litter at the base of the trees. From samplings made during the winters 1991-92 and 1992-93 in several localities of southern Belgium, a strong correlation was established between the numbers of overwintering individuals per litter sample, and the weight of infested bark present in the sample. This suggests that the beetles have passively moved into the litter with falling pieces of infested bark. Repeated samplings on the same sites showed that this process continued throughout the winter. Management implications are discussed.

16-056

SELECTION CUTTINGS AND POPULATION DYNAMICS OF THE SPRUCE BEETLES IN HOKKAIDO

K. Iguchi, H. Yamamoto, K. Furuta¹

University Forest in Hokkaido, The University of Tokyo, Furano Hokkaido, Japan-1 Department of Forestry, The University of Tokyo, Bunkyo Tokyo, Japan

After selection cuttings in Hokkaido, the spruce beetle (*Ips typographus japonicus* Nijima) attacks and kills standing spruce trees.

We studied the relationship between selection cuttings and the attacks of beetles for more than 10 years. Over five years we collected spruce beetles with pheromone traps at the same three places in the forest and investigated the relationship between selection cuttings and trap catches.

(1) Total number and the seasonal distribution of trap catches at the same place differed among years. However, in the year when the largest number of beetles were captured and which were large in body weight, not many trees were killed. (2) The number of beetles captured by traps in places where selection cuttings had taken place increased in the years after cuttings. (3) At log depots in the forest where cuttings had been done, a large number of newly emerged beetles were captured in the summer for several years after cuttings. Combined with other studies on the populations of spruce beetles, monitoring using pheromone traps will bring us some important information on the population dynamics of spruce beetles.

16-057

THE SUCCESSION OF BARK BEETLE DIVERSITY IN WINDTHROW AREAS

B. Wermelinger, M. Seifert, P. Duelli

Swiss Federal Institute for Forest, Snow and Landscape Research WSL, Birmensdorf, Switzerland

In three Swiss windthrow areas of the 1990 winterstorm "Vivian" the development of the scolytid beetle complex was monitored. Each experimental area, formerly forests of mainly spruce trees, was divided into a cleared and an uncleared plot. Results of window trap catches from 1991 to 1994 are presented.

In the uncleared windthrows, there was an average augmentation of the species number by almost 50 % and a more than 6-fold increase of the number of individuals during the two first years after the storm. Thereafter, species as well as individual numbers decreased. Cleared areas exhibited the same species dynamics, but individual numbers steadily increased, though at a low level.

Compared to the situation in an adjacent intact forest, species numbers in the windthrow areas were always higher. Species and individuals in the uncleared treatment always outnumbered those in the cleared plots and the forest.

The most frequent species in all years was *Pityogenes chalcographus* (thereby causing no damage in adjacent forests, in contrast to *Ips typographus*). The proportion of species living on broadleaf trees decreased with time.

Generally, the Shannon-Weaver diversity index showed an increase with time. No differences were found between clearing treatments. Diversity was lowest in the intact forest.

16-058

INSECT COLONIZATION ON EXOTIC VS NATIVE FOREST PLANTATIONS: THEORETICAL CONTENT AND EMPIRICAL EVIDENCE

M.R. Wagner, J.D. Nichols, T.E. DeGomez, S.S. Mann¹¹School of Forestry, Northern Arizona University, Flagstaff, AZ, 86011 USA

Forest entomologists have long argued that plantations of exotic tree species are more prone to attack by native insects than are native tree species. Theoretical ideas on the rates of species colonization on novel plants are discussed. A review of the literature indicates that exotic tree species often have lower colonization by indigenous insects. This pattern is examined across a gradient from tropical to temperate forests. Colonization of exotic tree species by native insects requires considerable adaptation and consequently may require many decades to complete. The implications of these findings to the use of exotic tree species is discussed.

16-059

EXPERIMENTATIONS OF BIOLOGICAL CONTROL OF FOREST DEFOLIATORS WITH BACTERIAL PREPARATIONS

G.Mihuleache¹; C.Ciornei¹; T.Roman²; D.Lupu³)

1) Forest Research Institute - Bucharest

2) AgrEvo Company - Bucharest, Romania

3) Romsilva - Bucharest, Romania

The laboratory tests carried out by using the bacterial preparations - Ecotéch-Pro and Dipel-8L demonstrated the different sensibility of the caterpillars of *Lymantria dispar* and *Tortrix viridana* depending on the outbreak phase of both defoliators.

In the field conditions, the aerial spray with ULV treatments assured a high efficacy (96-98%), if is applied an optimal dose and is established the most favorable moment of treatment.

16-060

ASSESSMENT AND MONITORING PINE CATERPILLAR DEFOLIATION WITH AIRBORNE VIDEO

Tiansheng Li

Research Institute of Forest Protection, Chinese Academy of Forestry, Beijing, China

Monitoring forest health with airborne video was developed by the USDA Forest Service for recent years. The airborne video system consists of two components-an airborne video image acquisition components and a video image processing component. Videography offers many advantages: lower cost than ground methods, higher accuracy than sketch mapping, and easy handling by users, meanwhile, the video data can quickly be converted to a digital form for analysis.

In China, monitoring pine caterpillar (*Dendrolimus punctatus* W.) defoliation in Jiangshan County, Zhejiang Province and suburbs of Nanning City, Guangxi Zhuang Autonomous Region using Y5 aircraft, combining video camera system with GPS navigation. The flying height is from 597m to 1900m, depending on the topography condition. The clear images were acquitted not only under clear weather but also under overcast weather. After video imagery has been captured on type, it can be viewing on monitor in Lab and processing using MIPS system. The results indicated that the 50% defoliation can be detected, the resolution is 1m to 2m. The combined use of GPS, GIS, and airborne video can provide geo-referenced spatial information about insect damage, and forest health managers are able to use it to detect and monitor forest pest over large area.

16-061

NANTUCKET PINE TIP MOTH, *RHYACIONIA FRUSTRANA* (COMSTOCK) (LEPIDOPTERA: TORTRICIDAE) SITE AND STAND RELATIONSHIPS IN EAST TEXAS

D. L. Kulhavy¹, W. G. Ross¹, J. Sun², J.R. Meeker³
College of Forestry, Stephen F. Austin State University, Nacogdoches, TX USA - 1 Northeast Forest University, Harbin, CHINA - 2 Division of Forestry, State of Florida, Gainesville, FL USA - 3

Site and factors were evaluated to explore the relationship of the Nantucket pine, *Rhyacionia frustrana* (Comstock), stands of loblolly pine, *Pinus taeda* L., ranging in age from 2 to 5 years. Variables affecting infestation rates included depth of the soil A horizon; depth to the clay layer for rooting depth; height of pine; age of pine; and a ratio of the depth of the A horizon and soil texture. A series of discriminant function equations were developed to assist in evaluation of site and stand factors affecting Nantucket pine tip moth infestations.

Soil amendments of nitrogen and phosphorus and applications of herbicides affected Nantucket pine tip moth in two ways: applications of phosphorus tended to reduce tip moth infestations, although the sites were phosphorus-deficient; nitrogen tended to either slightly increase or have no effect. Herbicides provided a host that was more visible and these pines tended to have increased infestations. Infestation rates were related to site and stand factors and management of these areas should incorporate soil factors, tree species, time since planting, regeneration methods and soil and tree amendments.

16-062

A PRELIMINARY SURVEY FOR OCCURRENCE AND SPREAD OF THE PINE WOOD NEMATODES *BURSAPHELENCHUS* SPP AND THEIR POSSIBLE VECTORS IN PINE FORESTS IN ITALY

V. Francardi, T. Irdani, L. Ambrogioni, F. Pennacchio, S. Caroppo
Istituto Sperimentale per la Zoologia Agraria, Firenze, Italy.

A survey has been performed in Italy for pine wood nematodes of the aerial parts of pine trees to verify whether the quarantine organism *Bursaphelenchus xylophilus* (Steiner & Buhner) Nickle or other species of the genus are present.

Samples were obtained by removing portions of pine stems in an advanced state of decline or which had been dead for no more than a year. Among cerambycid species found on pine woody material collected, *Monochamus galloprovincialis* Olivier resulted until now the only carrier of nematodes. Data on the biology of this long-horned beetle in Central Italy as well as on its distribution are presented.

In all sampled areas of our country no specimens of *B. xylophilus* were found. *Bursaphelenchus mucronatus* Mamiya & Enda has been found associated with *M. galloprovincialis* adults and inside the wood of *Pinus pinaster* Ait. in three localities of Liguria; *Bursaphelenchus leoni* Baujard inside the wood of *P. pinaster* (Ravenna), *Pinus pinea* L. (Livorno) and *Pinus halepensis* Miller (Foggia); *Bursaphelenchus sexdentati* Rühm on *P. pinaster* (Ravenna). Italian populations of *B. mucronatus*, reared in malt extract agar plates on *Botrytis cinerea* Pers. ex Nocca & Balb., were examined by LM and SEM. DNA extracted from five pine wood nematode populations identified as *B. mucronatus* (Italy and France) and as *B. xylophilus* (Japan, USA, Canada) were compared by the random amplified polymorphic DNA technique (RAPD) based on the polymerase chain reaction (PCR).

16-063

DIVERSITY OF ICHNEUMONIDAE ASSOCIATED WITH GYPSY MOTH *LYMANTRIA DISPAR* IN DECIDUOUS FORESTS OF OHIO, USA (LEPIDOPTERA: LYMANTRIIDAE)

D. J. Horn¹, S. E. Teraguchi², F. F. Purrington¹

¹ Department of Entomology, The Ohio State University, Columbus, OH USA - ² Cleveland Museum of Natural History, Cleveland, OH USA

Ichneumonidae have been collected from malaise traps in seven northeastern Ohio locations since 1989. The forests are predominantly mixed mesophytic hardwoods. The area has had a low density infestation by gypsy moth continuously throughout the sampling period. No significant defoliation has yet occurred, although three sites have been treated with *Bacillus thuringiensis* or gypsy moth nuclear polyhedrosis virus. Measurements of ichneumonid species diversity indicate greater consistency among sites within a single season than across several seasons. Ichneumonid species diversity displays a bimodal distribution with a major peak in early June and a second peak in August. Populations of genera that may parasitize gypsy moth (e. g. *Theronia*, *Pimpla*) appear to be stable from site to site and year to year. Application of virus or *B. thuringiensis* has had no discernible secondary impact on parasitoids, although *B. thuringiensis* had a significant impact on some nontarget Lepidoptera. This research has developed a useful baseline for ongoing studies of forest insect biodiversity in the midwestern USA.

16-064

GYPSY MOTH DEVELOPMENT ON FOLIAGE OF SEVERAL OAKS

A. Lentini¹, P. Luciano¹, V. Solinas², T. Nuvoli³, G. Pilo³

¹ Istituto di Entomologia agraria, Università di Sassari, Italy

² Di.S.A.A.B.A., Sez. Chimica agraria, Università di Sassari, Italy

³ Istituto Ricerca Controllo Biologico Ambiente, CNR, Sassari, Italy

Gypsy moth (*Lymantria dispar* L.) larvae obtained from egg-clusters collected in two sub-populations at different gradation phases (culmination and latency) were fed in laboratory, at temperatures from 25 to 29 °C, on leaves of cork-oak (*Quercus suber* L.), holm-oak (*Q. ilex* L.), and pubescent-oak (*Q. pubescens* Willd.). 200 larvae, in groups of 50 per cage, were reared for each sub-population on each oak species. Cork-oak produced greatest survival rate (85 and 75%, respectively for sub-population in culmination and in latency phase), fastest development (ca. 30 days for males and 35 for females in both sub-populations), heaviest pupae (0.54 and 0.57 g for males; 1.28 and 1.45 g for females), and highest fecundity (304 and 369 eggs/female). Pubescent-oak produced lowest survival (56.5 and 42.5% in the two populations), longest development (38 days for males and ca. 43 for females), lightest pupae (0.36 and 0.31 g for male; 0.66 and 0.57 g for females), and lowest fecundity (128 and 66 eggs/female). Holm-oak was intermediate in its effects. Chemical analysis of foliage collected i) at the start of larval rearing, ii) when the larvae was at III instar, and iii) at VI instar, demonstrated significative quantitative and qualitative differences in phenol component but not in emicellulose, cellulose and lignin contents. In particular, the phenols were about 2-times higher in cork-oak and holm-oak (ca. 12% of dry weight) than in pubescent-oak (6-7% of d. w.) in the first and in second sampling. Gallic, p-cumaric and ferulic acids were predominant in cork-oak and holm-oak, gallic and p-hydroxybenzoic acids in pubescent-oak. A positive correlation can be supposed between the fenolic content and the gypsy moth larval development and fecundity. These results can partially explain the different gypsy moth density variations in the principal Sardinian oak regions. Cork-oaks are susceptible to periodic defoliation occurring every 5-6 years in forests interspersed with pastureland, and every 8-9 years in forests with the typical Mediterranean undergrowth. On the contrary, gypsy moth population remains sparse and rarely causes severe defoliation in holm-oak and pubescent-oak forests.

THE INFLUENCE OF THE MINERAL NUTRITION OF *EUCALYPTUS* PLANTS ON THE ATTACK OF DEFOLIATING CATERPILLARS

S.S. Mello¹, R.L.V.A. Silveira², E. Berti-Filho¹, A.N. Gonçalves³

¹ Departamento de Entomologia, ESALQ-USP, Piracicaba, SP, Brazil ² Departamento de Ciências do Solo, ESALQ-USP, Piracicaba, SP, Brazil ³ Departamento de Ciências Florestais, ESALQ-USP, Piracicaba, SP, Brazil

This paper deals with the identification of different levels of boron on *Eucalyptus citriodora* plants which should influence the development of *Thyrinteina arnobia* (Lepidoptera, Geometridae).

The caterpillars were fed with *E. citriodora* leaves nutritionally characterized after different levels of boron and collected from the top and the bottom of the crown. The percentage of mortality of caterpillars fed with leaves from the bottom of the crown was higher than that of the caterpillars fed with leaves from the top the crown, probably due to the higher contents of boron on the bottom of the crown and consequently to the higher amount of phenolic compounds which act as growth inhibitor of insects.

16-066
ON THE RESPONSE OF *PHORACANTHA SEMIPUNCTATA* F. (COLEOPTERA, CERAMBYCIDAE) TO LOG TRAPS
L. Bonifácio, M. Serrão¹
CELPA-Associação da Indústria Papeleira, R. Marquês Sá da
Bandeira 74 1º Esq. 1000 Lisboa, PORTUGAL - 1 RAIZ-
Instituto de Investigação da Floresta e Papel, Apartado 15 2065
Alcoentre, PORTUGAL

Lacking long distance pheromones, *P. semipunctata* perception of released compounds from the eucalyptus is vital for susceptible host detection, matting and oviposition. Based on this assumption the most common control measure against *P. semipunctata* during adults flight season, from South Africa to Europe and South-America, is the use of log traps which are very expensive and labour intensive when correctly applied. The aim of this work is to improve its effectiveness through better understanding the beetle response to host stimuli, in isolated pure stands of *Eucalyptus globulus*. Known to be strong flyers the beetle reveals a highly significant upwind short distance flight pattern (within the range of trap influence) and a predominant downwind behaviour in longer movements, over 2 kilometers. The placement of log traps is discussed considering the wind direction, orientation, topography and tree coverage.

16-068
DISEASE INTERACTIONS IN GYPSY MOTH POPULATIONS IN SOUTHWESTERN VIRGINIA, USA
R. E. Webb, G. B. White, K. W. Thorpe, S. E. Talley¹
Insect Biocontrol Laboratory, Agricultural Research Service,
USDA, Beltsville, MD, USA - 1 Rockbridge Co., Virginia,
Gypsy Moth Program, Lexington, VA, USA

Southwestern Virginia is currently experiencing its first cycle of defoliation from the gypsy moth, which has recently invaded this area. As gypsy moth populations rise, natural enemies are moving into the area, including the gypsy moth nuclear polyhedrosis virus (NPV). NPV typically occurs at low levels until gypsy moth population rise; then, NPV becomes the dominant factor leading to gypsy moth population collapse. An intriguing new (to North America) disease of gypsy moth is the fungus *Entomophaga maimaiga* Humber, Shimazu, and Soper, which was introduced into SW Virginia by A. Hajek in 1991, and which is now widely established there. In 1995, we monitored gypsy moth populations in 33 woodlots near Lexington, VA, for the presence of the two pathogens. Gypsy moth populations in the woodlots varied from very sparse to high. Monitoring was most intense in the 5 blocks with the highest gypsy moth population density. Larvae were collected weekly, and those dying within 7 days were examined by light microscopy to identify the pathogen species involved. Also, burlap band larval counts were made weekly. The virus was strongly density dependent, being confirmed only from woodlots with higher density gypsy moth populations. In contrast, presence of the fungus was confirmed from gypsy moth cadavers found in woodlots containing sparse (less than 1 life stage found per burlap-band larval trap) gypsy moth populations. All higher density plots had extensive fungal induced mortality, but this failed to prevent a distinct second-wave NPV occurrence.

16-067
DEVELOPMENT OF MANAGEMENT PRACTICES FOR REDUCTION OF POPULATIONS OF THE INTRODUCED PEAR THRIPS, *TAENIOTHrips INCONSEQUENS* (UZEL) (THYSANOPTERA: THIRIPIDAE), IN SUGAR MAPLE FORESTS IN THE NEW WORLD
E. Alan Cameron, David A.J. Teulon¹, L.H. McCormick²
Department of Entomology, Penn State University, University Park, PA, USA - 1 (current address) Crop & Food Research, Christchurch, New Zealand - 2 School of Forest Resources, Penn State University, University Park, PA, USA

Sap obtained from sugar maple trees (*Acer saccharum*) is used annually to produce over 11,000,000 liters of maple syrup, valued in excess of \$US100,000,000. A single moderate or heavy defoliation of a sugar maple tree by the pear thrips, *Taeniothrips inconsequens* (Uzel) (Thysanoptera: Thripidae), a periodic defoliator, results in the loss of the equivalent of one year's sap production over the next three years. Populations of pear thrips, a species which also attacks other valuable species of hardwood trees in the northeastern United States and eastern Canada, are regulated primarily through synchrony between expansion of new buds on the trees, the occurrence of female flowers, and emergence of female thrips adults from their over wintering location in the soil. The use of biological agents such as parasitoids (e.g., *Ceranisus* sp.), nematodes, and fungal pathogens (e.g., *Verticillium* sp.) has been or is being investigated to develop, where possible, intervention techniques for purposes of control. Routine use cannot yet be recommended for any of these agents with assurance, but both *Ceranisus* sp. and nematodes are expected to contribute to successful management programs. Prescribed burning, in limited trials, shows promise as a manipulable abiotic factor for control.

16-069
MANAGEMENT AND CONTROL OF FOREST INSECT PESTS IN CHINA
Yang Zhong-qi, Hsiao Kang-Jou
Institute of Forest Protection, Chinese Academy of Forestry, Beijing, China

The structure of Chinese organizations dealing with the research and management and control of forest insect pests is outlined. Accordingly, conifer and broad-leaved tree species are harmed by about 60 species of important insect pests. The most destructive pests in northern China are two cerambycids, *Anoplophora nobilis* and *A. glabripennis*, and in southern China pine caterpillar, *Dendrolimus* spp. The main reasons for outbreaks of forest insect pests are analysed. Currently, the research and practice of IPM are considerably popular in China. Especially more attention are paid for not only the pest control, but also the biodiversity protection. Present pest-control methods include the use of high-effective and low-toxic insecticides, biological control with NPV, Bt, *Beauveria bassiana*, and parasitic wasps, e.g. *Chouioia cunea*, *Trichogramma dendrolimi* and *Coccobius azumai* (Hymenoptera, Chalcidoidea) and the beneficial birds, and silvicultural methods such as selective cutting, with planting mixed stands etc. .

16-070

INCREASING TREE SPECIES DIVERSITY TO IMPROVE THE PEST CONTROL BY NATURAL ENEMIES IN FOREST MONOCULTURES: AN ORIGINAL DEVICE.

H. Jactel¹, M. Goulard², J.Y. Rasplus³, C. Burban¹¹ Laboratoire d'Entomologie Forestière, INRA, Gazinet, France - ² Laboratoire de Biométrie, INRA, Montfavet, France - ³ Laboratoire de Génétique et Evolution des Populations, CNRS, Gif sur Yvette, France.

Regarding sustainable forestry, there is a growing concern that monospecific forest would experience more severe or more frequent decays. The large availability of host plants and the weakness of the natural enemies control would render forest monocultures more prone to insects attack. But evidence to support this widespread belief is inconclusive, mainly by lack of properly formulated experiments.

A field device was thus developed in the Landes of Gascony, the largest unit of monocultural forest in Europe (1.2 millions hectares of pure maritime pine stands). Artificial plantations of broad-leaved trees, strictly constant in species composition and density, were regularly distributed within two areas of 1000 hectares of pure pine stands. The potentialities of these experimental plots as new ecological niches for parasitoids and predators is evaluated by comparison to control pine plantations of the same sizes, age and density.

Geostatistical methods used for estimating plant-pest-natural enemies interactions are described. First results concerning natural enemies diversity and spatial distribution of *Dioryctria sylvestrella* rate of infestation, according to the distance from broad-leaved stands, are discussed.

16-071

WITHIN-TREE DISTRIBUTION OF INFESTATIONS OF THE PINE NEEDLE GALL MIDGE, *THECODIPLOSIS JAPONENSIS* UCHIDA ET INOUE (DIPTERA: CECIDOMYIIDAE)Y. J. Chung, J. H. Lee¹, B. Y. LeeDivision of Forest Entomology, Forestry Research Institute, Seoul, Korea
¹ Department of Agricultural Biology, Seoul National University, Suwon, Korea

Efficient sampling units for estimating infestations of pine needle gall midge, *Thecodiplosis japonensis* Uchida et Inoue, on individual trees was developed from data collected in young Japanese red pine, *Pinus densiflora* Sieb. et Zucc., stands in 1992-1995. Samples of terminal and lateral shoots taken from the upper, middle, and lower crowns of different tree height classes (<2m, 2 to 4m, 4 to 6m, >6m).

No significant differences of infestations were found between terminal and lateral shoots, and among height class of trees. However, percentage of galled needles per shoot increases from the lower crown to the upper, and leader shoots are generally three times more than lateral shoots of the lower crown. Terminal shoots of mid-crown proved superior as a representative of tree infestations.

16-073

TOMICUS PINIPERDA IN NORTH AMERICA: CURRENT STATUS AND FUTURE PROSPECTS

Robert A. Haack, Robert K. Lawrence

US Department of Agriculture, Forest Service, North Central Forest Experiment Station, East Lansing, Michigan, USA

There are more than 370 exotic forest insects now established in North America. The pine shoot beetle, *Tomicus piniperda* (Coleoptera: Scolytidae) is one of the most recent arrivals in North America, being first reported in the United States in 1992. Because of its potential to damage pines, a federal quarantine was implemented in 1992 that restricts movement of pine material (including pine Christmas trees, pine nursery stock, and pine logs with bark) from infested to uninfested areas in the United States and Canada. As of January 1996, *T. piniperda* was known to occur in 8 US states and 1 Canadian province.

We will report on the life history of *T. piniperda* in North America, its interactions with native *Ips* bark beetles, and the host suitability of several North American conifers for *T. piniperda* reproduction and shoot feeding. Host species in decreasing order of preference were: *Pinus*, *Picea*, *Pseudotsuga*, *Larix*, and *Abies*. We will also discuss the efficacy of different trapping techniques for survey and control programs.

Another topic to be addressed will be the potential release of the predaceous clerid beetle, *Thanasimus formicarius*. Clerids from France were shipped to the United States in 1995 and are now being reared in a laboratory in Michigan. Studies are underway to evaluate potential non-target impacts by the European clerid on native natural enemies of North American pine bark beetles, such as the native clerid beetle *Thanasimus dubius*. Results from these studies will be presented.

16-072

SUSCEPTIBILITY OF JAPANESE RED PINE TO INFESTATION BY PINE NEEDLE GALL MIDGE, *THECODIPLOSIS JAPONENSIS*, IN KOREA

B. Y. Lee, Y. J. Chung

Division of Forest Entomology, Forestry Research Institute, Seoul, Korea

The Japanese red pine, *Pinus densiflora*, is the main host-tree of the pine needle gall midge, *Thecodiplosis japonensis*, which is most threatening insect pest to pines in Korea. Methods of evaluating the midge damage are designed to provide information for detection, control, and preventive management, which based on the relationship between the damage levels and tree characteristics or stand/site variables.

The pine trees having narrow crown width and small crown volume in comparison with the stem volume were highly susceptible from the midge damage and it was considered due to insufficiency of sound needles for unit stem volume. The midge-caused tree mortality began to occur from the pine stands having 60 percent shoot mortality and increased rapidly from 80 percent. The major factors relating to the damage severity were ground covering with undergrowth, aspect, position of slope, stand density and slope. Comparative hazard-rating system of pine stands on the basis of shoot mortality were made by the discriminant analysis used the main environmental factors.

16-074

POPULATION DYNAMICS AND BEHAVIOUR OF THE
PROCESSIONARY MOTH *THAUMETOPOEA PITYOCAMPA*
(LEPIDOPTERA, THAUMETOPOEIDAE) IN PORTUGAL

Qing-He Zhang and Maria Rosa Paiva

New University of Lisbon (UNL), Faculty of Sciences and Technology (FCT / DCEA), P - 2825 Monte de Caparica, Portugal
In the Iberian Peninsula, outbreaks of the processionary moth *Thaumetopoea pityocampa* are frequently recorded. This insect poses the most important problem regarding the phytosanitary protection of pine ecosystems. Stands of the maritime pine, *Pinus pinaster*, and of the mediterranean pine *P. pinea*, located in two different geographic zones, in southern and central Portugal, have been monitored, and data on the population dynamics of *T. pityocampa* obtained. Particularly, rates of mortality and development of the different instars, were determined. The behaviour of the larvae was also analysed, with emphasis on intraspecific competition relationships. The main parasitic species were identified, and their impact on the life cycle of *T. pityocampa* evaluated. Preliminary life-tables for *T. pityocampa* in Portugal were prepared. Estimates of absolute population densities were conducted by counting larval nests and egg masses at different times of the year, and from adult catches with pheromone baited traps. The data obtained will be correlated with the rates of defoliation observed, and thus contribute to the improvement of management strategies for *T. pityocampa*.
If invited speaker, indicate title of session and name(s) of organizer(s):

16-076

PEST MANAGEMENT OF *TORTRIX VIRIDANA* (L.):
MONITORING POPULATIONS WITH PHEROMONE TRAPS
(LEPIDOPTERA TORTRICIDAE).
P.F. Roversi, M. Covassi, A. Binazzi, V. Francardi
Istituto Sperimentale per la Zoologia Agraria, Sezione di
Entomologia Forestale, Via Lanciola 12/A, Cascine del Riccio 50125
Firenze (I).

The green oak leaf roller (*Tortrix viridana* (L.)) is a serious forest defoliator widely spread in Eurasian regions, where its populations show temporary type outbreaks. A technique for monitoring populations trends based on the capture of males in traps would be a very valuable tool in the management of this pest.
Previous attempts carried out in Europe to use pheromone traps to provide information about the green oak leaf roller population density have yielded contrasting results and the potential of sex pheromone traps for providing an index of long term population changes, is not yet recognized.
For this reason from the last outbreaks found in Central Italy, populations of *T. viridana* have been monitored in Tuscany since 1986 in permanent sampling areas. The traps used were of the sticky type ("Traptest"). The different sampling areas have been combined in one cluster and the trend has been examined over a large area.
In this way the annual catches of males over a 10 - year period resulted well correlated with the egg-masses density in each subsequent year ($P<0,0001$; $r^2=0,722$). The strength of this relation suggest that the pheromone traps may be used to support the quantitative sampling technique.

16-075

DAY-DEGREE MODEL SHOWING EMERGENCE BY FOUR
SPECIES OF SEED CHALCIDS *MEGASTIGMUS SPP.*
(HYMENOPTERA: CHALCIDOIDEA)

P. OCHSNER

Department of Zoology, Institute of Biological Sciences, Aarhus
University, Aarhus, Denmark.

In Denmark four seed chalcids *Megastigmus pinus* Parfitt, *M. milleri* Milliron, *M. rafni* Hoffmeyer and *M. suspectus* Borries have been shown to infest seed of the four commercially grown firs: *Abies alba*, *A. normanniana*, *A. procera* and *A. grandis*. Emergence in the laboratory of the seed chalcids, was recorded at six different temperatures. Results were used to make a day-degree model, that can be used to predict the emergence of the seed chalcids in seed orchards or seed production stands. Emergence of seed chalcids in situ was found using emergence traps placed on the forest floor. These results show that seed chalcids emerge with about one week spacing between species in following order *M. milleri*, *M. pinus*, *M. suspectus* and *M. rafni*. In addition males are shown to be three or four days earlier than females.
Validity of the model is sought by comparing it with the in situ emergence data.

16-077

A MONITORING METHOD OF MOTH LARVAE (LEPIDOPTERA)
ON NORWAY SPRUCE BRANCHES
J. Kulfan, V. Šušlik
Institute of Forest Ecology, Slovak Academy of Sciences,
Zvolen, The Slovak Republic

In chosen monitoring sites ten terminal parts of branches (1 m long) are taken from the lower spruce canopy (up to 3 m) at the end of winter and then brought in plastic bags into the laboratory. Moth larvae or adults are obtained through photoelectors. After the branches dried up the weight and the number of all needles are determined.
This method possesses several advantages: a simplicity, a minimum impact on insect populations, a clearly defined phenological period, a repeatability of the methods and a comparability of the results. It also aims at obtaining all the species (pests as well as nonoutbreak species) occurring on spruce in this phenological period. Cutting off ten branches from each monitoring site every year and possible injury to moth larvae (especially those of Geometridae) in the course of handling the branches may be considered as its main disadvantages.
Argyresthia glabrata, *A. amiantella*, *A. bergiella*, *Batrachedra pimcolella*, *Chionodes electella*, *Dichelia histrionana*, *Pseudohermenias abietana*, *Epinotia nanana*, *Thera variata*, *Puengelera capreolaria* and *Hylaea fasciaria* are the most abundant and frequent species at the monitoring sites in the Pol'ana and Tatra Biosphere Reserves and the Malá Fatra National Park. The larvae burrowing in buds and shoots are more frequent at the sites in 1,000 m a.s.l. and higher. In contrast, the mining species are predominant at a lower elevation. The estimated number of needles on ten branches (one sample) was $517,623 \pm 112,689$ (mean value \pm standard deviation, $n = 52$).

16-078

PROTECTING LIVE DOUGLAS-FIR FROM INFESTATION BY THE DOUGLAS-FIR BEETLE USING AN ANTIAGGREGATION PHEROMONE

D.W. Ross, G.E. Daterman¹

Department of Forest Science, Oregon State University, Corvallis, OR USA - 1 USDA Forest Service, Pacific Northwest Research Station, Corvallis, OR USA

Studies over a four-year period demonstrated the efficacy of an antiaggregation pheromone, 3-methylcyclohex-2-en-1-one (MCH), for protecting live Douglas-fir, *Pseudotsuga menziesii* (Mirb.) Franco, from infestation by Douglas-fir beetle, *Dendroctonus pseudotsugae* Hopkins.

In 1992, MCH was applied to the perimeter of 1-ha circular plots at a rate of 60 g/plot. Multiple-funnel traps baited with frontalin, seudenol, 1-methylcyclohex-2-en-1-ol, and ethanol were located outside of but near the treated plots. The mean percentage of Douglas-fir host trees (≥ 20 cm DBH) that were mass-attacked was reduced by 80% within treated plots compared with untreated plots. However, there was a significant increase in the percentage of mass-attacked trees outside of the plots in the vicinity of the funnel traps. Therefore, in 1993, the efficacy of MCH alone was tested. The MCH was applied to plots ranging from 2.1 to 2.6 ha in size at rates of 45-76 g/ha. The percentage of host trees that were mass-attacked was significantly lower on the treated plots (0.2%) compared to the control plots (8.5%).

Dosage studies conducted in 1994 and 1995 determined that application rates as low as 20 g MCH/ha are effective in preventing infestation of high-risk trees.

16-080

THE POTENTIAL FOR INTEGRATED CONTROL OF *MINDARUS ABIETINUS* KOCH (HOMOPTERA:APHIDIDAE) IN *ABIES BALSAMEA* CHRISTMAS TREE PLANTATIONS.

P. K. Kleintjes. Department of Biology, University of Wisconsin, Eau Claire, WI USA.

Balsam fir comprises the majority of Christmas tree sales in the northeastern and midwestern United States. For growers, the balsam twig aphid *Mindarus abietinus* Koch is a major pest because it causes needle distortion and/or loss which prevents the sale of trees for up to three years after attack. To date, there are few systematic methods used to monitor aphids. Growers have been found to apply pesticides at times too late to control pest damage but on time to pose risk to beneficial insects and breeding birds. A monitoring system is now being developed for growers to predict if and when control is necessary to prevent economic damage. A randomized split-plot design incorporating whole plot variables (mowing/fertilizer, herbicide/fertilizer, legume intercrop and no treatment) with subunit variables (systemic insecticide, insecticidal soap, water and no treatment) is also being used to determine the influence of such variables on numbers of aphids and their natural enemies.

16-079

FEMALE REPRODUCTIVE BEHAVIOUR AND PHEROMONE MATING DISRUPTION IN THE EUROPEAN PINE SAWFLY, *NEODIPRION SERTIFER*, (HYMENOPTERA: DIPRIONIDAE)E. Östrand, R. Wedding, O. Anderbrant, E. Jirle
Department of Ecology, Lund University, Lund, Sweden

Females of the European pine sawfly, *Neodiprion sertifer* (Hymenoptera: Diprionidae) were released and observed in pine plantations treated with their sex pheromone, (2S,3S,7S)-3,7-dimethyl-2-pentadecanyl acetate, for the purpose of mating disruption, and in untreated areas within the same plantation. One experiment dealt with female reproductive behaviour and the other focused on the female's possibility to mate in areas treated with their sex pheromone (compared to untreated areas). In the first experiment, 30% of the females mated (n=127), during the release day in 1992 and 24% in 1993 (n=658). About 15% of the females mated more than once, and 4-9% of the females laid unfertilized eggs (parthenogenesis). About 55% of the females disappeared without having mated. After having mated, 60% of the females oviposited on the twigs, while 40% of the females disappeared. Predation was responsible for the majority of the disappearances, but also deliberate flight was noted.

In the mating disruption experiment about one third of the released females mated outside the treated area (n=258), but only 1-3% mated inside the area (n=295). About 50% of the females that mated stayed and laid their eggs on the twigs, and 50% of the females disappeared after mating. Significantly more females disappeared from their twig from inside the treated area than outside in both years. There was no difference in the proportion of unmated females ovipositing (2-12%) between the treatment and control. Possible different female reproductive strategies and the use of sex pheromone for mating disruption are discussed.

16-081

INTEGRATED MANAGEMENT OF *HYLOBIUS* WEEVILS IN POLAND

J. Skrzecz

Department of Forest Protection, Forest Research Institute, Warsaw, Poland

Weevils of the genus *Hylobius* are the most destructive insect pests of reforestation areas in Poland. There are four species of *Hylobius* recorded in Poland, but only *Hylobius abietis* (L.) and *H. pinastri* (Gyll.) have the economic importance in forest plantations.

In Poland pine weevils occur every year on the whole territory of the country showing a continual tendency of growing in number.

Different methods are integrated to effectively reduce damage caused by pine weevils. This integrated management is aimed at protection of plantations against pest insects and keeping losses at a tolerable level. The following elements are integrated into a management: 1) silvicultural protection by soil scarification and delayed planting of trees, 2) reduction of weevil abundance by mechanical (freshly cut billets of Scots pine and baited ground traps with synthetic attractants) and biological (stump deterioration by fungus *Phlebiopsis gigantea* (Fr.: Fr.) Julich) methods, 3) chemical protection of seedlings with contact and systemic insecticides, where the pine weevils cause great losses.

16-082

SUSCEPTIBILITY OF THE MORE IMPORTANT FOREST PEST INSECTS TO INSECTICIDES IN POLAND

H. Malinowski

Forest Research Institute, Warsaw, Poland

The susceptibility of forest pest insects such as *Lymantria monacha* L., *Dendrolimus pini* L., *Panolis flammea* Schiff., *Diprionidae* and *Hylobius abietis* L. to the used insecticides (pyrethroids, arylpropylether, acylureas, diacylhydrazine and preparations based on a bacteria *Bacillus thuringiensis*) was evaluated under laboratory conditions.

Two methods of evaluation were used. topical application and exposure of insects to treated food (pine twigs with or without needles).

Studies showed that although the selection processes of resistant populations to the frequently used insecticides (mainly to pyrethroids) are developed, the above mentioned insect populations can be effectively controlled with pyrethroid insecticides. The studies also showed that the examined insect populations are fully sensitive to acylurea and diacylhydrazine insecticides and biological preparations *B. thuringiensis*.

However, the sensitivity of insect species controlled to the used chemical and biological insecticides should be checked.

16-084

OBSERVATION ON A NEW DANGEROUS PINE SCALE- *INSULASPIS PINI* (MASKELL) -AND ITS CONTROL

Shu-gui Gao, Jin-feng Lin¹, Feng-ying Wang², Bao-qi Cui³, Zan-cai Yang⁴

Dalian Greenification Office of Developing Zone -1 Dalian Forest Protection Station -2 Jinzhou District Forest Protection Station -3 Dalian Forest Protection Station of Developing Zone -4 Dalian Plant Protection Station of Developing Zone, Dalian, China.

Through faunistic investigation from 1990 to 1994, *Insulaspis pini* (Maskell) was found out for the first time in Dalian Area and some other provinces and cities in China. It causes damages on some pine species, including *Pinus thunbergii*, *P. tabulaeformis*, *P. densiflora*, and *P. sylvestris* var. *mongolica* and also some fir species. The insects aggregate and suck at the bases of the pine leaves. Damaged leaf turns yellow at the beginning and then wilts and falls down to the ground. If the damage is serious, the whole plant will die. Its occurrence is usually accompanied by *Matsucoccus matsumurea* Kuwana. External morphological characteristics of shells of both sexes, adults, egg, prepupa, 1st-instar larva and 2nd-instar larva are described. Moreover, its life cycle and habits are reported. In addition, the design and application of a chemical control method is discussed.

16-083

NATURAL EMEMY ON THE BLACK PINE BAST SCALE (*MATSUCOCCUS THUNBERGIANAE*) IN COAST AREA OF KOREA

KYU CHIN KIM, JONG DAE PARK¹

Depart. of Agri-biology, College of Agriculture, Chonnam National University, Kwangju, Korea - 1 Reserach bureau, Chonnam Rural Development Administration, Naju, Korea

The black pine bast scale(*Matsucoccus thunbergianae*) that has been damaging the black pine of southern coastal areas of Korea. It has one generation a year, comming out of the pine bark to mate and lay eggs from early March to early May. Especially, its peak time is from late March to mid-April.

The observed natural enemies of black pine bast scale were 9 species of Birds, 1 species of Amphibian, 32 species of Insecta, and 23 species of Spiders.

Especially, *Parus majoy minor* and *Paradoxornis webbiana fuwicauda* among the Birds, *Velinus nodipes* and *Coccinella septempunctata* of Insects, *Agriope amoena*, *Lycosa suzurii* and *Lycosa pseudoannulata* of Spiders species arc frequently observed in the research areas.

16-085

THE RELATIONSHIP BETWEEN THE GALL WASP, *ANDRICUS MUKAI-GAWAE* (MUKAIGAWA) (HYMENOPTERA: CYNIPIDAE) AND THE GALL INHABITING MOTH, *OEDEMATOPODA* SP. (LEPIDOPTERA: STATHMOPODIDAE)

Y. Abe

Laboratory of Entomology, Faculty of Agriculture, Kyoto Prefectural University, Shimogamo, Kyoto, Japan

Gall parasitism by moth larvae in the unisexual galls produced by *Andricus mukaigawae* (Mukaigawa) on *Quercus serrata* in Nose, Japan was surveyed by dissection of the galls. Almost all moth larvae found in the galls were *Oedematopoda* sp. The gall parasitic moths did not significantly affect the survival of *A. mukaigawae*, though 53.4 % of the galls examined were attacked by the moths. Larval feeding habits of *Oedematopoda* sp. were examined under laboratory conditions. *Oedematopoda* sp. larvae were able to feed on *Q. serrata* leaves, but preferred unisexual gall of *A. mukaigawae*. Furthermore, almost all the larvae fed on artificially exposed *A. mukaigawae*, although the results of gall dissection indicate that some of the *Oedematopoda* sp. larvae became predators of the gall causers under natural conditions. Thus, the sclerenchymatous wall of the larval cell and its surrounding woody tissues protect the gall causers in *A. mukai-gawae* galls from attack by moths.

16-086

OBSERVATIONS ON *EUCALLIPTERUS TILIAE* (L.) AND *TINOCALLIS PLATANI* (KALT.) (RHYNCHOTA APHIDIDAE) POPULATION DYNAMICS IN MEDITERRANEAN ENVIRONMENT

P. Luciano, R. A. Pantaleoni

Istituto di Entomologia agraria, Università di Sassari, Italy

Eucallipterus tiliae and *Tinocallis platani* are pests of the urban shade trees. They infest in high numbers respectively limes and elms causing the rain of copious quantities of sticky honeydew.

Observations carried out in the urban avenues of Sassari (North-Sardinia) have annually shown for both species two peaks of abundance: the former between the late spring and the early summer, the later at the end of autumn. The two species had an annual alternation in the oviparae density (*E. tiliae*: 0.2 oviparae/leaf in 1994 and 3.05 in 1995; *T. platani*: 0.7 in 1994 and 7.57 in 1995) and in egg abundance (*E. tiliae*: 0.002 eggs/bud in 1994 and 0.29 in 1995; *T. platani*: 0.005 in 1994 and 1.34 in 1995). The same alternation occurred in the spring infestation peak timing, earlier (late may-early june) when there were many eggs otherwise about a month later. However the maximum density achieved by the aphids was strongly affected by the climatic conditions. For example, in 1994 the *E. tiliae* population growth was slowed down by an early leaf marginal chlorosis and subsequent scorching of the affected tissues caused by a limited spring raininess (only 98 mm in march-may). Every year the aphid populations rapidly declined in numbers in the early summer with few or no aphids left from half july to half october. This phenomenon seem strongly related to the changes in the food quality (particularly the limes in july always showed leaf scorching). On limes and elms, several predators (Aranea, Miridae, Anthocoridae, Chrysopidae, Coccinellidae and Sirphidae) were observed but their maximum abundance (0.36-0.53 predator number/leaf) was recorded only after one or two weeks from the aphid spring peak.

The population dynamics of *E. tiliae* and *T. platani* seems to be similar in the urban environment. The Mediterranean climatic conditions, characterized by dry summers, heavily influence their abundance trend which appears different from the one recorded in areas with greater raininess and cooler summers.

16-088

VARIATION OF THE FREE AMINO ACIDS PROLINE AND ALANINE AND LIPIDS IN *IPS TYPOGRAPHUS* (COL., SCOLYTIDAE) DURING DISPERSION

F. Bohlander

Department of Applied Zoology, Faculty of Forestry, Ludwig-Maximilians-Universität München, Freising, Germany

Dispersing adults of the European spruce engraver *Ips typographus* (L.) were caught with pheromones traps and unbaited flight barrier traps, which were placed 5 and 10 meters away to catch imagines which did not respond to the lure. On trap trees, which were placed 50 meters in the main wind direction, in front of the pheromone taps, landing beetles were collected too. The beetles were frozen in liquid nitrogen immediatly after being trapped or collected.

Alanine, proline and glutamate constituted about 83% of the free amino acids found in *I. typographus*. According to a metabolic scheme the ratio of proline and alanine is understood as a measure of the actual energy stage, increasing values indicating an enhanced level of fuels for flight.

In *I. typographus* caught with barrier traps a proline alanine ratio of 1:2 (males) and 1:1,6 (females) was found, whereas corresponding values in adults from pheromone traps were 1:3.7 (males) 1:3.3 (females). Beetles collected just after landing had a ratio of 1: 2.4 (males and females). A proline alanine ratio of 4,3:1 was found in freshly emerged beetles.

Males and females from barrier traps had the highest average lipid content 620 (+/- 152) and 550 (+/-185) nmol acylester/mg dry weight, respectively. The average fat content of beetles collected after landing was about 25% lower and adults from pheromone traps showed 45% less fat. It seemed, that landing was not only due to a certain reduction of the fat body, but to a specific proline alanine ratio.

16-087

EVALUATION OF A BINOMIAL SAMPLING PLAN FOR HEMLOCK WOOLLY ADELGID

D. R. Gray, R. A. Evans¹, and S. M. SalomDepartment of Entomology, Virginia Tech, Blacksburg, VA, USA - 1
National Park Service, Delaware Water Gap, Bushkill, PA, USA

The hemlock woolly adelgid, *Adelges tsugae* Annand (Homoptera: Adelgidae) (HWA), is an introduced pest of eastern hemlock, *Tsuga canadensis* in the eastern United States. Because of the insect's small size, estimates of population density require cutting twigs from trees and examining the twigs under the microscope in the lab; a very labor intensive effort. If the dispersion of HWA can be described by an empirical distribution, estimates of population density may only require a count of the proportion of samples where the pest density meets or exceeds a threshold of 1. Therefore, the objective of this study was to determine if a single empirically derived distribution would satisfactorily describe HWA dispersion in both the spring (progredien/sexupara) and fall (sistens) generations in both Pennsylvania and Virginia, USA. To accomplish this, twenty trees were sampled in both Pennsylvania and Virginia. Six twigs were selected from each of four branches from each of the sample trees. The twigs were examined with the naked eye for presence of HWA. If present, the number of HWA were counted with aid of a microscope.

A linear relationship between the number of adelgids and the proportion of branches with adelgids was significant for both states and generations. Taylor's Power Law was used to compare these relationships quantitatively. A homogeneity-of-slope model indicated that the state-generation combination significantly affected the HWA dispersion ($p < 0.0001$). Since a single distribution did not satisfactorily describe the four dispersions examined, then a separate distribution would have to be estimated for each new application of the sampling procedure. Until it can be determined what is causing the differences in dispersion, a standard binomial sampling method cannot be applied for estimating HWA populations throughout its geographic range.

16-089

JUNIPER WOODLAND (*JUNIPERUS THURIFERA* L.) OF MOROCCAN ATLAS MOUNTAINS AND THE PEST IMPACT ON THEIR NATURAL REGENERATION.

M.A. El Alaoui El Fels

Laboratoire d'Écologie Animale Terrestre, Département de Biologie, Université Cadi Ayyad, Marrakech, Morocco.

In Morocco, *Juniperus thurifera* (L.) grows up to 3000 m above sea-level. On account of its ecological value and social and economic role, this mountain tree is of great value, but is currently subject to intensive damage. Natural stands have been reduced by about 90%. Such losses can be attributed to the interactions of numerous factors. Among these, the impact of arthropods (mites and insects) which attack berries and seeds, appear to be one of the factors restricting the natural regeneration by reducing the number of seeds liable to germinate.

Investigations carried out in different juniper woodlands had the following objectives: (1) creation of a checklist of pest arthropods associated with female reproductive organs; (2) the detection of a phenological relationship between pest attack and the various steps of fruit development; (3) the identification of parasitic species associated with berry and seed pest species.

The investigations confirmed that arthropods can be damaging. The management and restoration of juniper woodlands require further investigations on the biology and ecology of pest arthropods and their predators such that a suitable control method can be devised.

16-090

MASS OUTBREAK OF *IPS DUPLICATUS* SAHLBERG, (Coleoptera, Scolytidae).

M. Knížek, P. Zahradník

Department of Forest Protection, Forestry and Game Management Research Institute, Jíloviště - Strnady, Czech Republic

Since 1992, the largest recorded outbreak of *Ips duplicatus* has been observed in the Czech Republic. This species spread here on approx. 1500 km² in the territory of north Moravia and Silesia.

It is commonly considered as a boreoalpine species, occurring in northern taiga from Sweden to north Sachalin and in solitary Alps localities. Because of planting monocultures of Norway spruce in unnatural conditions during last two hundred years, *Ips duplicatus* has enlarged its range from the beginning of this century. In connection with its spreading to warmer areas and with weather conditions in 90th years, *Ips duplicatus* has markedly shown its polyvoltine ability what resulted in rapid increasing its population density. *Ips duplicatus* seems to be even more aggressive than *Ips typographus*; mainly primary attack of healthy trees was observed. In area of the most infested forest districts, about 800000 m³ of spruce timber (infested mostly by *Ips typographus* and *Ips duplicatus*) were cut in the last years; we estimate that approximately one third of that is due to the attack of *Ips duplicatus*.

Classical control methods are tested during the years of the outbreak as well as known components of aggregation pheromone of this species. *Ips duplicatus* does not react to laying tree traps. Looking for attacked trees is very difficult because of no colour change of crown before emergence of beetles. Ipsdienol used in our experiments caused attack of first beetles on both cut and standing trees where they then produce their natural aggregation pheromone, which results in a heavy infestation of trees. Adding of the second known component of their pheromone - E-myrcenol - will increase attractiveness of a pheromone bait.

16-092

THE ROLE OF TERPENOID VARIATION AND PRODUCTION OF MIXTURES IN MEDIATING HOST TREE - HERBIVORE - PATHOGEN INTERACTIONS

Rex G. Cates

Department of Botany, Brigham Young University, Provo, UT USA

Multiple selection pressures from herbivores, pathogens, and plant-plant interactions have resulted in adaptations favoring mixtures of terpenoids that are highly effective against herbivores and pathogens. These same selection pressures also have resulted in numerous types of variation in the production of terpenoids. These include tissue-dependent induction vs. constitutive defenses, within-individual variation, among-individual variation within a population, developmental variation, and among-season variation. Terpenes are known to facilitate the deployment of other chemical defenses, to function in defense as mixtures and synergistically with primary nutrients, and perhaps lead to nonpreference due to their absenece. Abiotic stress ameliorates the regulating effect of mixtures and patterns of variation often leading to significant increases in herbivores and pathogens. Studies reported on reinforce the premise that in natural and managed systems, variation and diversity in phytochemicals are important to maintaining sustainable ecosystems.

16-091

EFFECT OF PINE NEEDLE TANNINS ON THE ACTIVITY OF TRYPSIN AND GUT PROTEASES OF *DIPRION PINI* (L.)

(HYM., DIPRIONIDAE)

Chr. Codreanu, A. Gruppe, R. Schopf

Lehrstuhl für Angewandte Zoologie

Ludwig-Maximilians-Universität München

Pine needle (*Pinus sylvestris*) tannins were extracted from 10 trees in total. Proteases were isolated from guts of 5th instar larvae of the sawfly *Diprion pini* (L.) (Hym., Diprionidae) a defoliator highly adapted to pine needles. In protease bioassays benzoyl-arginyl-p-nitranilid (BAPNA) was used as substrate. Increasing concentrations of procyanidins in the needles correlated positively with the precipitation of bovine serum albumine and the inhibition of purchasable trypsin. Gut proteases were inhibited by pine needle tannins, too, but a linear correlation with the concentrations in the needles could not be observed. A crude extract of pine needle tannins was separated in different fractions by column chromatography on Sephadex LH-20 and a stepwise elution with 20%, 30%, 40%, 45%, and 50% acetone/H₂O (vol/vol). Gut proteases and trypsin are inhibited by tannin fractions in a different manner.

16-093

AN INTRODUCTION TO THE FOREST INSECT FAUNA IN LIAONING PROVINCE

Zhi-yu Wang

Shenyang Forest Pest Control and Quarantine Station, Shenyang, Liaoning Province, China.

Liaoning is located at the northeastern part of China. Its flora is a combination of that from Changbai Mountain, North China and Mongolia; so the forest insect fauna is also complicated. According to our collection of 266,722 insect specimens, 2,595 species have been identified. They belong to 19 orders, 142 families and 1,463 genera. Among them, 7 orders, 48 families and 141 species are main forest pests; 11 orders, 40 families and 361 species are natural enemies of the pests and 72 species can be used in pest control. According to the taxonomic position of the pest species, and their distribution, we divided this province into 5 geographical and ecological regions:

1. East Liaoning medium and low mountainous region, important pests are: *Colephora laricella*, *Dendrolimus superans*, *Dryocosmus kuriphilus*, etc. 2. East Liaoning peninsular hilly region, important pests are : *Dendrolimus spectabilis*, *Cryptorrhynchus lapathi*, *Parathrene tabaniformis*, *Hyphantria cunea*, *Matsucoccus matsumurae*. 3. Northwest Liaoning windy and sandy region, important pests are: *Dendrolimus tabulaeformis*, *D. spectabilis*, *Pyrrhalta aenascens*, etc. 4. West Liaoning hilly region, important pests are: *Dendrolimus tabulaeformis*, *D. spectabilis*, *Anoplophora glabripennis*. 5. Middle Liaoning plain region, important pests are: *Cryptorrhichus lapathi*, *Paranthrene tabaniformis*, *Cossus cossus mongolicus*, ect.

16-094

ON FOOD PREFERENCES OF *CALVIA QUATUORDECIMGUTTATA* AND *SOSPITA VIGINTIGUTTATA* (COLEOPTERA COCCINELLIDAE) IN ALDER WOODS OF SOUTHERN ITALYV. Palmeri, A. Russo¹, S. Longo¹

Istituto di Difesa delle Piante, Università di Reggio Calabria, Italy - 1 Istituto di Entomologia agraria, Università di Catania, Italy

In alder woods of Calabria, several species of phytophagous insects are present; some of them as *Crypturaphis grassii* Silvestri (Homoptera Aphidoidea), *Psylla cordata* Tamanini (Homoptera Psylloidea) and *Galerucella solarii* Burlini (Coleoptera Chrysomelidae) are very common and, often, in high population densities. Associated with their pullulations, two species of lady-bird *Calvia quatuordecimguttata* L. and *Sospita vigintiguttata* L., are frequently collected; researches have been realized in order to investigate their food preferences. During 1989-90 and 1991-93, biological observations have been done in field and in laboratory. In the first two years, development of larvae respectively maintained with adults and nymphs of *C. grassii* and *P. cordata* and with eggs and larvae of *G. solarii*, have been studied while in 1991-93 the abdominal contents of *C. quatuordecimguttata* and *S. vigintiguttata* adults collected on woods have been observed. During 1989 mortalities of 93.3%, 50% and 100% have been recorded for larvae of *C. quatuordecimguttata* alimented respectively with *C. grassii*, *P. cordata* and *G. solarii* as far as these recorded for *S. vigintiguttata* have been 85.7%, 25% and 100% respectively. In 1990 only *S. vigintiguttata* have been bred and the recorded mortality percentages have been 50% on *P. cordata* and 100% on *C. grassii*. The development of the two ladybirds has been faster on *P. cordata* (a media of 20.88 days from egg to adult for *C. quatuordecimguttata* and of 23.78 days for *S. vigintiguttata*) than on *C. grassii* (a media of 27 days from egg to adult for *C. quatuordecimguttata* and of 26 days for *S. vigintiguttata*). Inside of the alimentary channel of adults of the two species of coccinellids only phragments of *P. cordata* have been detected.

16-096

ATTACKS OF BARK BEETLES ON DOUGLAS FIR IN ITALY

P. F. Roversi

Istituto Sperimentale per la Zoologia Agraria, Sezione di Entomologia Forestale, Via Lanciola 12/A, Cascine del Riccio 50125 Firenze (I).

The douglas fir *Pseudotsuga menziesii* (Mirb.) Franco var. *menziesii* at present is widely cultivated in Italy mainly along the Apennines. Together with the diffusion of that rapid growth conifer a rising pressing of several indigenous phytophagous insects were observed.

Preliminary results of an ecological and faunistic survey in Douglas fir stands of different ages, showed that some indigenous bark beetles are able to attack this new host, particularly in young stands with trees stressed by prolonged drought.

The detected species at present are: *Cryphalus piceae* (Ratzeburg), *Cryphalus abietis* (Ratzeburg), *Pityogenes quadridens* (Hartig), *Pityogenes bidentatus* Herbst, *Pityophthorus pityographus* (Ratzeburg), *Xyloterus lineatus* (Olivier) and *Hylastes* sp.

16-095

GROWTH OF *CAMERARIA OHRIDELLA* Deschka&Dimić (LEPID., LITHOCOLLETIDAE)N. Dimić¹, Lj. Mihajlović², M. Vukša¹, P. Perić¹, S. Krnjajić¹, M. Cvetković¹¹Institute for plant protection and environment, Belgrade, Yugoslavia²Faculty of forestry, Belgrade

Leaf miner of wild chestnut, as a new insect species, was proved for the first time in the region of Ohrid in 1985. As a rule its occurrence is mass, and temporary defoliation of wild chestnut occurs, with a series of harmful effects for plant and also for the environment.

From the moment of its discovery the investigations on *C. ohridella* growth has lasted ten years continuously. Preliminary investigations were carried out in Sarajevo (1985-1992), exclusively under the strictly controlled natural conditions (the species has not occurred in the region of Sarajevo so far). In the region of Belgrade the growth of *C. ohridella* was observed from 1993 to 1995 in the several localities in nature and afterwards under the controlled natural conditions.

C. ohridella is a monophagous species, living only in the leaf of *Aesculus hippocastanum* L.

The growth of *C. ohridella* is very specific. In the whole area of distribution, the species has three generation per year. Eclosion of the moths of the 3rd generation with a part of the populations of the 1st and the 2nd generation occurs in the course of April 1st in June and 2nd generation from the end of July to mid August. The species overwinters in pupal stage in cocoon inside the pupae mine, in fallen leaves. Besides the pupae of the 3rd generation, the pupae of the 1st generation (26% on the average) and the 2nd generation (45% on the average) remain in diapause.

16-097

SPRUCE CONE INSECTS IN SWITZERLAND: ABUNDANCE AND EFFECT ON SEED PRODUCTION

M. Seifert & B. Wermelinger

Swiss Federal Institute for Forest, Snow and Landscape Research WSL, Zoology Section, Birmensdorf, Switzerland

Cones from 29 spruce stands located in the five main regions of Switzerland were collected in 1989 and 1990. Cones of the first year were incubated and the emerging insects collected and identified. The regional abundance of spruce cone pests and a parasitoid genus (*Torymus* spp.) was studied. In cone samples from both years, the numbers of full, empty and damaged seeds were counted. Damaged seeds were classified according to the respective source of damage. The effect of the seed feeding insects on seed production was analysed.

From 14'000 individuals collected, 11 conophagous and seminiphagous species were identified. *Kaltenbachiola strobis* was the most frequent species, amounting to 40 %, followed by *Torymus* (29 %) and *Cydia strobilella* (26 %). The regional abundance showed a non-uniform pattern for the different species. Number of insects per cone were highest in the alpine region, with a maximum of 5.5 individuals in the South Alps.

Incidence of Seed Feeding insects averaged 71 % (1989) and 63 % (1990) of the cone crop, reducing the total number of full seeds by 27 and 19 %, respectively. *C. strobilella* as the most important pest caused seed losses of up to 48 % per cone. A multiple regression model was used to explain the variability in yield of full seeds, estimating the effect of seed feeding insects as well site characteristics. The resulting function indicates that loss variability depends on regional differences and site characteristics rather than on impact of seed feeding insects.

16-098

SPATIAL DISTRIBUTION AND SIGNIFICANCE OF SOME JEWEL-, LONGHORN- AND BARK BEETLES (COLEOPTERA: BUPRESTIDAE, CERAMBYCIDAE, SCOLYTIDAE) ON NORWAY SPRUCE [*PICEA ABIES* (L.) KARST.]

P. Zach

Institute of Forest Ecology, Slovak Academy of Sciences, Zvolen, The Slovak Republic

The beetle fauna associated with Norway Spruce in Central Europe has already been well recognized. In 1987-1992 the very characteristic assemblages of jewel-, longhorn- and bark beetles were understudied in the thick (diameter 5-10 cm) branches of Norway Spruce trees (some 200 years old) growing singly on mountain meadows of Central Slovakia at an elevation of 1,300-1,400 m a.s.l. Four beetle species were frequent and abundant on spruce in such ecosystems, namely: *Anthaxia quadripunctata*, *A. helvetica* (Buprestidae), *Callidium aeneum* (Cerambycidae) and *Pityophorus ptyographus* (Scolytidae). Although developing together in the same branch (diameter 2-10 cm) with closely packed annual rings, particular species require special microhabitat conditions. Main factor affecting their occurrence is insolation. If insulated, the dying branch offers good conditions for development of the larvae of both *Anthaxia* species, mainly in its upper part, temperature of which may be some 50 °C during hot summer days. A side part of a branch is usually colonized by *C. aeneum*. Not insulated (moist, much cooler) bottom part is then a characteristic habitat for *P. ptyographus*. Imagines of both *Anthaxia* species are flower visitors. This probably affects their vertical distribution within a tree. The number of *Anthaxia* specimens is the highest in the lower branches and decreases towards the tree crown, whereas the numbers of *C. aeneum* and *P. ptyographus* are increasing. In both *Anthaxia* species and *C. aeneum* development takes two years, *P. ptyographus* has one year life-cycle. Although not economically significant, the species have a high bioindicative value in determining the health of Norway Spruce trees in mountain areas. Mainly the black *Anthaxia* species contrasting with yellow flowers which they rest on, often in high numbers near the dying trees, should be given more attention in forest conservation programmes.

16-100

BARK BEETLES (COLEOPTERA, SCOLYTIDAE) AND THEIR FOREST IMPORTANCE IN ESTONIA

K. Voolma

Estonian Institute of Forestry and Nature Conservation
Tartu, Estonia.

Over 13500 specimens of *Scolytidae* collected since 1850 are present in the insect collections of Estonia. Examination of the collections gives evidence of that the Estonian bark beetle fauna comprises 61 species. In addition, the relevant literature reviewed gave the data for the distribution of 9 species.

All species of bark beetles distributed in Estonia are insects of woody host plants. They are often regarded as serious tree killers, but virtually only a few species have economical importance as pests in forests. Most of bark beetles infest dead or dying host material and can be appreciated considering the species diversity in forest ecosystems.

Ips typographus is the scolytid of the greatest forest importance in Estonia. Several large-scale outbreaks have occurred in Norway spruce (*Picea abies*) stands after windthrow, snow-breakage, drought or fire during the last two centuries. *Tomicus piniperda* and *T. minor* are the most important bark beetle species in Scots pine (*Pinus sylvestris*). *Dendroctonus micans* is not numerous in spruce forests but since 1971 severe outbreaks have occurred in about 20-years-old plantations of Scots pine on sub-optimum sites. In reforestation areas damage are caused by *Hylastes cunicularius*. *Trypodendron lineatum* is the main species in felled conifer stems and logs.

During recent years 5 bark beetle species have been reported from Estonia for the first time: *Hylesinus varius*, *Hylurgus ligniperda*, *Scolytus mali*, *S. scolytus* and *Trypodendron proximum*.

16-099

SPATIAL AND TEMPORAL DISTRIBUTION OF *PITYOKTEINES SPINIDENS* (COL.: SCOLYTIDAE) IN THE HOST TREE. VARIATION OF THE SEX-RATIO DURING THE ATTACK PERIOD

J.M. Riba, M. Blas

Departament de Biologia Animal (Artròpodes), Facultat de Biologia, Universitat de Barcelona, Barcelona, Spain

The study was carried out in the Silver fir forests of Valle de Arán (East Pyrenees), at 1,300 m, during the period October 1990 - June 1991.

The attack and colonization period of *P. spinidens* generation that emerges in summer can be extended until November, just before the adults begin overwintering.

The estimated total population in the trunk (1-7 m, 345 dm²) and during the maximum colonization period was 10,300 adults, with 25 % males. The maximum density was found at 4.7 m of height (17 cm diameter) with 9.3 males/dm² and 29.2 females/dm².

During the period of study a variation in the sex-ratio was observed, because of polygamy and the reemergence of the parent adults, characteristic behavior in this group of Scolytidae. In the first attack phases the sex-ratio of the parent adults reached values of 45-55 % males. In the maximum colonization period (October-March) the sex-ratio was 23-28 % of males. After the overwintering (March-June) the sex-ratio reached values of 30-35 % males.

16-101

XYLOTRECHUS VILLIONI (VILLARD) (COLEOPTERA: CERAMBYCIDAE), A PRIMARY BORER OF CONIFERS IN JAPAN: LOW DENSITY OF POPULATION AND HIGH DURABILITY OF SCARS ON THE STEMS CAUSED BY LARVAL BORING

Ryûtarô Iwata

Department of Forest Science and Resources, College of Bioresource Sciences, Nihon University, Fujisawa, Japan

Xylotrechus villioni (Villard) is possibly the largest species of Clytini (Cerambycinae), and as a primary borer, its outbreaks rarely cause severe damage on *Abies* and *Picea* forest stands in Japan. The larva makes a rather straight gallery more than 1 m in length from the oviposition site to the "whirl-like gallery", in the center of which the pupal chamber and adult exit hole are made, and these galleries cause scars on the stems. In forest stands of *A. firma* (Tokyo and Kyoto Prefectures) and *A. sachalinensis* (Hokkaido), straight and whirl-like scars on the stems show highly cumulative damage on the trees, and whirl-like scars are distributed towards the bottom part of the stems. The spatial distribution of scars suggests that there is a random distribution of larvae as the larvae never aggregate and there is no interference between individuals. As "whirls" can be present on the stem for 30 years after the formation of the gallery, the density of existing mature larvae is very low. In an *A. homolepis* stand (Nagano Prefecture), cumulative damage on major branches suggests that there are almost simultaneous multiple larval borings with a very low survival from larvae to adults mainly due to the predation of picid woodpeckers.

This species is thought to be an unusual primary borer in that it infests conifers with heavy sap flow, usually has a very low density, and still affects tree appearance for a long time.

16-102

BIOLOGY AND ECOLOGY OF *CURCULIO* (*CURCULIO*) *PROPINQUUS* (DESBROCHERS) (COLEOPTERA: CURCULIONIDAE) IN SOUTHERN ITALY.

O. Triggiani, E. Tarasco

Istituto di Entomologia agraria, Università di Bari, Italy

At the present there is any information on the biology and ecology of *C. propinquus* and incomplete data on the host plants. Observations on this weevil were carried out on different species of *Quercus* present in Apulian Region (Southern Italy) during 1995. Adults and larvae of *C. propinquus* feed on the glands but the most harmful ones are the larvae which can destroy up to 100% of fruits of some Oak plants. In the woods of *Q. trojana* Webb and *Q. pubescens* Willd. the first species is the most damaged and between *Q. frainetto* Tenore and *Q. cerris* L. the glands of the first one are the most attacked. In the laboratory they also develop in chestnuts.

In glands the parasites are rare and, so far, only two have been found: *Scambus calobatus* (Gravenhorst) (Hymenoptera: Ictneumonidae) and the fungus *Metharizium anisopliae* (Metch.) Sorok. (Deuteromycotina: Hyphomycetes).

16-104

SOME BIOECOLOGICAL ASPECTS OF THE *ONCIDERUS IMPLUVIATA* (GERMAR) (COLEOPTERA: CERAMBYCIDAE) FROM *ACACIA MEARNsii* WILD IN THE NORTHWEST OF PARANA, BRAZIL

M.M.M. Rupp, L.M. Dupchak

Departamento de Zoologia, Universidade Federal do Paraná, Paraná, Brazil

Onciderus impluviata (Germar, 1824) is a very important pest species, being considered as a limitant factor for the cultivation of *Acacia mearnsii* Wild.

The objective of this work is the study of some bioecological aspects of this insect in a research stand of *A. mearnsii* in the Northwest of Parana, Brazil.

Falled branches with characteristics of slits made by the pest were collected, randomly, and kept in cages in the same place where they were picked.

The period and percentage of emergence of *O. impluviata* were checked during 1994 - 1995.

The emergence of adults occurred from October to January, with the peak in November and December. After the observation, the infested branches were destroyed and entirely crumbled.

16-103

LIFE TABLE STUDY OF THE TEAK BEEHOLE BORER, *XYLEUTES CERAMICUS* (WALKER) (LEPIDOPTERA: COSSIDAE) IN NORTHERN THAILAND

T. Gotoh, S. Yincharoen¹, S. Eungwijarnpanya¹

S. Choldumrongkul¹, C. Hutacharern¹

Forestry and Forest Products Research Institute, Ibaraki, Japan - ¹ Forest Research Office, Royal Forest Department, Bangkok, Thailand

The teak beehole borer is the most serious pest of teak in northern Thailand. To analyze the factors responsible for population trend, four life tables for the pest insect were constructed in 4 localities with different level of population density. In the low population site, heavy mortality occurred on the egg and 2nd-3rd instar larvae, while the mortality of those stages was remarkably low in the high population site. The predation by ants was found to be the major mortality factor for eggs and young larvae. About 99 % of hatchlings was disappeared due to dispersion and predation by ants at all sites. Mortality due to undetermined factors during the period of mature larval and pupal stages was relatively low at all sites. Key factor analysis showed that predation by ants during the egg and the 2nd to 3rd larval stages would govern the population changes of the teak beehole borer. The frequency by ant species was quite different between high and low population sites. In the high site, ants were not observed on 46% of trees, while they were not on 21% in the low. *Tetraponera rufonigra*, an important predator of the 2nd-3rd instar larvae, was not observed in the low population site.

16-105

GODASA SIDAE (FABRICIUS) : TAXONOMIC POSITION AND MORPHOLOGY OF THE DIFFERENT STAGES OF DEVELOPMENT.

B. FOAHOM

AGRONOMIC RESEARCH INSTITUTE (IRA) FORESTRY RESEARCH STATION KUMBA - CAMEROON

Godasa sidae causes severe damage to *Mansonia altissima* an indigenous tree species used for forest regeneration in Cameroon. However, this Lepidopteran has not received adequate attention by entomologists and consequently has been transferred from a family to another. This article deals with the systematic position of the species, together with preliminary studies on its morphological characteristics, including the description of larval chaetotaxy. *G. sidae* belongs to the family of Noctuidae, subfamily of Aganainae.

16-106

SEXUAL ATTRACTION IN THE PINWOOD NEMATODE

BURSAPHELENCHUS XYLOPHILUS

T.Kiyohara

Forestry and Forest products Research Institute

P.O. Box 16, Tsukuba Norin Kenkyu Danchinai

Ibaraki 305, Japan

Sexual attraction in the pinewood nematode, *Bursaphelenchus xylophilus*, was studied on agar strips in petri dishes. Males were attracted to virgin females but not to 4th-stage female larvae, mated females or gravid females. Males were responsive to female secretions emitted into agar and vaporizing substances from virgin females. Attraction of females by males was also noted.

No evidence of homosexual attraction was observed in either males or females.

Both male and female attractants seem to be volatile as well as water-soluble in nature

16-108

GEOGRAPHIC VARIATION IN ESTERASE ISOZYME PATTERN OF THE JAPANESE PINE SAWYER, *MONOCHAMUS ALTERNATUS* (COLEOPTERA: CERAMBYCIDAE)A.Yamane¹, R. Iwata², M. Natori¹, P.K. Chang¹, H. Makiha-

¹College of Bioresource Sciences, Nihon University, Kameino 1866, Fujisawa, Kanagawa, 252 Japan, ²Division of Forest Biology, Forestry & Forest Products Research Institute, Kukizaki, Ibaraki, 305 Japan

The Japanese pine sawyer is well known as the vector of the pine wood nematode, *Bursaphelenchus xylophilus* (Nematoda; Aphelenchoididae) causing severe mortality of pines in not only Japan but also in neighbor countries. *M. alternatus* distributes widely in eastern Asia. Morphologically Japanese sawyer is not different from ones from mainland of China and Taiwan, except in color, but physiologically some of the latter do not need diapause before pupation. To detect genetic difference among the sawyers of various localities, the esterase isozymes of the sawyers were separated by polyacrylamide gel electrophoresis. It was clear that Chinese populations had different isozyme patterns from those of Japan, where also some grouping of the local strains was possible according to the isozyme pattern.

16-107

SAMPLING CHESTNUT FRUIT INSECT PESTS ON DIFFERENT CULTIVARS

A. De Cristofaro, G. Rotundo, G.S. Germinara

Dipartimento di Scienze Animali, Vegetali e dell'Ambiente, Università del Molise, Campobasso, Italy

During two years (1994-95) studies were carried out on three tortricid moths, *Pammene fasciana* (L.), *Cydia fagiglandana* (Zeller) and *C. splendana* (Hübner), and a weevil, *Curculio elephas* (Gyllenhal), in a chestnut area of Southern Italy. Pests populations were sampled on two cultivars, "Tempesta" and "Ufarella", characterized by early (second ten days of September) and late (second ten days of October) ripening, respectively.

Damaged fruits and husks, number of larvae of the different species and plant phenology were detected.

P. fasciana (Early Chestnut Tortricid Moth) did not cause significant losses (10-12% of the young husks) in both cultivars. Larvae of this species were not found in the ripe fruits.

Large amount of *C. fagiglandana* (Middle Chestnut Tortricid Moth) larvae were collected from the fruit of both cvs, but in higher number on "Tempesta". *C. splendana* (Late Chestnut Tortricid Moth) larvae were more present on "Ufarella".

Only few *C. elephas* larvae were collected on fruits of "Tempesta", while high population densities were observed on "Ufarella".

The egg-larval parasitoid *Ascogaster quadridentatus* (Wesmael) (Hym.: Braconidae) emerged in a similar percentage (19-23%) from the tortricid larvae collected on the different cultivars.

The early ripening cv partially avoids the damage by *C. splendana* and completely escapes the attack by *C. elephas* larvae. The late ripening cv is more exposed to the injury of the chestnut fruit insect pests complex.

These observations have a practical impact when setting rational control strategies.

16-109

IN VITRO INDUCTION OF THE DISPERSAL FORMS OF PINE WOOD NEMATODE, *BURSAPHELENCHUS XYLOPHILUS* (NEMATODA: APHELENCHOIDIDAE)

N. Ogura

Department of Forest biology, Forestry and Forest Products Research Institute, Ibaraki, Japan

When the pine wood nematode, *Bursaphelenchus xylophilus*, parasitizes pine tree, they vigorously propagate in the resin duct of the pine, become the dispersal third stage juvenile (DSJ3) after the tree wilt and become the dispersal fourth stage juvenile (DSJ4) just before and/or just after riding on vector insects belonging to genus *Monochamus*. This process was reproduced *in vitro*. Each of 1,000 nematodes was inoculated on cultures of an identified fungus isolated from a tylenchid nematode, *Contortylenchus genitalicola* parasitic to *Monochamus*. When the cultures were kept in desiccator at 25 °C for 180 days, number of nematodes became 47,249 + 20,276 (mean + SE, n=8) and 78.1 % of the nematodes were DSJ3. When the cultures containing DSJ3 were added 0-day-old adults of sawyer, *M. alternatus*, 40.8% of the nematodes became to DSJ4. When the cultures were added last instar larvae, pupae or 10-day-old adults, rates of DSJ4 were 0.1, 5.0 or 5.7%, respectively. It was concluded that desiccation induces formation of DSJ3 and presence of vector insects, especially newly emerged adult, induces formation of DSJ4.

16-110

THE APHIDS LIVING ON *PINUS MUGO* TURRA IN ITALY
(HOMOPTERA: APHIDOIDEA)A. Binazzi, M. Covassi, F. Pennacchio ¹Istituto Sperimentale per la Zoologia Agraria, Sezione di
Entomologia Forestale, Via Lanciola, 12/A, Cascine del Riccio,
Firenze, Italy - 1 Via U. Rattazzi, 21, Firenze, Italy

Researches carried out in the latest years on the aphid fauna of mountain pine (*Pinus mugo* Turra) in Italy are here summarised. This pine has a relatively rich aphid fauna in the Alps and particularly in the Oriental Alps where the entities recorded from that conifer tree belong to Adelgidae with one oligophagous species (*Pineus pini* (Macquart)) and to Aphididae Lachninae with seven monophagous entities (*Cinara carnica* Binazzi, *C. covassii* Binazzi, *C. montanicola* (Börner), *C. neubergi* (Arnhart), *C. setosa* (Börner), *Eulachnus alticola* (Börner), *E. intermedius* Binazzi). Some other aphids were only occasionally found on the mentioned host-pine. Fewer species, on the contrary, were found on the Apennines where only some mountain pine groups are nowadays existing which are the remaining ones of the ancient anathermic postglacial peak formations. In these mountain pine residual scrubs only three *Cinara* species were recorded (*C. neubergi*, *C. pinea* and *C. pini*) together with three *Eulachnus* entities (*E. alticola*, *E. brevopilosus* and *E. intermedius*) some of them being linked on the Alps to *Pinus sylvestris*. In this regard and basing on the different sharing of the species between the Alps and the Apennines, aphids can give useful informations in order to have a better understanding of the history of the aphid-host pine coevolution.

INTEGRATED APHID MANAGEMENT IN COWPEA PRODUCTION IN NIGERIA

T.I. OFUYA
Department of Crop Production, The Federal University of Technology, Akure, Nigeria.

Aphids, especially *Aphis craccivora* Koch, is usually a problem in the cultivation of the cowpea, *Vigna unguiculata* (L.) Walpers which is a dietary staple throughout tropical Africa. Non-chemical methods which have been investigated for aphid management in cowpea, specifically, cultural control, use of resistant cowpea varieties and biological control are highlighted. Combinations of these non-chemical methods into integrated pest management packages for the cowpea aphid are suggested and discussed.

17-002

THE CONTRIBUTION OF TRAP CROPS IN THE INTEGRATED CONTROL OF INSECT PESTS OF COTTON IN UGANDA.

A.H. EL-HENEIDY and M.B. SEKAMATTE
Serere Agricultural and Animal Production Research Institute, SAARI, Soroti, Uganda.

In the tropical countries the more traditional approaches to farming utilize polycultures. Population densities of herbivorous insects are frequently lower in vegetatively diverse habitats. A study on the insect pests-predators interaction on cotton associated with common farming crops in Uganda was conducted at each of Namulonge and Serere Agricultural and Animal Production Research Institutes in the two successive cotton seasons 1994/95 and 1995/96 respectively. Cotton pest and predator population densities on cotton as well as the surrounding trap crops; sorghum, maize, beans and malakwany were estimated weekly throughout the cotton growing seasons. Although the growing season of all the trap crops used in this study was relatively short compared to cotton, except that of malakwany, but they showed considerable attractiveness to major cotton pests, e.g. *lygus* to sorghum, *Helicoverpa armigera* Hb. to maize, whiteflies and jassids to beans and stainers to malakwany. At the same time the population of predators was relatively higher on cotton/trap crops than on cotton/control throughout the seasons. Seed cotton yields also were relatively higher in the cotton/trap crops (up to 20 %). Therefore, the contribution of the trap crops to integrated pest management of cotton pests in smallholder farming system is considerable.

17-003

TRITROPHIC INTERACTIONS IN THE MANAGEMENT OF *SPODOPTERA EXIGUA* IN CELERY

John T. Trumble
Department of Entomology, University of California, Riverside, CA 92521 USA

In the USA, celery is an important vegetable crop, with values exceeding \$300 million annually. *Spodoptera exigua* (Hübner) is the major pest. *Liriomyza trifolii* (Burgess) is an important secondary pest, often occurring at damaging levels when its parasitoids are killed by pesticide applications aimed at *S. exigua*. Thus, pesticides or other control strategies are needed to control *S. exigua* without affecting the parasitoids. Attempts to use host plant resistance against these pests have been unsuccessful due to the presence of the carcinogenic linear furanocoumarins. In fact, a number of other potential pest management practices have been shown to increase the levels of these undesirable compounds. Unfortunately, simply tolerating the pest is not a viable option, as feeding by *S. exigua* reduces marketability and can induce production of the linear furanocoumarins. Therefore, a series of experiments were designed to evaluate the interactions between 1) plant chemistry, 2) *S. exigua*, 3) *L. trifolii* parasitoids and, 4) *Bacillus thuringiensis*. Based on these data an IPM program has been developed and evaluated in both experimental celery plantings and on a large-scale commercial crop. The results are encouraging; an economic analysis indicated that the IPM program produced better net profits while minimizing the potential for environmental damage, pesticide resistance, or human health concerns from linear furanocoumarins.

17-004

INSECT PEST MANAGEMENT OF SOME TROPICAL PERENNIAL CROPS

R. A. Syed
PTPP London Sumatra Indonesia, Medan, Indonesia; PT Tania Selatan,
Palembang, Indonesia

Practical application of insect pest management strategies in large plantations of oil palm (50,000 ha.), cocoa (5,000 ha.) and Robusta coffee (2,000 ha.) are described.

Bag worms (*Mahasena corbetti* Tams., *Metisa plana* Wlk., *Cremastopsyche pendula* Joannis and *Clania* spp.) and nettle caterpillars (*Setora nitens* Wlk., *Setothosea asigna* van Eecke, *Birthissea bisura* Moore, *Darna trima* Moore and *D. catenatus* Snellen) were the main defoliators of oil palms in South-east Asia. The strategy to manage these pests was based on studies of their life history, dispersal pattern and natural enemies. Main emphasis was on prevention of pest outbreaks through strengthening the natural enemy complex by encouraging certain flowering herbaceous plants, and controlling the pest population in its early stage of establishment. Natural mortality was determined. Higher natural mortality indicated the pest might be controlled naturally. If natural mortality was inadequate, treatment was deemed necessary. Known pathogen of the pest was augmented to control the infestation. If pathogen was not known or was inadequately effective, insecticides were used sparingly.

Cocoa trees, temporary shade trees (*Gliricidia*) and permanent shade (coconut palms) constitute the cocoa crop system. The main pests of cocoa in Sumatra were *Helopeltis* spp. and *Zeuzera coffeae* (Sn.). Recently (1994) the cocoa pod borer has become established. *Brachyplatys* sp. and *Ectropis* (*Boarmia*) sp. on *Gliricidia*, *Hidari irava* (Mr.), *Rhynchophorus* spp. and *Oryctes rhinoceros* L. on coconut were endemic pests. *Helopeltis* was controlled by manipulation of black ants (*Dolicoderus bituberculatus* Mayr.). In places where black ants were not established infested pods were treated with insecticides. *Z. coffeae* was controlled by spraying suspension of *Beauveria bassiana* on the canopy. The cocoa pod borer was somewhat restricted by the black ants. *Brachyplatys* was controlled by augmentation of its egg parasites while *Ectropis* and *H. irava* by augmentation of respective virus. *Rhynchophorus* was managed by bait trapping.

The most serious insect pests of coffee in East Java (Indonesia) were *Planococcus citri* (Risso) on branches and *Hypothenemus hampei* (Ferr.) on berries. The former was controlled by manipulating conditions conducive for the natural enemies and the latter by controlling off season berries and spraying *B. bassiana* to infect the adults.

17-006

Convenient Synthesis and Field Activity of Isomers 2,8-Dioxa-1-ethyl-3,5,7-trimethylbicyclo[3.2.1]octane, A Male-Produced Aggregation Pheromone of the Banana Weevil (*Cosmopolites sordidus*).

S. Jayaraman, I. O. Ndiege, A. C. Oehlschlager,
Department of Chemistry, Simon Fraser University,
Burnaby, B. C., Canada

L. Gonzalez, ChemTica Int., San José, Costa Rica

D. Alpizar and M. Fallas, Ministry of Agriculture,
Guapiles, Costa Rica.

Cosmopolites sordidus, Germ. (banana weevil) is the most important world-wide insect pest of bananas. Several antennally active candidate pheromones have been detected in male-produced volatiles. The initial pheromone candidates to be identified are diastereoisomeric bicyclic ketals. Initial syntheses of mixtures of all possible stereoisomers did not provide sufficient material to establish laboratory or field activity (Beauhaire, J., et al.: Tet. Lett. 36, 1043, 1995). We report a convenient synthesis which provides large amounts of the candidate pheromone. We also report the relative attractiveness of diastereoisomers of the ketal candidate pheromone and development of an optimized pheromone-baited trap.

17-005

Pheromone-Based Management of Pests of Oil Palm

A. C. Oehlschlager,
Department of Chemistry, Simon Fraser University,
Burnaby, B. C. Canada

Oil palm occupies approximately 300,000 Ha in Central and South America and 4,500,000 Ha in Southeast Asia. In the Americas the American palm weevil, *Rhynchophorus palmarum*, is a major threat to oil and coconut palm as a vector of red ring nematode. In 1991 a male-produced aggregation pheromone for this weevil was reported. Pheromone-based trapping of *R. palmarum* has been shown to lower red ring nematode infection rates by 80% over 1 year using 1 trap per 5 hectare. Pheromone-based trapping is currently used throughout Central and South America to reduce red ring disease in oil palm.

The coconut rhinoceros beetle, *Oryctes rhinoceros*, is the most important pest of young oil palm in Southeast Asia. A male-produced aggregation pheromone has recently (October, 1995) been reported for this pest. An operational pheromone-based trapping system has been developed which avoids the use of insecticides and is more cost effective than current population management which involves periodic inspection and insecticide treatment of young palms.

17-007

DEVELOPMENT OF SYSTEMS TO MONITOR CERATITIS CAPITATA AND SEVERAL ANASTREPHA SPECIES (DIPTERA: TEPHRITIDAE)

R. R. Heath, N. D. Epsky

Insect Attractants, Behavior, and Basic Biology Research
Laboratory, Agricultural Research Service, United States
Department of Agriculture, Gainesville, Florida 32604

Liquid protein-baited traps are currently used to capture males and females of several pest Tephritidae species. A synthetic food-based attractant and a painted cylindrical dry trap that protects the synthetic lures from the environment were developed as a replacement for liquid protein-baited traps. This trapping system was tested for capture of the Mediterranean fruit fly, *Ceratitis capitata* (Wiedemann), and several *Anastrepha* species. The dry trap is constructed of acetate film and contains an internally-placed sticky insert. Field trials conducted in Central America and in several Mediterranean countries suggests that this newly designed trapping system affords a facile replacement of the liquid protein-baited traps currently in use. When used in conjunction with sterile insect release technology, the dry trap baited with food-based synthetic attractant often caught wild *C. capitata* in numbers equal to those caught by trimedlure-baited Jackson traps, but the dry trap caught many fewer sterile *C. capitata*.

17-008

THE IMPORTANCE OF THE INTERSPECIFIC COMPETITION BETWEEN TWO PARASITOID ON THE CONTROL OF BRUCHID POPULATIONS DURING STORAGE OF COWPEA IN BURKINA FASO.

P.A. Ouedraogo¹, A. Sanon¹, S. Sou¹, J. Huignard²

¹ Laboratoire d'Entomologie appliquée, 06 BP 9820 Ouagadougou, Burkina Faso - ² URA CNRS 1298, avenue Monge, Parc Grandmont, 37200 Tours, France.

In Burkina Faso, two species of Coleoptera Bruchidae, *Callosobruchus maculatus* (F) and *Bruchidius atrolineatus* (Pic) cause important losses during the storage of cowpea (*Vigna unguiculata* Walp) in traditional granaries during the dry season. These bruchids colonized the cultures of cowpea at the end of the rainy season and reproduced on the maturing pods. The new generations of adults emerged in the granaries after harvest. Two generations of *B. atrolineatus* developed in the store but the adults of the second generation were in reproductive diapause. *C. maculatus* remained always sexually active, but 7 or 8 generations of beetles developed in the granaries from November to May. The population density remained low at the beginning of the storage and progressively increased from January when temperatures and then humidity became higher. Two larval parasitoids, *Dinarmus basalis* (Rond) and *Eupelmus vuilleti* (CRW) were present in the granaries but their influence on the bruchid population dynamic remained limited. During the storage, the density of *E. vuilleti* progressively increased whilst the *D. basalis* population density remained at a low level. The laboratory experiments demonstrated that the interspecific competition between the two parasitoid species explained this dominance of *E. vuilleti*. This competition limited the increase of the population of *D. basalis* which is the most efficient natural enemy of the bruchids in the stores.

17-010

IMPACT OF LARVAL FEEDING OF *SMICRONYX* SPP. (COL.: CURCULIONIDAE) ON SEED PRODUCTION OF *STRIGA HERMONTICA* (SCROPHULARIACEAE): AN HISTOLOGICAL STUDY

J. PARÉ¹, I. PRONIER^{1,2}, D. TRAORÉ^{3,4}, C. VINCENT⁵, and R. K. STEWART³

¹ Université de Picardie Jules Verne, Faculté des Sciences, 33 rue Saint-Leu, 80039 Amiens CEDEX 1, France.-² Laboratoire Cytologie et Morphogénèse Végétales, Université de Pierre et Marie Curie, Bât. N2, Case courrier 150, 4 Place Jussieu, Paris CEDEX 05, France.-³ Department of Natural Resource Sciences, Macdonald Campus of McGill University, 21,111 Lakeshore Road, Ste-Anne-de-Bellevue, Quebec, Canada H9X 3V9.-⁴ present address : Institut d'Études et de Recherches Agricoles (I.N.E.R.A.), Programme Coton, B.P. 208, Bobo-Dioulasso, Burkina Faso, West Africa.-⁵ Centre de Recherche et de Développement en Horticulture, Agriculture et Agro-Alimentaire Canada, 430 Boul. Gouin, Saint-Jean-sur-Richelieu, Qc. Canada J3B 3E6.

Striga spp. (i.e witchweed) are parasitic weeds that cause severe reduction in yields of many crops grown in Africa especially in dry areas and on poor soils (Mboob,1989 ; Sauerborn, 1991 ; Parker & Riches, 1993). Among the 35 *Striga* species known to occur in Africa (Raynal-Roques, 1991), the most widely distributed is *Striga hermonthica* (Del.) Benth. (Scrophulariaceae). Our hypothesis was that *Striga* plant fitness should be reduced due to seed attack by developing larvae. Our objective was to assess, with histological techniques applied at the capsule level, the impact of *Smicronyx* larvae presence and feeding on *Striga* seed production. Doing so, we also obtained qualitative information on the histogenous and organogenous capacities of *S. hermonthica* ovary tissues during development of the *Smicronyx* larva. *Striga* plants were infested with *Smicronyx* in Burkina Faso. Galls were fixed in the field and brought back to the laboratory for histological work. Generally, only one larva lived per capsule. A single larva destroyed all seeds present in the capsule. *Smicronyx* curculios have therefore a potential as biocontrol agent of *Striga* spp.

17-009

HABITAT MANAGEMENT STRATEGIES FOR THE CONTROL OF INSECT PESTS IN THE TROPICS

K. Ampong-Nyarko and K.V. Seshu Reddy

The International Centre of Insect Physiology and Ecology (ICIPE), Nairobi, Kenya

Studies on habitat management strategies, based on 'push-pull' approach included manipulation of intercropping, strip cropping, trap cropping, cover crop, relay cropping and no-tillage were undertaken to determine practices that suppress insect pests. No tillage with maize stubble in-situ resulted in high stem borer infestation and dead hearts in maize. Earlier planted trap crop provided some protection against stem borers. Broader row ratios in strips were effective in reducing stem borer and could be used without sacrificing the pest reduction potential of single alternate row intercropping. Planting maize into an already established cover crop, *Desmodium* sp. gave a dramatic reduction in stem borer incidence and damage. The underlying principles for the low pest incidence in habitat management are proffered. The principles led to the development and introduction of new cropping system alternative 'strip-relay cropping'. The indication are that the system is insect pest suppressing, increases land intensification and enhances economic profitability and could be an alternative cropping system for the humid tropics. Habitat manipulation has potential for use in environmentally sound pest management strategies.

Aqueous suspensions of a local *Bacillus thuringiensis* (Berliner) isolate identified as *B.t. kurstaki* has shown good potential for use in the control of the spotted stem borer, *Chilo partellus* (Swinhoe) when applied to 3 different sorghum genotypes under field conditions. The different sorghum genotypes comprised: a resistant (Hybrid-1) (Tx 623A X IS-1044), a tolerant (Gadam El-Hamam) (open pollinated variety), and a susceptible line (IS-18363) genotypes. This strain was locally produced on soybean/molasses medium and applied at the concentration of 3.7 X 10⁷ spores/ml. The effects of sorghum genotypes and *B. thuringiensis* were found to be separate. Susceptibility of *C. partellus* to *B. thuringiensis* was greater on the resistant than on the tolerant or susceptible genotypes. These results support the hypothesis that the susceptibility of insects to entomopathogens is inversely related to host plant suitability. In sorghum, the degradation by ultraviolet (uv) light is possibly not a crucial factor in influencing the field persistence of *B. thuringiensis*. This is due to the nature of the plant which provides shelter to the pathogen applied to the leaf whorl. The use of the uv-protectant Congo Red did not result in any improvement in the control of *C. partellus* compared to the application of *B. thuringiensis* alone. Infestation of sorghum plants with first-instar *C. partellus* up to 10 days after application of the pathogen to sorghum plants did not result in reduced grain yield compared to plants treated and infested on the same day.

MANAGING STEM BORERS IN SORGHUM AND PEARL MILLET

K.F. Nwanze, O. Youm¹

International Crops Research Institute for the Semi-Arid Tropics(ICRISAT), Patancheru, Andhra Pradesh 502324, India - 1 ICRISAT Sahelian Center, B.P. 12404, Niamey, Niger.

Efforts in research to manage the major species of stem borers of sorghum (*Chilo partellus* in Africa and Asia, and *Busseola fusca* in Africa) and pearl millet (*Coniesta ignefusalis* in West Africa) have traditionally focused on the development of borer resistant cultivars. However, conventional breeding procedures are yet to produce acceptable genotypes. Recent shifts in focus are beginning to show good prospects.

In sorghum, increased farmer participatory inputs in the evaluation of improved sorghum cultivars and crop combinations have produced good results in Western Kenya. Recent studies both in Kenya and India show that parasitoids are more active in borer-damaged, moderately resistant sorghums and offer new prospects for interfacing biological control with host plant resistance. The potential impact of native ecosystems in this relationship is being studied. A modest effort has been initiated in India on marker-assisted selection procedures in pyramiding genes from diverse sources.

The pheromone-based management strategy for the millet stem borer has been successfully tested in several countries of Sahelian West Africa. This strategy involves a long-lasting pheromone dispenser impregnated with a synthetic blend and an in-expensive water-based trap designed from local materials. The wide-scale implementation of this strategy is expected to have a significant impact in reducing an estimated annual loss of \$91million caused by this pest.

17-014

TILLAGE EFFECTS ON WHITE GRUB LARVAE BY ANT PREDATORS IN TROPICAL MAIZE FIELDS.

Timothy J. Gibb, J. Zenger

Department of Entomology

Purdue University

1158 Entomology Hall

West Lafayette IN 47907-1158

An eight year study of white grub infestation levels in no-till and conventional-till maize fields in Honduras indicated that white grub larvae became more abundant during the first two years of reduced tillage, but afterwards significantly declined in number.

It was also found that two ant species were significant predators of white grub eggs and early instar larvae. It appears that tillage may significantly affect ant predation and may influence the grub population fluctuations described.

17-013

SORGHUM INSECT PESTS AND THEIR MANAGEMENT IN THE TROPICS

K.F. Nwanze

International Crops Research Institute for the Semi-Arid Tropics(ICRISAT), Patancheru, Andhra Pradesh 502324, India.

Although annual losses in sorghum grain production resulting from insect-induced crop damage are estimated at over \$1000 million in Africa and Asia and research on the major pest species: shoot fly (*Atherigona soccata*), stem borers (*Chilo partellus* and *Busseola fusca*), midge (*Contarinia sorghicola*) and head bugs (*Calocoris angustatus* and *Eurystylus oldii*) dates over 50 years, management strategies for these insects have been poorly focussed. The paper questions the scope for chemical insecticides in subsistence agriculture in India and sub-Saharan Africa, the non-adoption of recommended intercropping configurations and the limited impact in the breeding for pest resistant sorghums.

Pest management in the tropics is discussed in the context of indigenous farming systems and the need for a change in perception in the development of IPM programs. The prospects for applied biological control and the role of biotechnology in increasing levels of genetic resistance are examined. A call is made for increased attention to improved agronomic practices such as crop, soil and water management. Farmer-participatory inputs in the research process from the initial stages of constraint diagnosis, development and evaluation of options to the final stages of implementation are as crucial as the role of governments in adequate resource allocation, manpower development and better coordinated donor support.

17-015

THE IMPACT OF EGG PARASITISM ON BROWN PLANTHOPPER, *NILAPARVATA LUGENS* (STÅL) AND THE RELEVANCE TO PEST MANAGEMENT SYSTEMS FOR RICE IN ASIAM.F. Claridge, J.C. Morgan, A. Steenkiste, D. Damayante, D. Kertoseputro¹

School of Pure & Applied Biology, University of Wales Cardiff, UK

¹Central Research Institute for Food Crops, Bogor, Indonesia

The importance of invertebrate predators of the various life history stages of *N. lugens* in providing high levels of natural field mortality is now well established in many parts of Asia. In a classic population study in the Philippines, Kenmore *et al.* (1985) demonstrated the importance of egg mortality due to a variety of uncertain causes, but including egg parasitism.

In Sri Lanka and Indonesia we have demonstrated a rich species diversity of egg parasitoids, including species of *Anagrus* (Hymenoptera: Mymaridae) and *Oligosita* (Hymenoptera: Trichogrammatidae). Levels of field mortality up to 80% have been observed. Parasitoid species tend to be more host specific than previously thought and show complex patterns of oviposition behaviour.

In Indonesia - 1. levels of parasitism have been monitored by using egg infested trap plants set out in the field; 2. field cage systems have been used to establish with certainty the relative effects of predators and parasitoids; 3. detailed attention has been given to the analysis of species composition of egg parasitoids and their relative abundances. Attempts have also been made to determine the effects on egg parasitism of habitat enrichment by encouraging the growth of particular weeds, including *Leersia hexandra*.

17-016

TERMITE DAMAGE ON MAIZE AND CONTROL
OPTIONS FOR SUBSISTENCE FARMERS.

M. Gethi,¹ W. Gitonga² and R.S. Ochiel².

¹ Regional Research Centre, Kenya Agricultural
Research Institute, Embu, Kenya.

² National Agricultural Research Centre, Kenya
Agricultural Research Institute, Muguga, Kenya.

Termite, *Macrotermes Spp.* have been reported to cause considerable damage to maize in low rainfall areas of Eastern Kenya. Preventive and control methods have for a long time relied on persistent organochlorines. Due to environmental issues associated with these pesticides and their unavailability to subsistence farmers, experiments were conducted to investigate on other control alternative control methods using botanicals (Neem seed extract and wood ash) and manipulation of cropping systems that can reduce termite damage. Data collected included infestation and damage levels. Results indicated that maize beans intercrop reduced infestation, namely ground tunnelling, number of foraging termites and subsequent damage on maize. Wood ash and neem seed powder were also found to be effective in reducing infestation levels. However, termite infestation and damage on maize was found to be very much dependent on the amount of moisture in the soil. These alternative control methods might be cheaper for small scale farmers with no access to expensive pesticides.

17-018

IPM IN IRRIGATED RICE ENVIRONMENT : A SUCCESSFUL CASE
FROM BURKINA FASO.

D. Dakouo (1), S. Nacro (1), R. Post (2), Y. Traoré (2),
S. Nokoe (3) and D.M. Munyinyi (3).

1. INERA, Laboratoire d'entomologie des céréales, Station de Farako-Bâ, Bobo-Dioulasso, BURKINA FASO. 2. Projet Vallée du Kou, Bobo-Dioulasso, BURKINA FASO. 3. ICIPE, Biomathematics Research Unit, Nairobi, KENYA. The efficiency and profitability of an IPM system based on phytosanitary survey and threshold interventions was evaluated in 30 small - scale farmer fields at the Vallée du Kou irrigated rice scheme for two consecutive crop seasons. There was a considerable advantage in cost, number of insecticide applications and yield of the IPM system as compared to an arbitrary or routine insecticidal application. The proposed method is considered to be environmentally friendly. A remarkable feature of the system is that farmers were involved in the set up and operation, and therefore likely to be sustainable. After the efficiency and profitability of the system being established, it was easily adopted by most of the farmers in the rice scheme.

KEY WORDS : Irrigated rice, stem borers, chemical control, phytosanitary survey, threshold interventions, IPM.

INTEGRATED PEST MANAGEMENT PROSPECTS FOR MAJOR
GRAMINACEOUS STEMBORERS IN SOUTHERN AFRICA

D.E. Conlong

South African Sugar Association Experiment Station, Mount
Edgecombe, Kwazulu-Natal, South Africa

In southern Africa maize, sorghum and sugarcane are grown on a large scale commercial basis. As such, these crops provide a large refuge for numerous insect species, a number of which are pests. Stem boring Lepidoptera are probably the most damaging in all three crops.

This paper will review published problems associated with chemical, cultural, biological and management pest control options against *Chilo partellus* (Swinhoe) (Lepidoptera: Pyralidae) and *Busseola fusca* (Fuller) (Lepidoptera: Noctuidae) in maize and sorghum, and *Eldana saccharina* Walker (Lepidoptera: Pyralidae) in sugarcane. The prospects for integrating control options available to best control the different pests will be considered and examples of successful integrated pest management strategies against these stem borers in the various crops will be given.

17-019

PROSPECTS FOR THE CONTROL OF THE LARGER GRAIN BORER
PROSTEPHANUS TRUNCATUS (HORN.) IN AFRICA, USING
INTEGRATED PEST MANAGEMENT STRATEGIES.

J. N. AYERTEY

DEPT. OF CROP SCIENCE
UNIVERSITY OF GHANA
LEGON, GHANA.

The Larger Grain Borer, *Prostephanus truncatus* (Horn.) an indigenous insect pest of dry maize in Central America, entered Africa and was first reported in Tanzania in the 1980s. Since then, it has spread to several countries including Kenya, Malawi, Zambia, Burundi, Rwanda in East Africa and Togo, Benin, Nigeria, Ghana, Burkina Faso, Niger and Guinea in West Africa, causing considerable damage to maize and dry cassava chips. In each of the affected countries, several methods are employed in an attempt to control this devastating insect pest. This paper examines prospects for the control of the Larger Grain Borer in its new home in Africa, using Integrated Pest Management Strategies.

17-020

ASSOCIATION AND SYNCHRONY OF *SMICRONYX GUINEANUS* VOSS, *SM. UMBRINUS* HUSTACHE (COLEOPTERA: CURCULIONIDAE) AND THE PARASITIC WEED *STRIGA HERMONTHICA* (DEL.) BENTH. (SCROPHULARIACEAE)

D. Traoré¹, C. Vincent² and R. K. Stewart³

¹ IN.E.R.A, CRRA de Farakoba, Bobo-Dioulasso, Burkina Faso

² Centre de Recherche et de Développement en Horticulture, Agriculture et Agro-Alimentaire Canada

³ Dept. of Nat. Res., Macdonald Campus, McGill University, Canada

Field experiments were conducted in 1992 and 1993 at Kaya, Burkina Faso, West Africa, in fields of sorghum (*Sorghum bicolor* (L.) Moench and pearl millet (*Pennisetum americanum* (L.) K. Schum. (syn. *P. typhoides* (Burm.) Stapf and Hubb.). *Striga hermonthica* was sampled weekly using a square meter metal frame. The sample size for each field was ten quadrats making a total of 10 m² in each field. Concurrently, adult populations of *Smicronyx guineanus* Voss and *Sm. umbrinus* Hustache were sampled using a Univac portable suction sampler to assess the synchrony of *Smicronyx* with *Striga*. Chi-square tests for independence of the populations of *Smicronyx* and *Striga* indicate a good synchrony of the active stages of the life-cycle of the weevils with the period of occurrence of the witchweed.

A 0.5 by 0.5 m metal frame was thrown ten times at random in each field and a Univac portable suction sampler was used to determine the degree of association between *Smicronyx* and *Striga*. There was a positive association between the weevil and the witchweed.

Key-words: *Smicronyx guineanus*, *Sm. umbrinus*, *Striga hermonthica*, identification, synchrony, association, galls, alternate hosts, biological control, Burkina Faso.

17-021

THE ECOLOGY OF *NEPHOTETTIX VIRESCENS* (DISTANT) (HEMIPTERA: CICADELLIDAE) IN RELATION TO ITS ROLE AS A VECTOR OF RICE TUNGRO VIRUSES
T.C.B. Chancellor, A.G. Cook, K.L. Heong¹, S. Villareal¹
Pest Biology Department, Natural Resources Institute, Central Avenue, Chatham Maritime, Chatham, Kent ME4 4TB, England-Entomology & Plant Pathology Division, International Rice Research Institute, P.O. Box 933, 1099 Manila, Philippines

The flight activity of *Nephotettix virescens* (Distant) in the Philippines was monitored by suction traps at 0.75 m and 1.5 m and an upwardly-directed segregating light trap at 4.0m and was closely associated with rice cropping patterns. Trap catches were largest towards the end of both wet and dry seasons, with lowest numbers recorded during fallow periods. The majority of individuals recorded in suction traps were caught around dusk with a smaller peak at dawn and larger catches were associated with increasing temperature. Results from sticky trap catches at canopy height indicated that adult *N. virescens*, particularly males, dispersed freely within rice plots at all crop growth stages.

Immigration of adult *N. virescens* into rice plots was greatest in wet seasons and was also high in late-planted dry season crops. Population density peaks occurred by 50-65 days after transplanting in wet seasons, but varied more widely in dry seasons. Tungro disease incidence was not directly related to leafhopper vector number. Rapid spread of tungro disease occurred in a late-planted dry season crop when peak adult numbers of *N. virescens* were only two per rice hill and nymphal populations were also low, but inoculum pressure was high. The results suggest that leafhopper vector numbers per se are not a sufficient indicator of tungro disease risk. In addition, the findings indicate that there are seasonal differences in inoculum pressure which may be taken into account in designing appropriate tungro management strategies.

17-023

BEMISIA TABACI AND AFRICAN CASSAVA MOSAIC DISEASE IN UGANDA AND THE CÔTE D'IVOIRE

J.M. Thresh, G.W. Otim-Nape¹, J.P. Legg, L.D.C. Fishpool and

J. Colvin.

Natural Resources Institute, Chatham, United Kingdom -1 Namulonge Agricultural and Animal Production Research Institute, Kampala, Uganda

Detailed studies of the biology and ecology of the whitefly, *Bemisia tabaci* (Gennadius) (Homoptera: Aleyrodidae), the vector of African Cassava Mosaic Disease (ACMD), have recently been carried out in Uganda and the Côte d'Ivoire, providing an opportunity to compare two contrasting situations. In the Côte d'Ivoire, a relatively stable situation exists with ACMD infection consistently at c. 100% and yield-losses varying from 0-40%. Uganda, however, is currently experiencing an ACMD epidemic and transect surveys of the incidence of ACMD and *B. tabaci* abundance revealed a gradually moving 'front' of high ACMD incidence associated with increased *B. tabaci* numbers. Data on the phenology of *B. tabaci* populations and ACMD incidence in the contrasting agro-ecosystems will be presented and possible reasons for the observed differences will be discussed.

17-022

ECOLOGY OF SHARPSHOOTERS ASSOCIATED WITH *XYLELLA FASTIDIOSA* OF CITRUS IN BRAZIL

J.R.S. Lopes

Departamento de Entomologia, Universidade de São Paulo/ESALQ, Piracicaba, Brasil

Citrus variegated chlorosis is a new and destructive citrus disease caused by *Xylella fastidiosa*, first reported in São Paulo State, in 1987. Three sharpshooter leafhoppers (Hemiptera: Cicadellidae) frequently found in citrus trees, *Dilobopterus costalimai*, *Oncometopia fascialis* and *Acrogonia terminalis*, are likely field vectors of this bacteria. *D. costalimai* was already confirmed as an experimental vector. These xylem-feeding leafhoppers are widespread in southern Brazil, but are particularly abundant in northern São Paulo. Adult populations, as measured by yellow sticky cards, tend to increase during the summer, reach a peak in the fall (March-June), then decrease sharply in August and remain at low levels throughout the spring (September-November). Egg parasitism has been observed particularly in the spring. Spatial distribution of sharpshooters in the citrus orchards is usually aggregated. In the citrus trees, nymphs and adults show preference for young shoots facing the North. Observations of caged adults in the greenhouse indicated a higher flight activity around noon, when the temperature increases. Greenhouse studies showed that *D. costalimai* and *O. fascialis* can feed well and oviposit on various herbaceous weeds commonly found in citrus orchards. Some of these weeds are natural hosts of *X. fastidiosa* and might act as inoculum sources for primary spread of the disease.

17-024

BEHAVIOUR OF LEAFHOPPER VECTORS (*CICADULINA* spp.) WITHIN MAIZE AND ITS IMPORTANCE IN INCREASING MATING OPPORTUNITIES

W.W. Page
Natural Resources Institute, Chatham, United Kingdom

Studies in Uganda of the epidemiology of maize streak virus disease indicate that males and females of the vectors (*Cicadulina* spp.) differ in their behaviour within a maize crop. Up to 95% of *Cicadulina* caught in the upper canopy of maize are females and up to 90% caught close to the ground are males. The females show a preference for maize plants at 25-40 cm high (for var. Kawanda Composite A) and it is at this time that peak numbers of both sexes are found in maize plots. Results suggest that each maize plant can be visited by *Cicadulina* one to five times per day during the peak period. *C. mbila* and *C. storeyi* have been shown to communicate during mate seeking behaviour by vibrating on the plants they are resting on, the male instigating the communications. It is hypothesised that males accumulate in maize plots at the time that females are abundant, moving close to the ground where the vegetation is comparatively sparse, and testing maize stems in search of females sitting up in the whorls. It is suggested that weed-free maize plots provide good sites for mate seeking as the ability of males to locate females is enhanced. Most wild grasses, which are preferred hosts for feeding and oviposition, provide dense vegetation which is less suitable for mate seeking. This may explain why *Cicadulina* are, in general, only found in large numbers within or adjacent to crops. It should be possible to manipulate *Cicadulina* behaviour by making the crop less attractive for mating activities. Intercropping with plants which produce dense foliage near the ground appears to be one method of achieving a reduction in leafhopper mate seeking activity and thus reducing the incidence of maize streak virus disease.

17-026

BIOLOGY-ECOLOGY OF RICE HOJA BLANCA VIRUS VECTORS
M. Hernández, A. Xet, J. Madriz, E. Cabezas, J. Miranda, A. Espinoza

CIBCM, Universidad de Costa Rica, San José, Costa Rica
The delphacid *Tagosodes orizicolus* causes serious oviposition and feeding damage to rice cultivation in Latin America. It is also a vector for the severe rice hoja blanca virus disease (RHBV). Both rice and vector are hosts for the virus, which is transmitted both transovarially (80% efficiency) and horizontally from plant to insect (10% efficiency). The yeast-like endosymbionts essential for the insects' hormone metabolism, which are also transmitted transovarially, may be involved in either of the virus transmission modes. The characterisation of these endosymbionts from *T. orizicolus* and *T. cubanus* (vector of the related Echinochloa hoja blanca tenuivirus; EHBV) will be discussed. The insects' ability to acquire the virus from the plant is determined by a single recessive gene, hence the low horizontal transmission efficiency. In order to characterise this gene, and to analyse the population structure of the vector for epidemiological studies, the genetic variability of *T. orizicolus* was determined using RAPDs. These studies show little gene flow between isolated populations. So far, no PCR marker linked to the ability to acquire/transmit virus has yet been found. *T. orizicolus* is monophagous and one of its few alternative hosts is *Chloris radiata*, which may be a reservoir of insects or RHBV. Although closely related, *T. orizicolus* and *T. cubanus* do not feed on each others' main hosts (rice and *Echinochloa colona*), which may be the principal cause for the molecular divergence of RHBV and EHBV.

Funded by the UCR, the Rockefeller Foundation and the EC DG-XII.

DISPERSAL OF BEETLE AND LEAFHOPPER VECTORS TO AND FROM NATURAL AND AGROECOSYSTEMS IN THE NEOTROPICS

M. E. Irwin¹, L. R. Nault², R. Allen³, R. Gámez⁴, C. Godoy⁴
¹Department of Natural Resources & Environmental Sciences, University of Illinois, Urbana, IL 61801 USA; ²Department of Entomology, The Ohio State University, OARDC, Wooster, OH USA; ³Department of Entomology, Cornell University, Ithaca, NY USA; ⁴Instituto Nacional de Biodiversidad, Heredia, Costa Rica.

Scientists from the US and Costa Rica collaborated in a cooperative project to survey plant virus vector taxa within tropical forests and neighboring agricultural settings in Costa Rica to determine if they differentially move between forests and adjoining croplands. The research emphasized vector taxa in the family Chrysomelidae (leaf beetles) (Coleoptera), and the Auchenorrhyncha (leafhoppers, planthoppers, treehoppers) (Homoptera) and their movements between natural and adjoining agricultural ecosystems. Targeted insect taxa were surveyed using large malaise traps positioned not only in both forested and pasture settings but also at the intersection of these two environments. The malaise traps used at the interface of forest and pasture were directional, i.e., they separated those insects flying into the forest from those flying into the pasture. Nearly 10,000 specimens within the target insect families were collected during the two-month rainy period of the first year of research. The data will be available to improve crop management and conservation biology efforts.

17-027

Comparison of intraspecific competition between latent and eruptive auchenorrhyncha (Homoptera) species on rice: *Recilia dorsalis* (Deltocephalidae) versus *Sogatella furcifera* (Delphacidae)
ZENG-RONG ZHU* and JIAAN CHENG (Department of Plant Protection and Institute of Applied Entomology, Zhejiang Agricultural University, Hangzhou, Zhejiang, 310029, China.
* Present address: IAEA Project URT/5/016, Tsetse Fly eradication on Zanzibar, P.O. Box 2593, Zanzibar, Tanzania.

A comparison of the effects of intraspecific competition between the white-backed planthopper (WBPH) *Sogatella furcifera* and the zigzag leafhopper (ZLH) *Recilia dorsalis*, as representatives of eruptive and latent auchenorrhyncha (Homoptera) species on rice, was carried out in laboratory. Crowding during the nymphal stage extended the duration of development of WBPH but not of ZLH. The nymphal survival rate of WBPH, sex ratio, preoviposition period and fecundity of both species were however not affected. The brachypterous rate of WBPH and nymphal survival of ZLH were significantly reduced under high nymphal density. Crowding in adult stage reduced significantly fecundity and longevity of both species. Fecundity and longevity was further reduced when combined with high density at nymphal stage. Age-specific life table analysis showed that the integrated effect of crowding on ZLH is stronger than on WBPH. The mechanism of eruptive and latent species' response to crowding during nymph and adult stages is not always clearly expressed as a significant difference in fecundity. It is better described as the variation in the intrinsic rate of increase (r_m). Therefore the construction of an age-specific life table is helpful, and perhaps necessary, to understand these effects. The main ecological characteristics of ZLH, as a latent species are its longer immature period, lower total fecundity and decreased and retarded rate of oviposition, hence the lower r_m , as compared with WBPH.

17-028

BENEFICIAL EFFECTS OF MAIZE MOLLICUTES ON THEIR NEOTROPICAL LEAFHOPPER VECTORS

L.R. Nault, Ohio Agricultural Research and Development Center, The Ohio State University, Wooster, Ohio 44691, U.S.A.

The neotropical leafhopper genera *Dalbulus* and *Balbulus* are comprised of 16 deltocephaline species that specialize on the native perennial gamagrasses (*Tripsacum*) and the teosintes (*Zea*). One leafhopper species, the corn leafhopper, *D. maidis*, has become a serious pest of the teosinte domesticate, maize, *Zea mays* subsp. *mays*. Only occasionally does the leafhopper cause economic loss via feeding damage, however, it is the most important vector of two plant pathogenic mollicutes, the corn stunt spiroplasma (CSS) and the maize bushy stunt phytoplasma (MBSP). The mollicutes propagate in and use leafhoppers as alternate hosts. Most leafhoppers in these genera are found on the gamagrasses which are immune to mollicute infection. Many of these species are capable of colonizing maize but when exposed to mollicute infected plants, adult life is significantly shortened and fecundity is markedly lowered. This may benefit *D. maidis* and a second maize specialist, *D. elimatus* whose life spans and fecundity are not affected by mollicute infection, from competition from their congeners in the maize habitat. Moreover, recent evidence suggests that maize mollicutes provide advantage to infected corn leafhoppers during the dry season in the neotropics when maize is not grown. Infected leafhoppers are more likely to survive temperature extremes and can live longer on alternate food hosts or on free water than noninfected leafhoppers. This mutualism will be discussed in relation to survival of mollicutes and their vectors and for management of these pests.

17-030

INVESTIGATIONS FOR THE NATURAL BIOLOGICAL CONTROL OF *ORYCTES CENTAURUS* (STERNB.) (COLEOPTERA: SCARABAEIDAE: DYNASTINAE) ON THE MAINLAND OF PAPUA NEW GUINEA.

L. Beaudoin-Ollivier, J.P. Morin¹, D. Rochat¹.

PNG Cocoa and Coconut Research Institute/Centre International de Recherche Agronomique pour le Développement, Cultures Pérennes, Madang, Papua New Guinea - ¹ Institut National de la Recherche Agronomique, Versailles, France/Centre International de Recherche Agronomique pour le Développement, Cultures Pérennes, Montpellier, France.

Oryctes centaurus mainly associated with sago palm (*Metroxylon sagu* Rottb.) has been also found breeding and attacking coconut palm (*Cocos nucifera* L.) on the mainland of Papua New Guinea. It may attack coconut palms in a similar manner to *O. rhinoceros*.

Volatile collections and electroantennography revealed that males produced a strongly EAD-active compound which is not produced by females. This male *O. centaurus* compound is also active on *O. rhinoceros* and *O. monoceros* antennae.

A "blue disease" has been found to occur in the natural breeding sites. First investigations revealed no causal agent. Electronic microscopic observations must be able to reveal whether a presumed pathogenic agent (virus) is enclosed in the spheroid vacuolated corpuscles already described in the past for *Oryctes* spp.

O. centaurus natural biological control knowledge may be useful to identify a possible control strategy for the most destructive coconut pests which occur on the Papua New Guinea islands, *Scapanes australis* and *Oryctes rhinoceros* (Coleoptera: Scarabaeidae: Dynastinae).

17-029

ASPECTS OF THE BIOLOGY OF THE COCONUT TERMITE *NEOTERMES RAINBOWI* (HILL) AND IMPLICATIONS FOR ITS MANAGEMENT

M. Lenz

CSIRO Division of Entomology, GPO Box 1700, Canberra ACT 2601, Australia

Neotermes rainbowi has a restricted distribution on a number of coral atolls of the Cook Islands and Tuvalu in the South Pacific. The termites hollow out the trunks of coconut palms, rendering the palms vulnerable to windthrow, even by light winds. Young palms may be destroyed before reaching bearing age.

Alates, the king and queen, reach palms by air and establish a colony inside the bole. Alates are released from existing colonies in small numbers over extended periods of the year. On islands with no other competing (subterranean) termites, foragers of *N. rainbowi* can reach other palms via the soil or root connections. (Cook Islands). Where a species of *Nasutitermes* is present, colonies of the coconut termite are restricted to single palms (Tuvalu).

The coconut termite has a rather unique habit: it chews a system of channels and groves in the bark of the palm. The extent of bark markings roughly represents the occupied area of the trunk.

Once a palm snaps off, termites in the section of the palm left without the founding king and queen, will produce replacement reproductives (neotenics); the end result is two independent colonies. In *N. rainbowi* neotenics form within shorter periods and have a more balanced sex ratio than reported for other species of the genus. As palm stumps and broken trunks decay and the food supply becomes limited, development of most colony members will be channelled into alates. In response to pathogens, survivors can seal off contaminated areas of their tunnel system and wall off cadavers. Even small groups of survivors can re-establish themselves as fully functional colonies with the help of neotenics. Management options are (1) tree sanitation to reduce the release of colony-founding alates and (2) treatment of palms with the fungal pathogen *Metarhizium anisopliae*.

17-031

HEMIPTERA ON OIL PALM AND COCONUT, INCLUDING DISEASE VECTORS

D. Mariau

CIRAD-CP - 2477, avenue du Val de Montferrand - 34032 Montpellier Cedex 1 - France

Many widely varying Hemiptera species are found on the leaves of palms grown in humid tropical zones.

Many of them are highly polyphagous, and only accidentally, generally once adult, end up on palm leaves, on which they can nevertheless feed. Others are more closely linked to palms and spend the whole of their development cycle on them, and lastly, some species seem to live on palms alone.

Most of the Hemiptera have no economic impact on their hosts, since population levels are rarely high enough for them to cause significant damage. However, some Heteroptera *Coreoidea* and *Coccoidea* species can be very damaging primary pests. Others, amongst the *Fulgoroidea*, *Cicadelloidea* and *Pentatomoidea*, transmit very serious diseases that have decimated oil palm and coconut plantations worldwide, for example coconut lethal yellowing in Africa and the Caribbean and oil palm and coconut trypanosome diseases in Latin America.

Lastly, some *Pentatomoidea* and *Reduviidae* species are auxiliary, attacking Lepidoptera caterpillars.

17-032

SYNTHETIC PHEROMONES USED SIMULTANEOUSLY TO TRAP TWO GENERA OF COCONUT BEETLE PESTS; *ORYCTES RHINOCEROS* L. AND *RHYNCHOPHORUS BILINEATUS* (Montr.) IN PAPUA NEW GUINEA AND THEIR INFECTION WITH PATHOGENIC ORGANISMS

R.N.B. Prior, T. Kakul, S. Embupa
P.N.G. Cocoa and Coconut Research Institute,
Rabaul, Papua New Guinea.

Synthetic pheromones originally researched by Oehlschlager at Simon Fraser University, Canada, were field tested in Papua New Guinea. Traps for the Asian rhinoceros beetle, *Oryctes rhinoceros* L. and the Black Palm Weevil, *Rhynchophorus bilineatus* (Montr.) were combined by placing the two different pheromones in the same trap. The addition of insect pathogens to some traps enabled continuous infection of live beetles which are returned to the field. The potential for utilising pheromone traps for disseminating insect pathogens is discussed.

17-033

INTEGRATED MANAGEMENT OF RED PALM WEEVIL, *RHYNCHOPHORUS FERRUGINEUS* F., IN DATE PALM PLANTATIONS OF THE KINGDOM OF SAUDI ARABIA

R.A. Abozuhaiah, P.S.P.V. Vidyasagar, V.A. Abraham¹

Red Palm Weevil Project, Ministry of Agriculture & Water, P.O. Box-134, Saihat-31972 Kingdom of Saudi Arabia - 1 Red Palm Weevil Project, Ministry of Agriculture & Water, Directorate of Agriculture, Al Hassa, Kingdom of Saudi Arabia

The red palm weevil *Rhynchophorus ferrugineus* F. has become a serious pest of date palm in the Kingdom of Saudi Arabia, since its first report in 1987 in Al Qatif region of Eastern province. Subsequently the pest has spread to the regions of Al Hassa, besides 13 other areas in the Kingdom. For the management of the pest in these areas a comprehensive control program has been formulated and implemented with new strategies and methods developed and tested in the field. A systematic survey of the pest incidence in date palm farms was undertaken in all areas to identify the damaged plants. The palms detected in the early and medium stages of damage were treated by stem injections with an effective pesticide. The palms beyond recovery were either cut and burnt or treated with pesticide to kill all stages of the pest. To prevent attack, the palms were soaked regularly by an insecticide under low pressure.

Apart from these methods, pheromone lures baited with food were used for mass trapping as well as monitoring of the pest since 1994. For efficient pheromone trapping, lures with different release rates, trap design, density, location, food type, pesticide kind, food longevity etc. have been tested and standardized after field trials. In the areas of Al Qatif and Al Hassa pheromone based mass trapping has been successful in reducing the weevil populations and this was integrated with other methods for successful control of the pest. From an average infestation rate of 6.6% in 1993, in Al Qatif region the damage has been reduced to 4.0% in 1994 and 2.5% in 1995. In other regions also the results are satisfactory. By adopting various methods in an integrated way the infestations have been reduced over the past two years. The details of field trials and control program are presented in the paper.

INTEGRATED CONTROL OF *ORYCTES MONOCEROS* OL AND *RHYNCHOPHORUS PHOENICIS* (L.) IN NIGERIA

- PHEROMONE BASED MASS TRAPPING

A.C. OEHLISCHLAGER* and C.I. AISAGBONHI**

*Department of Chemistry, Simon Fraser University,
Burnaby, British Columbia.

**Entomology Division, Nigerian Institute For Oil Palm
Research, Benin City, Nigeria.

Three groups of 5 bucket traps containing *Oryctes monoceros* pheromone, enhanced with insecticide impregnated organic matter were set up on NIFOR date palm field at Dutse. A control set of 5 traps containing organic matter alone, without pheromone, was also set up. Traps were placed at 6 palms (52.8m) away from one another and examined once a week from April to May 1994. Pheromone traps enhanced with bits of sugar cane and cured cow dung or bits of palm fronds caught *Oryctes* while the traps without pheromone caught none. The difference was highly significant ($p < 0.05$). These traps lay out with little variation, and containing *Rhynchophorus phoenicis* pheromone were similarly set up on a replanted oil palm field in NIFOR, Benin City. Recoveries collated from February to May 1994 indicated that the *Rhynchophorus* pheromone was highly efficient ($p < 0.05$) in catching the adult insects. Pheromone based mass trapping will help immensely in protecting living palms from extensive destruction by these insects in Nigeria.

17-035

REDUCTION IN CANEGRUB POPULATION DENSITY WITH RETENTION OF CROP RESIDUES IN SUGARCANE (COLEOPTERA: SCARABAEIDAE).

L.N. Robertson and P.W. Walker¹, Bureau of Sugar Experiment Stations, Dallachy Road, Tully, Queensland, Australia - 2 BSES, Brandon, Queensland, Australia.

Sugarcane in Queensland, Australia, is harvested annually. An average of one plant crop and four ratoon crops is produced before replanting. Since 1940, sugarcane has been burnt before harvesting to remove trash and aid cutting. Modern machinery can harvest unburnt crops and retention of trash as a blanket on the soil surface is now widely practiced in North Queensland ratoon crops.

Lower population densities of greyback cane grub (*Dermolepida albohirtum*) (Waterhouse) were recorded in ratoon crops managed with green cane harvesting and trash blanketing (GCTB). A replicated trial at Tully Sugar Experiment Station compared GCTB with trash buried by cultivation, and with burnt trash. In the first ratoon, fewer grubs were found in GCTB (0.9 per stool) compared to buried trash (1.7 per stool) and burnt trash (1.6 per stool) (ANOVA $F_{(2,6)} = 4.6$; $P < 0.06$). Initial numbers of small cane grubs in the ratoon crop were similar in each treatment in the replicated trial at Tully. Rate of development and survival of cane grubs are lower under GCTB compared to burnt trash.

Four unreplicated trials compared GCTB with burnt trash on commercial farms, three in the Burdekin district in first ratoon blocks and one in Tully in fourth ratoon. Three sites had at least three times as many late-stage cane grubs per stool in crops with burnt trash compared to GCTB. One site gave 27% increase in tonnage of cane (103 cf. 131 tonnes/ha), and 30% higher sugar yield (13 cf. 17 tonnes/ha) in GCTB compared to burnt trash. The presence of grass weeds may have increased numbers of cane grubs in GCTB at the fourth site.

17-036

PROSPECTS OF USING PARASITIDS FOR TICK MANAGEMENT IN AFRICA.

E. Mwangi and G. P. Kaaya

The International Centre of Insect Physiology and Ecology (ICIPE), Nairobi, Kenya.

Although the existence of tick parasitoids has been known since the turn of the century their usability for tick control has not been fully investigated or exploited. Seven species of tick parasitoids have so far been described from the genus *Ixodiphagus*. In Africa tick parasitoids have been reported from South Africa, Uganda, Kenya, Nigeria, and Cote d'Ivoire.

Recent studies in Kenya have shown that tick parasitoids play a more important role in regulation of tick numbers in nature than previously thought.

In studies of *Ixodiphagus hookeri* a parasitoid of *Amblyomma variegatum* in Kenya, an experimental release of the parasitoid reduced the tick by over 80% within a period of one year. The experiment suggested that strategic releases of the parasitoid twice a year can keep the tick numbers down in semi-zero grazing type of husbandry.

This paper discusses the results of the pilot release study, analyses the status quo as regards studies on tick parasitoids in Africa and highlights what needs to be done if parasitoids are to be fully exploited for tick management in the continent.

17-037

THE ROLE OF WOMEN IN PEST MANAGEMENT: THE KENYAN PERSPECTIVE

E. Mwangi

International Centre of Insect Physiology and Ecology (ICIPE), Nairobi, Kenya.

Despite food crop losses of about 50% due to pests, agriculture remains the main income earner for Kenya. Women manage 70% of the 4 million small scale farms in the country. They contribute in pest management by using cultural methods of farming such as inter-cropping, early planting, weed removal, crop rotation and burning of crop residues. This is however incidental rather than deliberate. They also use home made remedies for crop and post-harvest pests, as well for pests of animals such as ticks and tsetse.

Professionals such as veterinarians and those trained in agriculture contribute by teaching in universities, doing research and giving advice to farmers about pests. There are about 200 trained vets and a similar number in agriculture who have graduated from Kenyan Universities.

Involvement of women in pest management should include women groups. There are 23,000 such groups already registered in Kenya. Fundamental problems which women face, *inter alia*, lack of basic education, non participation in decision making, lack of professional training will have to be addressed if women are to participate in pest control more intelligently. There is need to inform and teach about IPM strategies, preservation of natural enemies of pests, and the benefits of cultural methods of farming as far as pests are concerned.

17-038

SPECIFICITY OF RESPONSE TO SEX PHEROMONES AMONG THE SWEET POTATO WEEVILS, *CYLAS PUNCTICOLLIS* BOHEMAN AND *C. BRUNNEUS* FABRICIUS (COLEOPTERA: APIONIDAE)

M.C.A. Downham¹, N.E.J.M. Smit², P.O. Laboke³, D.R. Hall¹, B. Odongo³. ¹Natural Resources Institute, Chatham, United Kingdom - ²International Potato Centre, Kampala, Uganda - ³Namulonge Agricultural and Animal Husbandry Research Institute, Kampala, Uganda.

The major components of the sex pheromones produced by females of the sweet potato weevils, *Cylas puncticollis* Boheman and *C. brunneus* Fabricius (Coleoptera: Apionidae), have been identified as decyl and dodecyl (*E*)-2-butenates respectively. Field tests in Uganda showed that the synthetic pheromones were highly attractive to males of the respective species, but, whereas synthetic lures for *C. puncticollis* were species-specific, those for *C. brunneus* also attracted significant numbers of *C. puncticollis* males. Females of both species attracted essentially only conspecific males, and further studies were carried out to determine how species-specificity of mating is ensured. In laboratory studies, no other pheromone components could be detected in female-produced volatiles from either species using gas chromatography linked to electroantennography (GC-EAG), and male weevils were found to give EAG responses to the pheromone of the other species. In the field, addition of even small amounts of the *C. puncticollis* pheromone to that of *C. brunneus* stopped attraction of *C. brunneus* males. However, investigation of the diurnal timing of captures at pheromone traps showed that peaks of male activity for the two species occur at quite different times during the night, ensuring species-specificity of mating. It is concluded that chemical identification of the pheromones is probably complete, and the consequences of these results for practical application of the synthetic pheromones are discussed.

17-039

LONG-RANGE SEX PHEROMONE OF THE LONGHORN BEETLE, *Migdolus fryanus* WESTWOOD: IDENTIFICATION AND APPLICATION

W. S. Leal, E. F. Vilela¹, M. S. Bento¹, T. M. C. Della Lucia¹, and M. Ono²

Lab. of Chemical Prospecting, National Institute of Sericultural and Entomological Science, MAFF, Tsukuba, Japan - ¹ Departamento de Biologia Animal, Universidade Federal de Viçosa, Viçosa, Brazil - ² Fuji Flavor Co. Ltd, Tokyo, Japan

The first long-range female-released sex pheromone for the family Cerambycidae is reported from a sugarcane pest in South and Central America, *Migdolus fryanus*. Two female-specific compounds were identified, namely, N-(2'S)-methylbutanoyl 2-methylbutylamine and N-formyl L-isoleucine methyl ester. Although the amide was very active in field tests, the amino acid derivative neither increased nor decreased trap catches by the amide. Recent experiments for the utilization of the synthetic sex pheromone in mating disruption will also be discussed.

17-040

WHY THE HARVESTER TERMITE, *HODOTERMES MOSSAMBICUS* (HAGEN), IS STILL A PEST IN SOUTH AFRICA.

F.D. Duncan
Department of Zoology, University of the Witwatersrand, Johannesburg, South Africa.

The harvester termite, *Hodotermes mossambicus*, has been considered a pest of natural pastures since 1934, because it competes with cattle for the available grazing, especially in drought years. However, its pest status needs to be re-evaluated as this termite has potential value in pasture ecosystems. Due to the continued pest status of the harvester termite, several techniques for chemical control have been developed. A thorough understanding of the biology and behaviour of the harvester termite should be used to improve the success of the methods used for control measures. Poisons need to target the final larval stage not the worker caste, as these larvae are responsible for feeding the colony. Research is continuing to investigate other non chemical means of control, such as fungicides or biological control, that can be used for termite population reduction.

17-042

DEVELOPING AND IMPLEMENTING INTEGRATED PEST MANAGEMENT OF CASSAVA GREEN MITES IN AFRICA

J. S. Yaninek and B. Mégevand
Plant Health Management Division, IITA Benin Station, Cotonou, Benin

The exotic cassava green mite, *Mononychellus tanajoa* (Bondar), is a major pest of cassava in Africa causing an estimated 30 to 50 percent reduction in yield. Increasingly, cassava farmers are demanding solutions. Ecological characterization of the pest has been used to target ecozones and to identify appropriate intervention technologies. These include classical biological control, host plant resistance and cultural practices. Two exotic phytoseiid mite predators have established, spread and significantly reduce pest populations in parts of the cassava belt. In addition, a virulent strain of an exotic fungal pathogen is being testing. Evidence of genetic resistance is prompting more cassava breeding programs to screen for mite damage symptoms. New varieties are now being developed, and their impact on the pest evaluated on-farm. Cultivars, soil fertility, time of planting, cropping system and time of harvest all influence the build-up of damaging pest populations and can be manipulated to reduce pest densities. Integrating these interventions into a comprehensive strategy remains a challenge.

17-041

FURTHER EVIDENCE FOR OVICIDAL AND LARVICIDAL ACTION OF NEEM, *AZADIRACHTA INDICA* A. JUSS, ON THE COWPEA POD BORER, *MARUCA TESTULALIS* GEYER

L. E. N. Jackai and G.C. Forjoe
Plant Health Management Division, International Institute of Tropical Agriculture (IITA), Oyo Road, PMB 5320, Ibadan, Nigeria, West Africa

Various neem preparations have been shown to interfere with feeding and/or growth and survival of larval stages of the legume pod borer, *Maruca testulalis* Geyer. However, nothing is known about the effect of neem on the eggs of this insect which are more vulnerable than the larval stage because they are fragile and laid in exposed locations on the cowpea plant. We therefore conducted laboratory studies to determine the effect of aqueous neem preparations on eggs, and included larvae for comparison.

High egg mortalities (30-71%) were obtained with 5, 10 and 20% (w/v) extracts. In addition to growth inhibition and high larval mortalities (28-94%) caused by the leaf extracts, seed extracts at the three doses tested completely prevented pupation.

If application of neem is timed to coincide with egg laying on cowpea by this pest, fewer individuals would be recruited into the larval stage. This should result in less crop damage and enhance larval control with neem or other interventions. Field studies are underway to test this hypothesis.

17-043

HOST-SIZE MEDIATED INTERACTION BETWEEN *GYRANUSOIDEA TEBYGI* AND *ANAGYRUS MANGICOLA* (HYMENOPTERA: ENCYRTIDAE), TWO PARASITOIDS INTRODUCED IN GABON AGAINST THE MANGO MEALYBUG

Juste BOUSSIENGUET
Laboratoire CHEIKH ANTA DIOP, Université du Gabon-IRAF (CENAREST), Libreville, Gabon

Establishment, spread of *Anagyrus mangicola* Noyes and coexistence of the latter with the previously introduced parasitoid, *Gyranusoidea tebygi* Noyes, were assessed using emergence samples. Surveys indicated that *G. tebygi* which almost exclusively emerged from small hosts was present all over the surveyed area and predominated. In contrast, three years after introduction, *A. mangicola*, whose rates of emergence were similar among hosts sizes, was not recovered over a radius of 15 km from the release site where the host was scarcer. No evidence of differential hyperparasitism rates among survey areas with and those without *A. mangicola* was observed, indicating that speed of dispersal of this parasitoid was not affected by hyperparasitism.

Limited establishment and spread of *A. mangicola* to survey areas of highest to intermediate host densities could be explained by species differences in the number of offspring produced under various conditions of host sizes and densities.

17-044**EFFECT OF MIX-CROPPING ON PEANUT INSECT PEST POPULATIONS AND THEIR PREDATORS**

I. O. Dicko, H. Tapsoba and K. Traoré

Institut du Développement Rural (IDR), Université de Ouagadougou,
Burkina Faso (West Africa)

Tests were initiated in 1990 and continued in 1991 at the University of Ouagadougou's experiment station at Gampela, Burkina Faso, to evaluate the effect of mix-cropping groundnut with sorghum or with pearl millet on insect pest damage and population densities. The impact of mix-cropping on predator population and groundnut pod yield was also examined. While population densities of the jassid, *Empoasca dolichi*, on groundnut were significantly reduced by mix-cropping. Both insect predator populations and pod yield were notably higher in diculture than in monoculture of groundnut.

Finally, our results show reduced foliage damage and already reported factors, such as improved light interception and soil moisture utilization by mix-cropped groundnut plants, to be complementary in enhancing pod yield in diculture of groundnut.

Key-words: mix-cropping, groundnut, sorghum, pearl millet, insect pest, predator arthropods, pod yield.

INSECT PREDATION BY SOME PONERINE ANTS AND
WEAVER SPIDERS IN COFFEE ORCHARDS IN
CHIAPAS, MEXICO

G. Ibarra-Núñez¹, J.-P. Lachaud^{1,2}, J.A. Lopez Méndez¹, M.A. Moreno Prospero¹, J.A. García Ballinas¹.
1 ECOSUR, Apdo Postal 36, 30700 Tapachula, Chiapa, Mexico - 2
LEPA, URA-CNRS 1837, Université Paul-Sabatier, 31062 Toulouse
cedex, France

Ants and spiders are among the most interesting predators for biological control in agroecosystems, due to their influence on pest-insects populations. To know the effect of these predators on insects populations, we sampled the prey caught by seven groups of predators, in coffee orchards in the Soconusco region of Chiapas, Mexico. The studied predators were two dominant ponerine ants: *Ectatomma ruidum* and *E. tuberculatum*, and five common weavers-spiders: *Cyclosa caroli*, *Gasteracantha cancriformis*, *Leucauge mandibulata/venusta*, *Anelosimus jucundus*, and Linyphiidae sp1 (probably *Lepthyphantes longispinosus*). We noted both the size of the webs and of the ants foraging areas, and their placement inside the orchards. Previously we sampled the coffee orchards to know (at family level) the kinds of arthropods living there, and their relative abundance. For the seven predators groups, the bulk of the prey (47.2% to 90.5%) belonged to four most abundant orders of insects: Hymenoptera, Diptera, Homoptera, and Coleoptera. In general, the frequency of relative predation on any prey, is proportional to their relative abundance. In spite of the differences in predation efficiency found among the studied predators, their activity did not result in a competition, but in a synergy. On the whole, their predation ranges did not overlap: the soil for *E. ruidum*, the coffee plants for the spiders (each web type placed on certain zone inside the foliage, or between coffee plants), and the shadow trees and branches of the coffee plants for *E. tuberculatum*. So the integration of the predation ranges of these seven groups of predators, makes them a very important assemblage of biological control agents for the coffee orchards in this neotropical region.

17-047

TETHERED FLIGHT PERFORMANCE OF LEAFHOPPER
VECTORS, *NEPHOTETTIX VIRESCENS* (DISTANT), *N.*
NIGROPICUS (STÅL) AND *RECILIA DORSALIS*
(MOTSCHULSKY) (HEMIPTERA: CICADELLIDAE) OF RICE
TUNGRO DISEASE.

R.J. Cooter and D. Winder
Pest Biology Department, Natural Resources Institute, Chatham, UK
A collaborative project between the Natural Resources Institute and the International Rice Research Institute (Philippines) is studying the epidemiology of rice tungro disease (RTD) and ecology of its leafhopper vectors. The flight performance of the main tropical vectors of RTD, *Nephotettix virescens* (Distant), *N. nigropictus* (Stål) and *Recilia dorsalis* (Motschulsky) has been studied. The effects of various biotic factors, including host plant age and variety and rearing on RTD virus infected plants, on the flight performance of leafhoppers tethered to flight mills has been investigated. It has been shown that under certain conditions a proportion of the adult *N. virescens* population have the potential to make flights of maximum duration similar to those recorded from individuals of *Nilaparvata lugens* Stål from migrant populations. When field-caught *N. virescens* produced progeny on late season (mature) rice plants a higher proportion of the resulting adults could be induced to fly and a significant number undertook very long flights. When reared on *Nephotettix*-resistant rice plants the small number that survived to adults were also 'good' fliers. Insects reared through one generation on RTD-infected plants were less willing to fly whereas those tested after a 24 hour access period to RTD-infected plants were more flight-willing compared to controls (maintained on and moved to uninfected plants of the same age and variety). The possible relevance of these findings to the spread of RTD is described and related to possible integrated pest management interventions for the control of the disease.

17-046

NEW OPTIONS FOR THE INTEGRATED MANAGEMENT OF
SORGHUM HEAD BUG *EURYSTYLUS OLDI*
(HETEROPTERA:MIRIDAE) IN WEST AFRICA

A. Ratnadass & B. Cissé

ICRISAT-CIRAD Joint Sorghum Program, Bamako, Mali

Host plant resistance (HPR) has so far been the mainstay of control strategies of *Eurystylus oldi* Poppius (Heteroptera: Miridae), a major panicle feeding pest of sorghum in West Africa. However, research work carried out in Mali in 1994-95 provided new options for the management of this insect. Several natural enemies, particularly assassin bugs (Heteroptera: Reduviidae) were identified. Castor (*Ricinus communis* L.) was identified as an alternate host for *E. oldi* during the dry season, providing an explanation of the population carry-over of this pest. The protection of sorghum panicles with extracts of physic nut (*Jatropha curcas* L.) translated into a reduction of infestation and damage by *E. oldi*. These promising results are discussed in view of the integrated bio-intensive management of *E. oldi* in West Africa based on HPR and other components such as: conservation of natural enemies; interruption of infestation cycle through control of alternate hosts; and use of locally available plant-derived pesticides.

17-048

DATE PALM TREES DAMAGED BY SOME INSECTS
IN THE STATE OF QATAR

R.M. ABDOL
Dept. of Zoology; Faculty of Science, Univ. of Qatar, Doha,
State of Qatar Arabian Gulf.

The date palm is an important plant which provides a primary article of food and commerce in the great desert areas extending from western north Africa to India. The total number of Date-palm trees in the world is about 88.50 millions, More than about 70% of this number is found in Arab countries. The Arab world produces more than 80% of the world production of the Dates. In the state of Qatar more than 500.000 Date-palm trees are found. Many insects attack, leaves fruit and trunks. Such as *Porlоторia blanchardi* Targ., *Asterolecanium phoenici* Rao. and different Spp. of termites. The most dangerous insect-pests are the Indian palm weevils {Red palm weevils} *Rhynchophorus ferrugineus*, palm stem bores *Pseudophilus testaceus* Graham. and fruit stalk bores *orytes elegans* preL. Biology, estimation of damage as well as methods of control are under investigation.

17-049

ARTIFICIAL REARING OF THE ASIATIC PALM WEEVIL, *RHABDOSCELUS LINEATICOLLIS* HELLER (COLEOPTERA: RHYNCHOPHORIDAE).

Setsuko Iwanaga

Laboratory of Sugarcane Insect, Okinawa Prefectura Agricultural Experiment Station, Naha, Okinawa, 903 Japan

The Asiatic palm weevil, *Rhabdoscelus lineaticollis*, has been known as a pest of palm. But this weevil was collected from sugarcane stalks in Gushikawa City, Okinawa Island in 1993. Since then, this species has become a serious pest in sugarcane field on a few islands of Okinawa. However, a few studies for ecology and life history of the weevil had been conducted.

In this study, an artificial rearing method of *Rhabdoscelus lineaticollis* using an established diet for silkworm (INSECTA-LF) was developed. The method has made possible successful rearing from egg to adult of the weevil. The weevil had 5~7 larval instars and its prepupal stage, and the mean egg, larval, prepupal, and pupal periods were 4.75 ± 0.44 , 29.33 ± 8.88 , 18.97 ± 5.68 and 9.17 ± 0.94 days, respectively, at 28°C under the artificial rearing condition.

17-050

DEVELOPMENT OF PHEROMONE TRAPS FOR CONTROL AND MONITORING OF SWEET POTATO WEEVILS, *CYLAS PUNCTICOLLIS* BOHEMAN AND *C. BRUNNEUS* FABRICIUS (COLEOPTERA: APIONIDAE) IN UGANDA

N.E.J.M. Smit¹, M.C.A. Downham², B. Odongo³, D.R. Hall², P.O. Laboke³. ¹International Potato Centre, Kampala, Uganda - ²Natural Resources Institute, Chatham, United Kingdom - ³Namulonge Agricultural and Animal Husbandry Research Institute, Kampala, Uganda.

Following chemical identification of the sex pheromones of the sweet potato weevils *Cylas puncticollis* Boheman and *C. brunneus* Fabricius (Coleoptera: Apionidae), work is in progress in Uganda to develop pheromone traps for use in control and monitoring programmes. Experiments have been conducted to optimise several parameters associated with the traps.

Of six designs evaluated, a 5 litre plastic jerry-can trap proved effective and was adopted as the simplest and most robust design. A sticky-disc trap, originally designed for catching armyworm moths in Malawi, and a skirted funnel design modelled on that used in the USA with *C. formicarius*, successfully caught weevils but were impractical to use and expensive to make. With the jerry-can trap the effects of colour and height above ground were investigated. Comparisons of lure dispenser type and different pheromone loadings were also carried out, and lures were developed for both species which showed no loss of attractiveness during up to eight weeks field exposure.

These traps and lures have potential for use in the control and monitoring of sweet potato weevils in Uganda, and results of experiments to determine trap sampling range and to evaluate the effectiveness of control by mass-trapping will be presented.

17-051

INFLUENCE OF AGE AND DIET ON MATING SUCCESS OF *PLUTELLA XYLOSTELLA* (L.)

M.M. Clyde, T. Maimun

Department of Genetics, Faculty of Life Sciences, Universiti Kebangsaan Malaysia, 43600 Bangi, Malaysia.

Plutella xylostella raised on *Brassica juncea* and artificial diet were used in reciprocal and control crosses to study mating success at various ages (1-5 days) of the adult moths. Positive results were indicated by transfer of the spermatophore to female individuals within 48 hours. Age has a significant effect on spermatophore transfer, with greatest mating success for 5 day old males and females. Age also has significant effect on number of larvae produced, with 1 day old females and 2 day old males producing most progeny. However there is no significant difference between number of eggs laid by females of different ages. The cross of males raised on *Brassica* with females raised on artificial diet gave more progeny as compared to the reciprocal cross and the controls. These findings may need to be considered in sterile insect technique programmes for control of *Plutella xylostella*.

17-052

DUNG BEETLES (COLEOPTERA: SCARABAEOIDEA) FEEDING ON DIPLOPOD CARCASSES

F.-T. Krell and F. Krämer

Theodor-Boveri-Institut für Biowissenschaften, Zoologie III, Würzburg, Germany

Among the enormous number of dung beetle species in West Africa some feed on diplopod carcasses instead of dung. In Ivory Coast CAMBEFORT (1984) found 5 species of Scarabaeidae more or less specialized on this resource.

In the Parc National de la Comoé in the Guinea savanna region of this country we found 50 species ($n = 1151$) of Scarabaeoidea on dead diplopods (mostly Spirostreptidae) during the wet season in the gallery forest. Some of them are generalists feeding on dung and/or different carcasses (*Anachalcos*, *Onitis*, *Trox*). Others are specialists, among them the dominant species (75,6 % of all specimens), *Onthophagus latigibber* D'ORB.

PRELIMINARY STUDY ON NECROCENOSSES IN THE GUINEA SAVANNA IN THE IVORY COAST (COLEOPTERA)

F.-T. Krell and C. Linder

Theodor-Boveri-Institut für Biowissenschaften, Zoologie III, Würzburg, Germany

In the Afrotropical region necrocenoses are dominated by Scarabaeoidea (Trogidae, Hybosoridae, Scarabaeidae). The role of carrion beetles (Silphidae) is negligible.

During the wet season (July 1995) in the Parc National de la Comoé in northern Ivory Coast (in both Guinea savanna and gallery forest), we found among 2744 beetles only 16 Silphidae, but 1826 Scarabaeoidea on fresh goat skins. Skins deposited in the gallery forest are less attractive to beetles than those placed in the savanna. During the first days, Gymnopleurini are the dominant diurnal and Onthophagini the dominant nocturnal group. After the fourth day Onthophagini become dominant at day and Trogidae at night.

First countings during other months show that in the beginning of the wet season (April/May) the number of beetles per carrion is much higher than in July. Especially the diurnal *Gymnopleurus puncticollis* (Scarabaeidae) and the nocturnal *Phaeochrous* (Hybosoridae) occur at very high numbers.

During the dry season (December), the number of beetles per carrion is reduced; the dominating scarab guild are the Onthophagini; Trogidae are rare, *Phaeochrous* seems to be absent.

17-055

CONTROL OF THE CARAMBOLA FRUIT FLY, *Bactrocera carambolae* (DIPTERA : TEPHRITIDAE) BY MALE ANNIHILATION METHOD AND WRAPPING

A. D. Permana, I. Ahmad, T. Anggraeni

Department of Biology FMIPA - ITB and IUC Life Sciences - ITB, Bandung Indonesia.

The Carambola fruit fly, *Bactrocera carambolae* Drew & Hancock, is one of the major pests of star-fruit or carambola, *Averrhoa carambola*. Control study of this fly was carried out from March 1994 to January 1995 at a commercial carambola fruit orchard in Cirebon, West Java, Indonesia. Two type of trap (Delta and Round Trap) with four different solution of Methyl Eugenol (ME) as an attractant were applied at the beginning of the florescence. One month after this period, conventional preventive method was applied by wrapping individual fruit with a plastic transparent bag. The results showed that Round Trap with pure ME attracted the most number of flies. The number of flies caught by ME diluted by two times of commercial oil, were not significantly different with that caught by pure ME with both in Round Trap and Delta Trap. During this study, the population number of carambola fruit flies started to increase in May, at the beginning of florescence, then reached the peak in July to August 1994 when the fruit ripened. The population was then decreased at the end. This pattern was the same to the following season (September, 1994 - January, 1995). From fruit production data, it is indicate that application of the male annihilation method and wrapping using ME reduce the infestation of the fruit flies up to one fourth, which is from 25% to 6%.

17-054

EDGE EFFECTS ON AMBROSIA BEETLE COMMUNITIES IN A LOWLAND TROPICAL RAIN FOREST, BORDERING OIL-PALM PLANTATIONS, IN PENINSULAR MALAYSIA

K. Macto, K. Fukuyama¹, L.G. Kirton²

Forest Biology Division, Forestry and Forest Products Research Institute, Tsukuba, Japan - 1 Hokkaido Research Centre, Forestry and Forest Products Research Institute, Sapporo, Japan - 2 Forest Research Institute Malaysia, Kepong, Malaysia

When the aim of forest conservation is to preserve interior forest conditions as being representative of the original forest, it is essential to understand how they may be influenced by edge or border effects. We investigated edge effects on ambrosia beetle communities in Pasoh Forest Reserve (2,450 ha), a lowland rain forest in Peninsular Malaysia, which largely borders oil-palm plantations established in the 1970's.

Species richness and composition of the ambrosia beetles (Scolytidae: Xyleborini) sampled with ethanol traps was similar along a gradient from the core area to the boundary of the forest. However, a polyphagous species, *Xylosandrus crassiusculus*, consistently increased in numbers from the core to the forest edge, being super-dominant in the boundary. It was as abundant in the surrounding oil-palm plantation as in the forest boundary. The results strongly suggest that there is a large flux of the cosmopolitic species from the oil-palm plantations deep into the forest. The population may also be, to a lesser extent, enhanced by forest disturbance in the margin of the reserve. It is suggested that interior forest conditions are affected by the influx of the ambrosia beetle since, for example, there is a possibility the insect may carry microorganisms originating from the surrounding, disturbed habitat. A wide buffer zone, at least 2 km in width, will be necessary to efface such external influence.

17-056

BIOLOGY OF PULSE BEETLE *CALLOSOBRUCHUS CHINENSIS* (L.) ON GREENGRAM, *VIGNA RADIATA* (L.) WILCZEK UNDER LABORATORY CONDITIONS

SHIV K. SINGAL

Department of Entomology
CCS Haryana Agricultural University, HISAR-125 004, Haryana, INDIA.

Consequent upon the establishment of 1.8% field infested greengram pods and emergence of 6 males and 5 females beetles from these pods in the laboratory, observations on biology of pulse beetle, *C. chinensis* were recorded on greengram, *V. radiata* by releasing freshly emerged one pair of beetle in glass vial enclosing four dry and ripened greengram pods. There were 25 replications. Preoviposition, oviposition and post-oviposition periods of pulse beetle were found to be on an average 10.8 (8-11 hrs.), 5.6 (Range 4-8 days) and 1.5 (Range 1-3 days) respectively. The longevity period of female of pulse beetle was 6.6 days (Range 4-8 days) as compared to 6.3 days (Range 5-9 days) of male. A single female of pulse beetle laid on average of 44.5 eggs (Range 28-59 eggs) and the maximum egg laying was recorded on the first day of oviposition after that egg laying went on decreasing till the last day of oviposition. Incubation and total development period from egg to adult emergence were observed to be with an average of 6.1 (Range 6-7) and 28.3 days (Range 26-31 days), respectively. Out of 1112 eggs, a mean of 12.3% adults (Range 6.8-18.1% adults) emerged under laboratory conditions.

17-057

ADELENCYRTUS MODERATUS (HOWARD) (HYME-NOPTERA: ENCARTIDAE) IN THE CONTROL OF *ASPIDIELLA HARTII* (COCKERELL) (HOMOPTERA: DIASPIDIDAE) ON *DIOSCOREA* CFR. *ALATA* L. IN WEST AFRICA

S. Manzella, G. Liotta¹

Osservatorio Regionale per le Malattie delle Piante, Assessorato Agricoltura e Foreste, Regione Siciliana, Palermo, Italy - 1 Istituto di Entomologia agraria, Università degli Studi, Palermo, Italy.

A major infestation of yam scale, *Aspidiella hartii* (Cockerell), was found on tubers of *Dioscorea* cfr. *alata* L., imported to Italy from Ghana for food use and intercepted by the Servizio Fitosanitario Regionale.

On random samples of parings of infested tubers, measuring about 5 cm², representative of the whole batch imported and isolated in a laboratory, on 2nd-instar larvae and females of *A. hartii* (number of scales present averaged 24,11/cm² tuber) there was found *Adelencyrtus moderatus* (Howard) parasitization ranging from 37,04% to 86,36%, with an average of 56,57%. In laboratory conditions, it was observed that there is very high emergence, amounting to 96,62%.

From the samples there also collected some individuals of *Azotus* sp. (Hymenoptera: Aphelinidae). It remains to be verified whether this was a case of primary parasite activity on yam scale, or hyperparasite activity on *A. moderatus*.

17-058

THE ROLE OF SEMIOCHEMICALS IN DIFFERENTIAL INFESTATION OF CALLOSOBRUCHUS MACULATUS IN WILD AND CULTIVATED PULSES

S. Ignacimuthu, B. Balachandran, A. Jeyakumar, R. Seenivasagan, G. Karuppasamy J.K. Sivakumar and A. Sen
Entomology Research Institute, Loyola college, Madras - 600 034. India.

Primary metabolites comprising of protein, carbohydrates, lipids and free amino acids, as well as secondary metabolites such as total phenols and ortho-dihydroxy phenols were analysed in wild and cultivated pulses. Trypsin inhibitor level was also quantified. Studies on development of *Callosobruchus maculatus* on wild and cultivated pulse seeds were made. The content of primary metabolites in the cultivars was higher than in the wild relatives. The secondary metabolites of the cultivars did not differ much from the wild relatives. The trypsin inhibitor levels were quite varied within the wild pulse populations both at intra and interspecific levels. A drastic reduction in the egg laying capacity of *Callosobruchus maculatus* was observed in the wild pulses. Our biochemical analyses suggest that the wild pulses contain compounds which inhibit egg laying.

17-059

BRUCHID ECOTYPES IN NIGERIA - THE CASE OF *CALLOSOBRUCHUS MACULATUS* FAB ON COWPEA, *VIGNA UNGUICULATA* (L.) WALP.

L. E. N. Jackai¹, T. I. Ofuya²

¹International Institute of Tropical Agriculture (IITA), Oyo Road, PMB 5320, Ibadan, Nigeria, W. Africa. ²Department of Crop Production, Federal University of Technology, PMB 704 Akure, Ondo State, Nigeria.

Variation in insect response to resistant crop varieties is a common phenomenon. This is sometimes the result of ecological exclusion or other barriers that restrict gene flow between individuals or regions, and appears to be true of the cowpea storage bruchid, *Callosobruchus maculatus* Fab. We studied oviposition, growth and development of six populations of *C. maculatus*, designated simply as IT, PH, UM, MD-1, MD-2, MD-3, from different locations in Nigeria on the resistant cowpea cultivar, TVu 2027 and four cultivars of African yam bean (AYB) (*Stenostylis sternocarpa*) obtained from the same eastern Nigeria location as one of the bruchid populations, and on Ife Brown cowpea cultivar (susceptible). F1 progenies obtained by cross-mating individuals from different populations were similarly tested on the control cultivars.

Oviposition was variable, and differences were not significant. The lowest egg count was from the UM population. The IT and PH populations had higher adult emergence and shorter developmental times on TVu 2027 than did the other populations. This was not surprising for the IT population that, unlike the PH population, had previous experience with TVu 2027. All F1 populations with IT female parents also had better emergence and developmental period than their reciprocal crosses, or those involving other populations but this varied with the virulence of the male parent. The UM population was one of those most sensitive to TVu 2027 (average <10% emergence), but also seemed better adapted to the AYB cultivars (66% emergence compared to 71.9% for the susceptible control). All others ranged in emergence from 1.4-22.8%. Total development time was correspondingly shorter in the UM population. These results suggest that there is only one species involved. However, there appears to be distinct ecotypes of this species in Nigeria. This has far-reaching implications for the development and deployment of cowpea cultivars that have resistance to only one of the ecotypes.

17-060

Anastrepha fraterculus (Diptera: Tephritidae) dispersal in Brazilian apple growing area

A. Kovaleski^{1,2}, R.L. Sugayama² & A. Malavasi²

¹EMBRAPA/CNPV, Vacaria; ²Dept. Biologia, Inst. Biociências, USP, São Paulo, Brazil

Apple growing area expanded from 137 ha in 1970 to more than 30,000 ha in 1995. *Anastrepha fraterculus* is a major pest and hosts in native vegetation areas adjacent to commercial orchards are responsible for population growth.

A feral population was released in order to study *A. fraterculus* dispersive behavior. Marked adults were maintained in lab conditions up to 10 days with water and food *ad libitum*. McPhail traps containing grape juice 25% were used: 15 in a 0.5 ha native vegetation area, 24 in an open grass field, and 48 in a 7 ha commercial orchard. Adults were released in the edge of the native vegetation area.

Out of 2,154 released flies, 7.1% were recaptured from the 2nd to the 20th day after release. Four, 12 and 17 days after release, 27.6, 88.0 and 98.4% of recaptures had occurred. Out of 8 flies (7 females: 1 male) recaptured in the orchard, 6 were recaptured in the edge (580 m from release point), one at 670 m and one at 700 m. These flies may have been helped by the wind. In the orchard, recaptures occurred 3 and 4 days after release. An insecticide cover spray may have affected results. In the native vegetation area, 144 marked flies were recaptured and behaved similarly to wild flies. No flies were recaptured in the grass field.

Results suggest that *A. fraterculus* dispersive behavior from native vegetation areas into orchards explains the large attack intensity in orchard edges.

17-061

Status of 'Golden Delicious' apples as *Anastrepha fraterculus* (Diptera: Tephritidae) hosts in BrazilR.L. Sugayama¹, A. Kovaleski^{1,2}, E.S. Branco³ & A. Malavasi¹¹Dept. Biologia, Inst. Biociências, USP, São Paulo, ²EMBRAPA/CNPV, Vacaria, ³ESALQ/USP, Piracicaba, Brazil.

Behavioral and physiological constraints can limit host range expansion in phytophagous insects. Apples were introduced in Southern Brazil in the early 70's and *Anastrepha fraterculus* (Wied.) became an important pest. It is a neotropical and polyphagous fruit fly and its major hosts are from the family Myrtaceae.

Behavioral observations in an unsprayed orchard showed that females oviposited intensely in apples. They were observed to bore up to 7 times in 5 min. It should be considered that there is a strong behavioral pressure to colonization of apples.

In this orchard, infestation level was 0.22 pupae/fruit in 1995/96, although all fruits were severely attacked (> 20 punctures/fruit), suggesting a high mortality in egg and larval stages. Dissection of immature fruits showed a large proportion of unhatched eggs. Larval development took up to 90 days in natural condition. Wild pupae obtained from apples and primary hosts did not differ in size. When compared to adults obtained in primary hosts, those from apples had lower survivorship leading to lower reproductive rates but do not affecting intrinsic rate of increase (*r*). This reflects the colonizing characteristic of the species. Since adults from apples are as aggressive as those from primary hosts, physiological constraints should also be considered overcome.

'Golden Delicious' apples can be considered satisfactory *A. fraterculus* hosts. Results indicated that the species is adapted to utilization of heterogeneous resources and that, in the absence of primary hosts, alternative hosts can support population growth.

TRICHOMES AS A PLANT TRAIT INFLUENCING HERBIVORE DISTRIBUTION AND ABUNDANCE

I. R. Diniz

Departamento de Zoologia, Instituto de Biologia, Universidade de Brasília, 70910-900, Brasília, DF, Brasil

The study was carried out during 1993-95 at three field sites within the cerrado *sensu stricto* near Brasília in central Brazil. We compared three *Byrsonima* (Malpighiaceae) host plant species with different degrees of leaf pubescence as larval food for some specific larvae species. The plant species were: *B. verbascifolia* (denser pubescence), *B. crassa* (less dense), and *B. coccolobifolia* (glabrous). A survey conducted on 5530 individuals of *Byrsonima* spp showed that, of the 53 caterpillar species found, approximately 23% belonged to Oecophoridae, with *Cerconota achatina*, *Gonioterma exquisita*, and *G. indecora* the most representative moths. Other common species were a gelechiid (*Anacampsis* sp), a hesperiid (*Chiomara punctum*), and two chrysomelids (*Chlamisus* spp) (Coleoptera). All these species were apparently specialists on *Byrsonima*. By comparing the frequency and distribution of insects on each host plant species, we noted the species *G. exquisita* and *Anacampsis* sp were never encountered (*n* = 1956) on the glabrous host *B. coccolobifolia*, which was preferred by *C. achatina*, and *C. punctum*. These results reflect not only the feeding preference but also may be related to larvae sheltering strategy. The first two species, were always found using the leaves trichomes for their larvae shelter while *C. achatina* and *C. punctum* that use a glabrous host, building their shelter by folding a piece of leaf. Another differential response to trichome density was also found for the beetles *Chlamisus* which cover their larval shelter with several layers of leaf hairs. All these strategies may be very important in the cerrado area which has a marked dry season from April to September. *G. indecora* feeds on all three plant species, but does not fold leaves or use the trichomes; instead, it ties leaves with silk around shelter. This study provides preliminary information indicating that plant pubescence may be related to herbivorous sheltering strategies and hence may influence their distribution and abundance among host plant species.

PRESENT STATE OF THE LIRIOMYZA LEAFMINER (DIPTERA: AGROMYZIDAE) PROBLEM IN CHINA

L. Kang

Department of Insect Ecology, Institute of Zoology, the Chinese Academy of Sciences, Beijing, 100080, China

For the past 3 years China has undergone wide-ranging outbreaks of the *Liriomyza* leafminers. The leafminers that severely damaged several ten species of vegetable and ornamental crops in China are obviously polyphagous species. There are leafminer problems and outbreaks in at least fifteen provinces of China. The leafminers mainly destroy the vegetable crops on the opening fields in South, and in greenhouse in North of China. Compared to other regions, for example, North and South America, Europe, where *Liriomyza* leafminers have caused damage to vegetable and ornamental crops since the end of the World War II, the *Liriomyza* problem in China is relatively recent. Although international trades play an important role in leafminer problems, the major factors that have originated this problem in China are related to the increase of vegetable planting area, wide use of pesticide, introduction of new crops, and to some extent the lack of monitoring and vigilance. The suppression of the leafminers relies largely on the chemical pesticides in China, because some chemicals can provide satisfactory control. However, the resistance of the leafminers to pesticides still maintains unknown. The studies on alternative control methods, ecology and biological control of the leafminers are being carried out in China in order to undertake a long term project to establish an integrated leafminer control program. Prospective control strategies are discussed, including cultural management, introduction of natural enemies, and effective utilization of appropriate chemical measures based on phenology forecast and growing stages of the plants.

BIOLOGICAL STUDIES OF *Leptoglossus chilensis concaviusculus* BERG, 1892 (HEMIPTERA: COREIDAE) ON ITS NATURAL HOST PLANT, *Schinus terebinthifolius* RADDI (ANACARDIACEAE) UNDER CONTROLLED LABORATORY CONDITIONS.

C.E.P. SOUZA, B.F. AMARAL FILHO

Dept. of Zoology, Inst. of Biology, State University of Campinas (UNICAMP), SP, Brazil. 13.083-000. Box 6109.

The coreid bug *Leptoglossus chilensis concaviusculus* frequently occurs in pepper trees, *Schinus terebinthifolius*, which is widely used as an ornamental plant in Brazil. The genus *Leptoglossus* is predominantly neotropical and contains some economically important species attacking fruits and seeds of many useful plants. The present study aimed to investigate the biology of this coreid bug on its natural host under laboratory conditions. The study was carried out at the insectary of the Zoology Department, UNICAMP during 1992-1995, at $25 \pm 2^\circ\text{C}$, $60 \pm 10\%$ R.H. and 14 h. photofase. The incubation period of eggs lasted from 9 to 15 days, with an average of 12.27 ± 0.026 days. Effect of aggregation on the nymphal and adult developments was studied. The entire nymphal stage consists of five instars, which lasted 35.45 ± 0.15 and 33.70 ± 0.38 days, for aggregated and individualized nymphs, respectively. The average longevity of mated adults, originated from aggregated nymphs, was 60.53 ± 5.23 days, while those originated from individualized ones lasted an average of 95.92 ± 7.83 days. The females suffering the aggregation effect deposited an average of 43.5 ± 20.9 , with a maximum of 228 and a minimum of 10 eggs/female. However, adults without such a stress deposited an average of 68.33 ± 28.96 , with a maximum of 356 and a minimum of only one eggs/female. Other aspects concerning developmental and reproductive activities were also investigated. Significant differences confirmed the stress effect of aggregation under laboratory conditions.

17-065

REPRODUCTION AND DEVELOPMENT OF *Camptischium clavipes* (FABRICIUS, 1803) (HEMIPTERA, COREIDAE) UNDER LABORATORY CONDITIONS

B.F. AMARAL FILHO,
Dept. Zoology, Inst. Biology, State Univ. of Campinas (UNICAMP),
Campinas, SP, 13081-970, Brazil.

Camptischium clavipes, a coreid bug, attacks leaves, buds and fruits of some Euphorbiaceae, Leguminosae, Solanaceae and Cucurbitaceae. Some reproductive and developmental aspects were investigated in the present work. Nymphs and adults were fed on *Ricinus communis* L. (Euphorbiaceae) leaves and sugar solution (10%) and the observations were realized under laboratory conditions of $25 \pm 2^\circ\text{C}$, $60 \pm 10\%$ of R.H. and 14 hours of photophase.

Adult longevity ($n=30$) was averaged 94.15 ± 4.83 days, reaching a maximum of 126 and a minimum of 41 days. No significant differences were observed between mated males and females. The female deposits an average of 304.46 ± 46.18 eggs during the oviposition period, with a maximum of 650 and a minimum of 55 eggs. The eggs are deposited in clutches, which averaged 15.40 ± 1.94 per female, with a maximum of 27 and a minimum of 4 clutches. Other approaches concerning reproductive activities were investigated.

The incubation period of the egg stage ($n = 3006$) reached an average of 12.54 ± 0.01 days with a maximum of 16 and a minimum of 8 days. Morphological descriptions and measurements as well as the viability of this stage were also obtained. The nymphal stage, consisting of 5 instars, lasted an average of 50.94 ± 2.4 days with a maximum of 71 and a minimum of 38 days. The sex ratio was calculated as 0.47.

17-067

IDENTIFICATION OF KEY-FACTORS OF GROUNDNUT MORTALITY IN THE FIELD

I. O. Dicko* and S. Traoré

* Institut du Développement Rural (IDR), Université de Ouagadougou, Burkina Faso

** Institut d'Études et de Recherches Agricoles (INERA), CRRA de Farako-bâ, Bobo-Dioulasso, Burkina Faso

Experimental studies were conducted in 1990 and 1991 at the Research Stations of Gampela and Matourkou, Burkina Faso, to assess plant, flower and peg pod mortality of ground-nut grown in the field, to identify main mortality factors and to determine the impact of various mortalities on potential yield loss. Evaluation techniques used included mortality tables and chemical exclusion. Our results show that plant mortality occurs mostly during plant growth stages preceding flowering. Soil fungi, *Aspergillus* sp., *Sclerotium* sp. and *Fusarium* sp. were the main factors involved in ground-nut mortality at these stages. In contrast, pest arthropods, i. e., millipedes, termites, thrips and blister beetles damage ground-nut mainly during the reproductive stages.

It appears from the present study that seed treatment with appropriate fungicide and insecticide apply from ground-nut flowering stage could prevent yield loss up to 19-20%.

Key-words: *Arachis hypogaea*, Ground-nut, mortality tables, pesticides exclusion, mortality factors, soil fungi, pest arthropods, potential yield loss, phytopathology.

17-066

SURVEY OF ANTS (HYMENOPTERA:FORMICIDAE) ASSOCIATED TO *Eurhizococcus brasiliensis* (HOMOPTERA:MARGARODIDAE) IN ROOT SYSTEM OF GRAPE VINE *Vitis* sp. IN SOUTHERN BRAZIL
S. de J. Soria, J. Delabie¹, J.E.V. Moraes², A.M. Encarnação³
Laboratório de Entomologia, CNPq/EMBRAPA, Bento Gonçalves, RS, Brasil - 1, 3 Laboratório de Mirmecologia, CEPEC/CEPLAC/MAARA, Ilheus, BA, Brasil - 2 Divisão de Agro-Químicos, Rohm and Haas, São Paulo, SP, Brasil.

A survey of soil ants associated to ground pearl *Eurhizococcus brasiliensis* (Homoptera: Margarodidae) in the root system of grape vines *Vitis* sp. was carried out in southern Brazil. The method was to take systematic samples by the extraction of vines and collect insects from soil. Identification was made with the help of specialists using classical museological techniques. Results indicated following identifications: Dolichoderinae: *Dorymyrmex* sp.; *Linepithema humile* (Mayr); Formicinae: *Brachymyrmex* sp.; *Camponotus blandus* (Smith); *C. crassus* (Mayr); *C. melanoticus* (Emery); *C. renggeri* (Emery); *C. rufipes* (Fabricius); *Camponotus* sp.; *Paratrechina fulva* (Mayr); Myrmicinae: *Acromyrmex crassispinus* (Forel); *Crematogaster* sp.; *Pheldole aberrans* (Mayr); *Ph. megacephala* (Fabricius); *Ph. triconstricta* (Forel); *Solenopsis saevissima* (Smith); *Wasmannia auropunctata* (Roger); Ponerinae: *Hypoconerops* sp.; *Pristonopelta* sp.; Pseudomyrmecinae: *Pseudomyrmex* sp. Among these species, *Dorymyrmex* sp., *L. humile*, *Pheldole* spp., *S. saevissima* and *W. auropunctata* seem to have mutualistic relationship with *E. brasiliensis*. The species *L. humile* was, by far, the most frequent in the above mentioned samples.

BEHAVIORAL TIME BUDGET OF ADULTS OF *SMICRONYX GUINEANUS* VOSS (COLEOPTERA: CURCULIONIDAE) ON *STRIGA HERMONTICA* (DEL.) BENTH. (SCROPHULARIACEAE) IN SEMI-FIELD CONDITIONS

D. Traoré¹, C. Vincent² and R. K. Stewart³

¹ IN.E.R.A, CRRA de Farakoba, Bobo-Dioulasso, Burkina Faso

² Centre de Recherche et de Développement en Horticulture, Agriculture et Agro-Alimentaire Canada

³ Dept. of Nat. Res., Macdonald Campus, McGill University, Canada

The behavioral time budget of adults of *Smicronyx guineanus* Voss was studied in semi-field conditions. Pairs of weevils were observed on a 24-h cycle starting from 0800 to the next day at 0600 and repeated for 21 days in cages containing *Striga hermontica* (Del.) Benth plants parasitizing sorghum. Each female and male was observed every second hour. Occurrences for the various behaviors exhibited by the weevil were recorded. In decreasing order, the weevils were observed to exhibit standing still, feeding, mating, walking, moving and foraging. In addition, the difference in time spent on the different parts of the host plant was highly significant. These parts were classified in four groups. The weevil adults spent 46.8% of their time on the *Striga* inflorescence (bud, corolla and calyx). *Striga* plants were stratified with respect to distance from the base and categories were designated as upper, central and lower parts. *Smicronyx* adults spent 85.2% of their time in the upper stratum, 9.8% in the central stratum and 5% of their occurrences were in the lower third of the *Striga* shoot. They were more active in daytime, suggesting that the best period of day to sample these weevils in the field is from 0700 to 1100 or from 1600 to 1800.

Key-words: *Smicronyx*; *Striga*; behavior; time budget; activity; Burkina Faso.

Introductory Lecture for Section 18:
CONTROL OF STORED FOOD PESTS IN ANTIQUITY

HERMANN LEVINSON and ANNA LEVINSON

Max-Planck-Institute for Behaviour Physiology, Seewiesen, Germany

The problem of preventing or controlling pest infestations in dried foodstuffs dates back to the Old Kingdom (~2575-2134 B.C.), when long-term storage was first practised in ancient Egypt. Early attempts of pest control, performed during the Middle (~2040-1785 B.C.) and New Kingdom (~1554-1080 B.C.) involved (a) divine charms and intimidations, (b) suitable design and location of food stores, (c) "antipathetic cures" and (d) pest-averting treatments. Most rational control measures (b,c,d) were prophylactic rather than curative, which resulted from the insistence of the priests to repel rather than exterminate harmful organisms. "Antipathetic cures" were based on the repulsive odour and insectistatic components of predatory animals, e.g. the feather lipids of entomophagous birds and the fur fat of rapacious cats. Protection of stored cereals was attained by addition of unthreshed grain (corn ears) and earth dust to the former, causing cuticular abrasions and water loss in detrimental insects. This ingenious procedure was probably invented by Jacob's son Josef (Koran 12,47) during the Hyksos period (1640-1532 B.C.). Fumigation by incense blends was frequently employed in sacred and profane premises. Disinfestation was actually paralleled by fulfilment of religious obligations. Several incense ingredients may act, according to concentration, as repellents, insectistatics or insecticides. The most effective ingredients were: myrrh (*Commiphora abyssinica*, *C. gileadensis*), frankincense (*Boswellia sacra*, *B. carteri*), essential oils of Citronella grass (*Andropogon nardus*, *A. winterianus*), Calamus roots (*Acorus calamus*), Cinnamon bark (*Cinnamomum ceylanicum*), dill seeds (*Anethum graveolens*) and Juniper berries (*Juniperus communis*, *J. phoenicea*). In ancient Rome, M.P. Cato (234-149 B.C.), L.J.M. Columella (1st cent. A.D.), M.T. Varro (116-27 B.C.) and Vitruvius Pollio (1st cent. B.C.) considered the proper location and design of food stores as a prerequisite for protecting foodstuffs against insect infestation. Granaries were raised above the ground in north-east direction (allowing air currents to dry and cool the cereals), advancing emigration of harmful species. Subterranean storage, causing suffocation to pest species, was an effective means of grain preservation. The above authors also recommended to apply an insectistatic mixture of "amurca" (aqueous extract of olives), clay and chaff to the interior of granaries. Moreover, Plinius Secundus (23-79 A.D.) and R.T.A. Palladius (4th cent. A.D.) suggested the addition of an insectistatic blend of "amurca", chalk and foliage of wormwood (*Artemisia absinthium*), Coriander (*Coriandrum sativum*) or fleabane (*Inula conyzia*) to stored grain, in order to minimize pest development. If compared with ancient times, the 20th century A.D. reveals a marked increase in the global amount of stored food, availability of a large variety and efficiency of storage protectants (biological, chemical and physical) as well as occurrence of pesticide-resistant species infesting stored food. The salient problems arising from food storage still resemble those encountered in antiquity, and improvement of these shortcomings remains a challenge for inventive minds.

18-002

PESTS, PATHOGENS AND PEOPLE: INTERACTIONS

J. R. Gorham

Coordination Center for
Disaster Preventive Medicine,
2537 Ridge Road, Xenia, Ohio, USA

Pests, pathogens and people have at least one common denominator: food. Pest-food relationships can be categorized: accidental, opportunistic, obligatory. The obligatory pests tend to stay with the food; the opportunistic pests come and go as they please, sometimes visiting human food, sometimes visiting places that are grossly contaminated with bacteria, some of which may be pathogenic. The opportunistic pests carry the pathogens to human food; the obligatory pests spread them throughout the food. There is another much more common and more important way that people become exposed to contaminated food: the fecal-oral route. Typically, feces (bearing pathogens) find their way onto fingers, and fingers find their way into food. Fingers are the "transport hosts" of the fecal-oral route of enteric disease transmission. Pests are the functional counterparts of fingers; they, serving as transport hosts, pick up pathogens and carry them to food or food-contact surfaces. The load of pathogens may be small or large or any gradation in between. Even a large load may not infect a robust host. Even a small load may infect an immunocompromised host. No one should have to face the challenge of an infective dose, especially not in a hospital, the whole purpose of which is to help people get well, not to make them sicker. But put yourself in the role of a competent scientist who has studied all the evidence concerning pests as mechanical vectors of pathogens and has decided that there is nothing to it. But then you become seriously ill and must undergo a complicated surgery. You may choose one of two hospitals. One is known to have an effective program of integrated pest management; the other is known to have a thriving colony of cockroaches in every one of its food carts. Now, my dear rational, objective scientist, which hospital will you choose?

18-003

CAN FOOD PROVISION INCREASE THE EFFICACY OF BIOLOGICAL CONTROL AGENTS IN STORAGE SYSTEMS?

Felix L. Wäckers

Institute of Plant Sciences, Applied Entomology, Swiss Federal Institute of Technology, ETHZ/NW, CH-8092 Zürich, Switzerland.

Adult parasitic wasps generally require food both as an energy source for searching activities and for the production and maturation of eggs. The availability of sugar sources can increase the parasitoid's longevity, fecundity, and overall activity. The introduction of (artificial) sugar sources, consequently, provides a promising strategy to increase the effectiveness of natural enemies, during both crop cultivation and storage.

However, in those cases in which pest organisms benefit from the additional food source as well, introduction of nectar sources could backfire. Therefore, the effects of nectar provision on both the pest insects and their antagonists should be addressed.

In the present study, the effect of artificial food sources on the longevity and fecundity of the cowpea weevil *Callosobruchus chinensis* and its parasitoid *Anisopteromalus calandrae* was investigated. Weevils and parasitoids were either provided with water only, or exposed to water in combination with either honey, unfested beans, *C. chinensis* infested beans (host feeding), or infested beans plus honey.

Nectar feeding was found to increase both longevity and lifetime fecundity of *C. chinensis*, while the weevil's lifespan was not affected by the other treatments. Both honey and weevil infested beans increased the parasitoid's longevity dramatically. Parasitoid lifetime fecundity was found to be primarily affected by host feeding.

The implications of these findings for biological control of storage pests will be discussed along with possible strategies for making food application selective.

POPULATION COMPOSITION AND IMMIGRATION -
IMPLICATIONS FOR SELECTION OF CONTROL METHODS FOR
PHYCITINE MOTHS IN A FOOD PROCESSING PLANT.

D. P. Rees, E. J. Wright

Stored Grain Research Laboratory, CSIRO Division of Entomology,
Canberra, ACT, Australia.

Knowledge of the nature, extent and movement of populations is important in the selection and likely success of control measures. A study was made of the seasonal occurrence and species composition of phycitine moth populations in and around a breakfast cereal manufacturing plant in the State of Victoria, Australia. Moths inside the processing facilities and outside in the surrounding district were monitored using pheromone baited sticky flight traps. Five species were captured; *Plodia interpunctella* and four *Ephesia* spp.: *E. cautella*, *E. kuehniella*, *E. elutella* and *E. figulilella*.

In the processing facilities, the main pest species was *E. cautella*. A few *E. kuehniella* and *P. interpunctella* were also caught. Catches varied seasonally but remained relatively constant all year.

Catches in outdoor traps, placed in surrounding towns and country, peaked in summer and stopped briefly mid-winter. *P. interpunctella* was the dominant species in urban residential areas. *E. kuehniella* and *E. elutella* were particularly associated with feed mills in the area. Very few *E. cautella* were caught outdoors. In contrast, *E. figulilella* was only caught at outdoor locations.

E. cautella in the manufacturing plant appeared to be an isolated population. Moths captured outside were almost always other species. While active for much of the year, these species either did not enter or did not thrive in processing facilities. Novel control measures against moths in food processing plants, such as using parasites and mating disruption, which would be compromised by significant pest immigration, could prove efficacious in this case.

LACHESILLA QUERCUS (KOLBE) (PSOCOPTERA:
LACHESILLIDAE) A NEW PEST OF GRAIN STORES IN AUSTRALIA

D. P. Rees, E. J. Wright

Stored Grain Research Laboratory, CSIRO Division of Entomology,
Canberra, ACT, Australia.

Since November 1992, the psocopteran *Lachesilla quercus*, an insect previously unknown in Australia, has been found infesting coastal grain storage facilities in the south west of Western Australia. More recently it has also been found in grain stores on the Eyre peninsula of South Australia.

In these areas *L. quercus* has become a pest of a status apparently unrecorded in other countries in which it is known to occur. It has the ability to thrive in numbers in places kept sufficiently clean to prevent the establishment of most other storage pests. *L. quercus* appears to browse on minute particles of dust that settle on surfaces as a result of grain movement. Undisturbed populations produce large quantities of silken webbing under which they live. This quickly becomes unsightly as it gets covered with dust. Large numbers of dead insects can accumulate, together with deposits of fine black frass, on ledges below infestations. Workers are distracted and sometimes distressed when working in areas in which large numbers are flying.

Changes in pest control practices in the Australian grain industry in response to market demands may have inadvertently favoured this insect. Market demands for low or no insecticide residues has meant the reduction or cessation of spraying of store structures or the admixture of insecticides into grain. Grain dusts would now likely be free of insecticide residues and available for exploitation by this insect.

It is not clear how long this insect has been in Australia or if it is yet established in natural habitats on the continent. However, its current status in grain storages is a very recent phenomenon.

TRAIL FOLLOWING BEHAVIOR IN THE GERMAN
COCKROACH, *BLATTELLA GERMANICA* (L.)
(ORTHOPTERA: BLATTELLIDAE)D. M. Miller, P. G. Koehler¹, R. S. Patterson²Department of Entomology and Nematology, University of Florida,
Gainesville, FL USA - 1 Department of Entomology and
Nematology, University of Florida, Gainesville, FL USA - 2
USDA-ARS MAVERL, Gainesville FL USA.

The ability of German cockroaches (adult males, adult females and late instar nymphs) to use an extract of their fecal material as a trail pheromone was evaluated in visually deprived arena tests. Using the Dynamic Animal Movement Analyzer program we were able to determine that $\geq 90\%$ of the cockroaches correctly oriented toward and moved in the direction of a preapplied trail of fecal extract upon release into the test arena.

In tests where cockroaches were provided with two identical plexiglass edges to follow either along a trail of fecal extract or along a trail of methanol (control), 90% of the adult male cockroaches correctly selected and followed the trail of fecal extract accurately. Ninety percent of adult females also followed the fecal extract trail accurately as well as 93% of the late instar nymphs.

When no edge was present and all cockroaches had a 360° choice of directional orientation upon leaving the harborage, trail following accuracy was reduced for all three cockroach groups. However, 80% of the adult males still followed the trail of fecal extract accurately as well as 60% of the females and 47% of the nymphs.

Morphology and Distribution of the Sensilla of Antennae,
Maxillary and Labial Palps, and Tarsi of *Callosobruchus*
maculatus and *C. subinnotatus*George N. Mbata, Srinivas Chinta, and Sonny Ramaswamy
Department of Entomology & Plant Pathology, Mississippi State
University, MS 39762-9775, USA.

Abstract: Sensilla on antennae, maxillary and labial palps, and tarsi of *Callosobruchus maculatus* and *C. subinnotatus* were studied using light and scanning electron microscopy. Six types of antennal sensilla occur in both species. Type 1 are 86-92 μm long and 2.6-2.9 μm in diameter, and have longitudinal ridges and a conspicuous basal socket. These sensilla occur in rings at the distal margin of each antennule; the distal antennule bears two such rings. Type 2 sensilla are found on all segments and are 38-41 μm long, with a well developed basal socket, and less conspicuous cuticular ridges. Type 3 sensilla are numerous and found only on flagellar segments. These range in length from 36-41 μm , have no socketed base, and are devoid of cuticular ridges. Type 4 are basiconic sensilla, 23-28 μm in length, smooth surfaced, lack a membranous base, numerous and present only on flagellar segments. Types 5 and 6 sensilla are short (<10 μm), few, and are found along with type 4 sensilla in groups distally on the distal antennule. Type 5 sensilla are basiconic, have a fluted surface and a pitted basal socket. Type 6 are basiconic pegs, and are devoid of basal socket and cuticular sculpturing. Types 1 and 2 are sensilla chaetica, type 3 are trichodea, and types 4, 5 and 6 are sensilla basiconica. Maxillary and labial palps in both species have three types of sensilla: type 1 (32-35 μm long), type 2 (21-26 μm), and type 3 (2.9-3.8 μm). Types 1 and 2 lack surface sculpturing, have basal sockets, and are found on maxillary and labial segments. There are about 20-25 type 3 sensilla, and in females, maxillary tip sensilla are fluted. Tarsi of both species have 4 types of sensilla; type 1 sensilla (43-48 μm long), type 2 (26-44 μm), and type 3 (18-26 μm); type 4 (26-36 μm) are curved and present only on the pad like structures on the second tarsomere. Types 2 and 3 have socketed, flexible bases.

CARBOHYDRATE FOOD-SOURCES OF COPROPHAGOUS SEPSIDAE (DIPTERA) IN AN URBAN SEWAGE-PLANT

U. Draeger, St. Scheurer
Institut of Environmentanalytic and Humantoxicology, Berlin, Germany

Themira putris (L., 1758) (Diptera: Sepsidae) occurs in a sewage plant during the whole vegetation period with several generations. These coprophagous flies utilize varied sources for vital carbohydrate food:

- 1) The nectar from blossoms of a wide range of plants belonging to different families (e.g. Brassicaceae, Compositae, Geraniaceae).
- 2) During the midsummer mass occurrence the honeydew of different species of aphids (Homoptera: Aphidina) (e.g. *Aphis fabae* Scop., *Brachycaudus cardui* (L.), *Uroleucon sonchi* (GEOF.), *Rhopalosiphum padi* (L.)). *T.putris* sucks up the deposited honeydew. *T.putris* also absorbs accessible honeydew deposits from aphids (e.g. *Eucallipterus tiliae* L.) not native to the habitat of *T.putris*.
- 3) In late summer *T.putris* sucks up the honeydew of scales (Homoptera: Coccoidea) from infested plantparts.
- 4) At the end of the summer and beginning of autumn *T.putris* absorbs the sugar containing secretion produced by ripping ergots (Fungi: Ascomycetes) on ears of wild grass.

MAIZE STACKBURN IN SUB-SAHARAN AFRICA: CAUSES AND CONSEQUENCES

G. Barros, A. Maia, A. Mexia¹
¹Centro de Estudos de Fitossanidade do Armazenamento, Instituto de Investigação Científica Tropical, Lisboa, Portugal

During the last decade in sub-Saharan Africa, the discoloration of stored maize as a direct result of heat build-up in the interior of bag stacks, has emerged as a significant threat of food security. As a result of such phenomena, internationally called "stackburn", the maize is then regarded by users as less suitable for food milling and is nutritionally altered, reducing its value as human or animal food. The possible causes for stackburn are under investigation by ecological studies on interactions between grain conditions, storage microclimate and insect and fungal development in Zimbabwe, Ghana, United Kingdom and Portugal. The introduction of woven polypropylene sacks and its associatior with increased levels of insect infestation remains the most likely cause.

18-009

TAPINOMA MELANOCEPHALUM FABR. (FORMICIDAE, DOLICHODERINAE) IN BUILDINGS OF GERMANY - OBSERVATIONS TO ITS BIOLOGY AND CONTROL

St. Scheurer
Institut of Environmentanalytic and Humantoxicology, Berlin, Germany

This tropical ant was found 1982 in Halle-Neustadt (kindergarden), 1985 in Rostock (bakery) and was also observed and controlled in Berlin 1994-1996 (dwelling-houses). Important exterior characteristics are: size 1,3-1,5 mm (♀♀), 2,3-2,5 mm (♀♀,♂♂), petiolus is not scale-like, gaster with 4 from dorsal visible segments. Colour: caput blackbrown to black; gaster is cream to brownyellow (♀♀), brownish (♀♀), blackbrown to black (♂♂), coloured. Preferred food: lieing about food, dead flies and cockchroaches, cake, milk, sweets. This species was fed in labratory with mixture from yolkpowder, biskuitmeal and honey, dead insects. The inquiry of attack-locality results with pig-lever and saturated sugar-solution. Baits-boxes were placed on the attack-locality directly. It was distinctly, that Maxforce-Bait (Hydramethylnon) was visited middling. Baits with a mixture of peanut-fat and boric or of yolkpowder, honey and boric were attractive about a longer time. The infestation was destroyed with these baits, but it continues in only one flat. A big *T.melanocephalum*-colony was found in this flat under very moist and mouldy bathroom-floorsettling from this species. *T.melanocephalum* was introduced likely with tropical flowers in dwelling houses, then a flower-friend lives there.

18-011

INFLUENCE OF THE CO₂ AND TEMPERATURE INCREASE BY SITOPHILUS ZEAMAI MOTCH. (COLEOPTERA: CURCULIONIDAE) POPULATIONS IN CAUSING MAIZE STACKBURN

J. Perilhão,¹ A. Barbosa, A. Mexia²
.1 - Instituto Superior de Agronomia,Universidade Técnica de Lisboa, Portugal. 2 - Centro de Estudos de Fitossanidade do Armazenamento, Instituto de Investigação Científica Tropical, Lisboa, Portugal.

The respiration rate of insects infesting stored maize while producing heat in the maize stock grains, may have the potential to contribute for the stackburn. In the present work the authors are concerned with the rate of carbon dioxide production of *Sitophilus zeamais* at various levels of infestation at 28° C, as a way to assess respiration rates and its effect on the rise of temperature.

18-012

REPRODUCTIVE BIOLOGY IN RELATION TO TRANSPORT OF DICHOTOMOUS SPERMATOZOA IN POTATO TUBER MOTH *PHTHORIMAEA OPERCULELLA* ZELLER (LEPIDOPTERA: GELECHIIDAE)

Usha Chauhan and L.R.Verma
Department of Entomology, University of Horticulture and Forestry, Nauni, Solan - 173 230 India.

Potato tuber moth is a serious pest of potato in the stores as well as in the fields in India. Sometimes it has also been reported to attack other solanaceous crops. This moth shows multiple mating behaviour. More than 70% of the moths mate twice in their life span. Average time of mating vary with temperature with a mean of 2.27 ± 0.25 hours in summer and 4.22 ± 0.19 in winter months. Two types of sperms are produced by this moth in the testes in bundle form and both are transported to the female tract during mating. The migration of apyrene spermatozoa from testes to vas deference starts earlier than eupyrene ones that also in pupal stage. In the vas deference the eupyrene sperms retain their bundle form whereas apyrene sperm bundle gets dissociated into individual sperms. Both types of spermatozoa are packed into a spermatophore in the ejaculatory duct and is deposited in bursa copulatrix of female within 25 to 60 minutes of mating period (at $27 \pm 2^\circ\text{C}$) in the next 30 to 50 minutes eupyrene and apyrene spermatozoa get lodged separately into utriculus and lagena lobes of the spermathecae. Later they get mixed up in these lobes. The vigorous movements of the apyrene spermatozoa in the bursa copulatrix and other parts seem to be the force for separating eupyrene bundle into the individual ones and transporting them.

18-014

THE BIOLOGY OF THE PARASITOID *LAELIUS PEDATUS* (SAY) (HYMENOPTERA: BETHYLIDAE), AND ITS POTENTIAL FOR THE BIOLOGICAL CONTROL OF *TROGODERMA GRANARIUM* EVERTS AND *TROGODERMA ANGUSTUM* (SOLIER) (COLEOPTERA: DERMESTIDAE)

A.-G. Al-Kirshi, H. Bochow, W. E. Burkholder¹, Ch. Reichmuth²
Institut für Grundlagen der Pflanzenbauwissenschaften, Humboldt-Universität zu Berlin, Berlin, Germany - 1 USDA-ARS, Department of Entomology, University of Wisconsin, Madison, U.S.A - 2 Federal Biological Research Centre for Agriculture and Forestry, Institute for Stored Product Protection, Berlin, Germany

Laboratory studies were conducted to assess the potential of the ectoparasitic wasp *Laelius pedatus* (SAY) for controlling *Trogoderma granarium* EVERTS and *Trogoderma angustum* (SOLIER). The female *L. pedatus* paralyzes the host larvae and deposit its eggs. The stung larvae are completely or partially paralysed. The total number of eggs laid, and the larvae paralysed, were significantly lower on *T. granarium*. One female of *L. pedatus* was able to paralyse on an average 50 larvae of *T. granarium* and 150 larvae of *T. angustum*. All paralysed larvae of *T. angustum* died after 14 days, but 40 % of the paralysed larvae of *T. granarium* recovered after 4 to 5 weeks and continued their development to adults. The number of host larvae killed by paralysis was higher than the number killed by parasitisation. If no males are available the female wasp deposits eggs by arrhenotoky reproduction. These eggs develop to males only. A mated female was able to deposit fertilized eggs for a maximum period of 14 days after copulation with a hatching rate of 75 - 83 %. The sex ratio of the progeny of mated females was 1:2 (male:female). An average of 52 eggs were deposited on *T. angustum* by a single female of *L. pedatus*. The duration of the development was influenced by temperature and lasted 31 - 37 days at 28°C . The lifetime of the wasps depended on the food quality and required 1 to 2 and 4 to 5 weeks, respectively for males and females supplied with host larvae only. When the wasps were supplemented with honey, adult life of males and females was extended to 4 and 7 weeks, respectively. Unfed females and males lived for less than 14 days.

At the parasitoid: host ratio of 1: 25, *L. pedatus* reduced the population of *T. granarium* by 73.5 % within 6 weeks.

18-013

POSSIBILITIES OF CONTROLLING PESES FOLLOWING THE PHASE-OUT OF METHYL BROMIDE

S. Navarro

ABSTRACT NOT RECEIVED

18-015

THE OUTLOOK FOR USING OF JUVENILE HORMONE ANALOGUES (JHA) AND CHITINE SYNTHESIS INHIBITORS (CSI) FOR THE DEPRESSION OF URBAN MOSQUITO POPULATIONS SIZE

M. Kostina
Laboratory of Arthropods Control System Development, Scientific Research Institute for Preventive Toxicology and Desinfection, Moscow, Russia

The existence of favourable conditions for mosquitos development and reproduction in large towns (flooded basements of dwelling houses, barrels, sewage, capacities for water collection, ponds) have result in the sharp increasing of mosquitos population size, *C.p. molestus* Forsk especially, and in the "problem of urban mosquitos" arising.

It is proved a possibility of depression of urban mosquitos population size in 6 large towns with the help of JHA and CSI. CSI Dimilin 25% w.p. and Alcistin 48% e.c. and 25% w.p. after employment of 40-60 g of AI/hectare have prevented winged mosquitos exclusion during 23 - 59 days at the expense of larvae development disturbances during moulting passage. JHA Altozid SR-10 (50 g/hect) ensured mosquitos exclusion absence during 32-35 days at the expense of anomalies under imago moulting (pupa-imaginal forms, defective imago). Metopren 4.7% (1 briquette/10 m²), Metopren 6% (6.4 g of granules/m²) and Sumilar (10 g of 0.5% granules/m²) ensured mosquitos exclusion absence during 46-50, 40-50 and 32-34 days. The employment of granules and tablets is the most perspective since its effect is attained at the expense of slow preparation diffusion into the water; the latter reduces xenobiotics content in the environment and leads to the lowering of desinfection costs.

18-016

RELEASE OF *TRICHOGRAMMA EVANESCENS* AS A COMPONENT OF AN INTEGRATED PEST MANAGEMENT PROGRAMME IN ORGANIC FOOD BAKERIES AND STORES (HYMENOPTERA: TRICHOGRAMMATIDAE)

S. Prozell¹, M. Schöller¹, S. A. Hassan² and Ch. Reichmuth¹
Federal Biological Research Centre for Agriculture and Forestry,
Germany - 1 Institute for Stored Product Protection, Berlin-Dahlem -
2 Institute for Biological Pest Control, Darmstadt

The pyralids, *Ephestia kuehniella* ZELLER and *Plodia interpunctella* (HÜBNER), are the major stored product pest moths in the food processing industry in Central Europe.

Field trials with *T. evanescens* egg parasitoids were conducted in organic food processing industry and the linked retail-trade. During the field trials, the parasitoids were not affected by chemical control since in these branches synthetic chemical insecticides are not applied.

The pest populations were monitored in 1994 and 1995 using TDA baited funnel traps and delta traps. Integrated pest management including biological control with *T. evanescens* and a hygiene programme started in 1995. The egg parasitoids were released weekly from cardboard egg-cards in the areas of the bakeries and stores where moth infestation was expected.

Compared to the year before without integrated control under similar weather conditions, the number of moths trapped in 1995 was reduced by one third.

The control programme did not affect the production process. The acceptance of biological control by the workers and retailers was very encouraging. The programme will be continued and extended in 1996.

18-018

ACOUSTICAL/ELECTRONIC DETECTION AND AUTOMATED MONITORING OF STORED-PRODUCT INSECTS

D. Shuman, D. K. Weaver and R. W. Mankin
USDA Insect Attractants, Behavior, and Basic Biology Research
Laboratory, Gainesville, FL USA

Acoustical and electronic technology has been applied to aid in the management of stored-product insect pests. A computer-based system was developed to quantify infestation of internally feeding larvae by ascertaining the number of sound source locations in a grain sample. This is accomplished using a cross-correlation and cluster analysis algorithm applied to data acquired from an array of acoustical sensors mounted in a sample container. This system was quite accurate for counting low-level infestations of late-instar *Sitophilus oryzae* larvae, except when the insects were very near one another. The device is also very accurate for determining uninfested samples. An automated system was developed to provide continuous monitoring of insects at multiple sites within large volumes of stored-products and to remotely display acquired data indicative of infestation levels at these sites. The system uses infrared beam sensors to count insects as they drop through pitfall grain probes distributed throughout the storage volume. The collected data are transmitted to a central computer via a tree structured data transmission network capable of efficiently connecting to thousands of probes in a large grain bulk. This system was very accurate for counting many commonly occurring species of adult stored-product insects in laboratory trials using both wheat and maize substrates.

18-017

BIOLOGICAL CONTROL OF TERMITES - *METARHIZIUM* AS A MYCOINSECTICIDE

J.A. Staples, R.J. Milner, M. Lenz
CSIRO Division of Entomology, GPO Box 1700, Canberra ACT
2601, Australia

Recent research has shown that the insect pathogenic Hyphomycete fungus *Metarhizium anisopliae* is a promising biological insecticide for the major pest species of subterranean termites in Australia. From an Australia-wide survey of termite nest mounds and feeding material of 42 species of termites, more than 100 different isolates of *Metarhizium* were obtained. The most virulent fungal strains were selected by a bioassay based on the natural grooming behaviour of termites. Temperature and humidity tolerances of the isolates *in vitro* were tested, and the best isolates were assessed in laboratory termite "mini-colonies". Field trials using the most effective isolate, FI610, by blowing conidia directly into mounds of *Coptotermes acinaciformis*, *C. lacteus* and *Nasutitermes exitiosus*, have shown that up to 100% control of the colonies is achievable with as little as 1g of pure conidia, depending on correct application of the conidial formulation and the time of the year in which it is applied. The fungal conidia persist within the termite nest environment for at least 2 years. Indirect treatment of colonies by treating termite feeding sites, including house timbers, with *Metarhizium* is currently being assessed. Australian termites can detect *Metarhizium* and therefore further studies on behaviour and implications for control strategies using *Metarhizium* are being evaluated. Suspensions of *Metarhizium* conidia sprayed directly onto and/or into timber structures could be used to protect against termite damage. *Metarhizium* is also being tested as a barrier treatment using conidia mixed into soil; over 2 years protection of timber has been achieved in SE Australia, whereas a shorter protection time resulted at tropical field sites.

18-019

MORTALITY OF TWO STORED-PRODUCT INSECT SPECIES EXPOSED TO MICROWAVE RADIATION

N. Shayesteh¹ and N.N. Barthakur²

¹Department of Entomology, University of Oroumieh, Oroumieh, Iran - ²Department of Natural Resource Sciences, McGill University, Macdonald College, Ste-Anne-de-Bellevue, Québec, Canada

Microwave radiation emitting at 2,450 MHz frequency was used continuously and intermittently to evaluate the mortality of stored-product insects *Tribolium confusum* and *Plodia interpunctella* as a function of exposure time and incident power. The survival kinetics was highly quadratic ($0.82 \leq R^2 \leq 0.99$) for each of the growth stages studied. The target theory was invoked to model the dose-survival relationship. Mortality was dependent on insect development stage at any microwave power input. Insects were killed by overheating and the lethal medium temperature for both species was estimated at about 80°C for the most resilient growth stage. Intermittent exposures were generally more effective in killing insects of both species compared with those of continuous irradiation. The fraction survived increased as the moisture content of the medium increased from 6 or 9 to 12%. The insects in the mobile state were observed to move towards the surface from inside the nutrient medium during irradiation. The authors could not detect any generation of "hot spots" in the medium despite concern of scientists involved in industrial heating of materials by microwaves.

18-020

EFFECTS OF GAMMA RADIATION ON THE DEVELOPMENT OF CIGARETTE BEETLE (*LASIODERMA SERRICORNE* (F.))

S.S.SHARMA, G.R. SETHI¹, A.K. GARG²
 DEPARTMENT OF ENTOMOLOGY, C.C.S. HARYANA AGRICULTURAL UNIVERSITY HISAR - 1 DIVISION OF ENTOMOLOGY, INDIAN AGRICULTURAL RESEARCH INSTITUTE NEW DELHI - 2 DIVISION OF ENTOMOLOGY, INDIAN AGRICULTURAL RESEARCH INSTITUTE NEW DELHI

The effects of gamma radiation doses on the metamorphic stages of Cigarette beetle *Lasioderma serricorne* (F.). were studied in the laboratory of Division of Entomology, Indian Agricultural Research Institute, New Delhi. Four different age groups viz., 1,2,3,4 days old eggs were irradiated between 0.5 to 4.0 krad doses. Results showed that older eggs were more radio resistant and hatching reduced with the increase in dose. A dose of 4.0 krad completely prevented the hatching of eggs. The development of adults from treated eggs was prevented by 3.0 krad dose. When 20 days old larvae of this insect were irradiated between 1 to 20 krad doses of gamma radiation, 8.0 krad dose completely prevented the pupal formation, while the doses between 3-6 krad prolonged the larval period, delayed pupation and adult emergence. The adults emerged from irradiated pupae survived in lesser numbers and a dose of 60 krad completely prevented the adult emergence. Freshly emerged adults when irradiated between 10-100 krad doses the survival time of irradiated adults decreased with increasing dose. A dose of 70 krad was sufficient to achieve complete mortality of adults 15 days after treatment. It is concluded that egg was the most radiosensitive stage.

18-022

COMBINED EFFECTS OF SILICA AEROGELS AND INSECT GROWTH REGULATORS AGAINST *SITOPHILUS ZEAMAE* MOTCH. (COLEOPTERA: CURCULIONIDAE) INFESTATIONS

C. Conceição¹, A. Mexia, A. Barbosa²

1 - Universidade Agostinho Neto, Luanda, República de Angola. 2 - Centro de Estudos de Fitossanidade do Armazenamento, Instituto de Investigação Científica Tropical, Lisboa, Portugal

Laboratory experiments were conducted to determine the effectiveness of two silica aerogels (Neosyl TS and Gasil 23D) and two Insect Growth Regulators (IGRs), (diflubenzuron and fenoxycarb) when used alone and in combinations against populations of *S. zeamais*.

The silica dusts applied to grain were both effective but there were differences between the two materials.

The IGRs treatments showed satisfactory effect in preventing the FI emergencies of *S. zeamais*. However, in order to minimise the chemical residues left on the food grains a reduction in dosages of the IGRs components and its effects with the joint action of the silica dusts is under research.

18-021

INSECT DISINFESTATION OF NUTS AND DATE BY IRRADIATION IN ISLAMIC REPUBLIC OF IRAN

H.R.ZOLFAGHARIEH

Nuclear Research center for Agriculture and Medicine
 Atomic Energy Organization of IRAN

Abstract

Iran produces annually about one million tonnes of nuts and Date. The average storage losses caused by insects are found to vary from 30-35% despite the traditional methods of pest control. The insects identified as causing considerable damage to the above - mentioned agricultural products include. *Plodia interpunctella* (Hbn) and *Oryzaephilus surinamensis* (L.) The dose range for the control of different developmental stages.e.g.egg larval, pupa and adult of the above mentioned insects were found to vary from 0.3 to 0.45 KGY and 0.35 to 0.5 KGY, respectively.

INSECTICIDAL ACTIVITY AND MODE OF ACTION OF A NEW SYNTHETIC PYRETHROID, IMIPROTHRIN

T. Ishiwatari¹, K. Umeda², S. Senbo³ and M. Hirano¹

1 Agricultural Chemicals Research Laboratory, Sumitomo Chemical Co., Ltd., Takatsukasa, Takarazuka, Hyogo 665, Japan -2 Plant Protection Division - International, Sumitomo Chemical Co., Ltd., Kitahama, Chuo-Ku, Osaka 541, Japan -3 Sumika Life-Tech Co., Ltd., Takatsukasa, Takarazuka, Hyogo 665, Japan

A new synthetic pyrethroid, imiprothrin; [2,5-dioxo-3-(2-propynyl)-1-imidazolidinyl] methyl (1*R*)-*cis,trans*-chrysanthemate shows the highest knockdown activity against household insect pests, especially against cockroaches among the known pyrethroid compounds.

The toxicological and electrophysiological studies for imiprothrin were carried out using cockroaches. We will discuss the difference in the mode of action between imiprothrin and the other pyrethroids.

The new method for the evaluation of knockdown activity will be also discussed.

18-024

INVESTIGATIONS ON THE SUITABILITY OF SILAFLUOFEN TO CONTROL NOXIOUS ANTS, WASPS AND TERMITES

M. J. Kern, J. Geiß, A. Sagenmüller, H. Stübler

Hoechst Schering AgrEvo GmbH, Biological Research, H 872, D-65926 Frankfurt/Main, Germany

Within the Order *Isoptera* and *Hymenoptera* there are some social insect pests, for example termites such as *Coptotermes formosanus* or *Mastotermes darwiniensis*, leaf cutting ants such as *Atta*- and *Acromyrmex*- species, and wasps such as *Vespa vulgaris* and *Vespa analis*, which destroy wooden buildings, damage important crops, beekeeping and tropical forestry or jeopardize and attack human beings.

With silafluofen (Neophan®, Silonen®), which has a „delayed action kill“ and, if applied specifically, it is possible to combat pest insects of these kinds „systemically“.

Quick kill of individual foragers of social insects, such as ants, wasps and termites does not affect the main colony. However, if silafluofen is mixed with an insect attracting ingredient, the foragers carry the toxicant-attractant formulation back to the home colony where it is shared by larvae, workers and queen.

With silafluofen (0.0005% - 0.0025% a. i.) sprayed upon taro, sweet potato, manioc and coffee, whole hives of leaf-cutting ants are destroyed.

Wasp numbers can be reduced by destroying nests using silafluofen 0.005% a. i. in a honey : water bait (1:5).

Hives of the Australian subterranean termite can be destroyed „systemically“ when fed with a wooden block which was dipped into a silafluofen solution (0.004% a. i.).

The laboratory experiments with ¹⁴C-labelled silafluofen have shown, that silafluofen is a versatile insecticide to control noxious ants, wasps and termites.

18-026

TARGETED DELIVERY OF MOSQUITO LARVICIDES FROM MATRICAP™ COMPOSITIONS

R. Levy, M.A. Nichols and W.R. Opp

Lee County Mosquito Control District, Post Office Box 60005, Fort Myers, Florida, 33906, U.S.A.

A novel formulation system for controlled delivery of pesticides was developed for targeting a variety of aquatic organisms that occupy specific surface, subsurface or both surface and subsurface areas of a water column. Polymer/nonpolymer-base formulations consisted of admixtures of one or more insecticides, and one or more matrix and encapsulation/coating components, with or without binder components.

A series of short and long-term bioassays demonstrated positional distribution of bioactive agents such as *Bacillus thuringiensis* var. *israelensis* (B.t.i.) or methoprene, or a combination of B.t.i. and methoprene from powdered, granular or agglomerated compositions in zones of a water column that were optimal for controlling immature stages of *Anopheles*, *Aedes*, and *Culex* species of mosquitoes that typically feed and/or orient in different horizontal and vertical areas of an aquatic habitat. In general, bioassays against mosquito larvae indicated that the encapsulation level, controlled-release rate, and controlled-release profile of an insect growth regulator or bacteria were dependent on the type and concentration of admixing components utilized in the powdered, granular or agglomerated compositions. The duration of delivery of mosquito larvicides was shown to be mainly related to the type and concentration of coating(s) utilized in a controlled-delivery composition.

Controlled-delivery Matricap™ technology was also applicable to terrestrial pest control. As an example, novel polymer-pesticide (e.g., organophosphate or growth regulator) bait stations were developed for prolonged control of adult and immature stages of the German cockroach *Blattella germanica*.

THE EFFECTIVENESS OF DIATOMACEOUS EARTH AGAINST STORED-GRAIN INSECTS PESTS IN FARM STORAGES.

Z. Korunic¹, P.G. Fields², N.D.G. White², A. MacKay² and B. Timlick²

1. Hedley Pacific Ventures Ltd., Vancouver, Canada, 2. Agriculture and Agri-Food Canada, Cereal Research Centre, Winnipeg, Canada

Diatomaceous earth (DE) has gained interest as a grain protectant as it is non-toxic to mammals, and it does not affect end use quality (baking, malting, or pasta production). However, DE use has been limited because it reduces grain bulk density and must be used at high concentrations, 500 to 3500 ppm (parts per million), to be effective. We have developed a new diatomaceous earth-based insecticide, Protect-It, that is approximately 2-3 fold more effective than currently available diatomaceous earth grain protectants. We present the results of field trials conducted in southern Manitoba.

Field trials were conducted at one site in 1994 using 3 treatments (0, 50 and 300 ppm dust) and at three sites in 1995 using 4 treatments (0, 75, 100 ppm dust, 100 ppm aqueous spray). We used 27 - 80 tonne capacity metal storage granaries with 16 - 40 tonnes of wheat in each granary. To insure infestation, rusty grain beetles (*Cryptolestes ferrugineus* (Stephens)) and red flour beetles (*Tribolium castaneum* Herbst) were released on the top of the wheat bulks. Insect populations were measured using probe pitfall traps and by extracting insects from wheat taken from the granaries.

Cryptolestes ferrugineus populations were consistently controlled, over 90% reduction compared to control granary populations, by treatments at 75 ppm or greater. *Tribolium castaneum* populations were reduced by 100 ppm dust application, and controlled at 300 ppm. Neither species were consistently reduced at 50 ppm, and *T. castaneum* was not reduced at 75 ppm or 100 ppm aqueous spray applications.

Grain bulk density (kg/hL) was reduced by 2.1 at 50 ppm, 2.2 at 75 ppm, 2.3 at 100 ppm, 2.1 at 100 ppm spray application and 4.6 at 300 ppm. The grain grade in treated wheat was not reduced due to bulk density reduction, but grain with bulk densities at the limit of a grain grade could have reduced grades due to bulk density reduction.

QUANTITATIVE LOSS ANALYSIS OF THE DAMAGE CAUSED BY *LEPISMA SACCHARINA* LINNÉ (ZYGENTOMA: LEPISMATIDAE) ON DIFFERENT BOOK-MATERIALS AND THE EFFICACY OF BORIC ACID AND DIATOMACEOUS EARTH TO CONTROL THIS HOUSEHOLD PEST

M. Pöschko, Ch. Reichmuth, D.-E. Petersen¹

Federal Biological Research Centre for Agriculture and Forestry, Institute for Stored Product Protection, Berlin, Germany-1 Restoration Department of the Herzog-August Library, Wolfenbüttel, Germany

Silverfish are common in bathrooms all over the world. In most cases nobody takes care about these harmless guests. But in a library or in a museum this pest can cause considerable damage to valuable historical books, letters, documents, paintings and pictures.

In laboratory experiments the losses caused by *Lepisma saccharina* to different book-materials such as hand-made paper, tissue paper, vellum, leather, linen etc. were quantified. The efficacy of two non toxic powders, boric acid and diatomaceous earth to control *L. saccharina* was also tested. Boric acid gave good results in controlling *L. saccharina* under all the conditions tested. Diatomaceous earth was less effective especially under humid conditions. Quantitatively, 100 silverfish destroyed about 1 g a year of some of the book-materials tested, equal to 100 cm² to 700 cm² depending on the type of material.

EMPLOYMENT OF HEAT AND COLD AGAINST PEST INSECTS IN STORAGE

Ch. Reichmuth, M. Pöschko, W. Rassmann, Ch. Ulrichs

Federal Biological Research Centre for Agriculture and Forestry,
Institute for Stored Product Protection, Berlin, Germany

The susceptibility of insects towards exposure to heat and cold is generally known since long time. Compared with chemical control the application of heat and cold to disinfest storages, museums and collections from pest insects was much more expensive and rarely chosen in practice. Due to changing public awareness and attitude including more intense measures to ensure the safety of employees, the treated goods and the environment, chemical treatments are increasingly more expensive. This new consideration opens the horizon for the implementation of the above mentioned control methods into an integrated system of pest control with biological, physical, chemical and technological procedures in storage.

The paper presents data from literature, laboratory and practical results of the use of heat and cold to control pest insects.

Temperatures in the range of 50°C are sufficient in flour mills for control of insects within a few hours. The possible destruction of electronics and other sensible materials sets a narrow margin for efficacy against pests and avoidance of damage as far as the temperature regime is concerned. New systems with use of accurately regulated relative humidity try to include heat control as a method against material destroying insects in precious artefacts. Heat treatment is discussed as an alternative for use of methyl bromide, which is considered to be replaced in pest control wherever possible.

With cold it is more the aspect of high costs which limits the application in such cases where time is very limited and the goods to treat are very sensible and of high value. Practical results with liquid nitrogen supporting the applicability cold are presented.

BIOLOGICAL EFFECTS OF SOME NATURAL AND CHEMICAL COMPOUNDS ON THE POTATO TUBER MOTH, *PHTHORIMAEA OPERCULELLA* ZELL. (LEPIDOPTERA: GELECHIIDAE).Aziza Sharaby¹, M.M. El-Missiry², S. Abdel-Hamed³
^{1,3} Pests and Plant Protection Department,
National Research Centre, Dokki, Cairo, Egypt.
² Pharmaceutical Science Department, National
Research Centre, Dokki, Cairo, Egypt.

The olfactory reaction of larvae and moths was investigated towards 18 oils (6 natural oils and 12 commercial chemical oils). Some of these oils as peppermint and camphor (natural oils), eugenol and camphene (commercial oils) were repellent to both larvae and moths. Other oils as straw berry and D-Limonene were attractive to both larvae and moths.

Eugenol and peppermint oils, each at the 0.01 % conc. caused significant depression in the fecundity of moth and decreased the percentage of egg hatchability at 1 %. Eugenol oil, however, was much more effective than peppermint oil.

Dried (leaves or fruits or seeds) powders of 14 different plant species were tested in different concentrations with talcum powder (carrier material) against egg deposition. Results indicated that:

Dried powders of *Allium cepa*, *Curcuma longa*, *Colocasia antiquorum*, *Ocimum basilicum*, *Dodonaea viscosa* and *Thuja orientalis* displayed a high significant role in reducing egg deposition. The most impressive effect was displayed by powders of *Dodonaea viscosa* and *Allium cepa*, which caused the highest depression in egg deposition as well as in the emerging offspring.

Ethanollic extracts of *Pituranthos tortosus* and *Iphiaona*, scabra caused the maximum inhibition of egg hatchability, followed by *Curcuma longa*.

RED IMPORTED FIRE ANT (HYMENOPTERA: FORMICIDAE) CONTROL: SHOULD BAITS OR STRATEGIES BE IMPROVED?

S.M. Semenov¹, L.C. Thompson and D.B. JonesSchool of Forest Resources, University of Arkansas, Monticello,
Arkansas, USA - 1 Institute of Global Climate and Ecology, Moscow,
Russia.

We used field tests and population modeling to compare efficacy of commercial baits used in red imported fire ant (*Solenopsis invicta* Buren) control. Check and treatment plots (each >0.4 ha) were established at 54 sites in southern Arkansas using twice-yearly (June and October) broadcast applications of commercial hydramethylnon and fenoxycarb baits applied at a rate of 0.68 kg/ha. Ant colonies were counted monthly within 0.1 ha subplots. For analysis, colonies were placed into five size classes and colony density (per 0.1 ha) and total percentage coverage of colony foraging territories in plots were estimated. Computed values for colony density and territory coverage were averaged over the period July 1992 to June 1993, producing a new variable called active period average (APA). These APA values for check and bait plots were averaged spatially as well, and used to assess the efficacy of this bait strategy. For check plots, mean mound density (and its standard error) was 26.0 (± 3.4) and mean territory coverage was 21.5% ($\pm 3.3\%$). For hydramethylnon these measurements were 5.1 (± 1.1) and 2.6% ($\pm 0.6\%$), respectively, and for fenoxycarb they were 5.1 (± 1.1) and 2.1% ($\pm 0.7\%$), respectively. Population modeling yielded 2.6 mounds per 0.1 ha as the lower limit of density under twice yearly 100% suppression. Observed mean efficacy of baits in reducing colony density and territory coverage was 80% and 84%, respectively; there were no statistical differences between baits. Therefore, applied twice per year, these baits were effective at killing ants. The model of fire ant population growth, with 100% population suppression twice a year, produced a theoretical maximum reduction in colony density for the year of 90% due to rapid recolonization of treated areas. Because the 80% reductions achieved in field experiments are close to the calculated theoretical upper limit of 90%, the strategy of using twice-yearly applications of baits for managing fire ant populations appears to be reaching its maximum potential. Consequently, alternative strategies for controlling fire ants seem to be imperative.

18-031

CONTROL OF INSECT PESTS IN STORED GRAIN WITH CONTROLLED ATMOSPHERES RICH IN CARBON DIOXIDE AT TEMPERATURES BETWEEN 0°C AND 40°C

C. Adler

Federal Biological Research Centre for Agriculture and Forestry,
Institute for Stored Product Protection, Berlin, Germany

Controlled Atmospheres (CA's) low in oxygen and/or high in carbon dioxide have been registered for stored product protection purposes in many countries during the last decade. Due to the high density of carbon dioxide it is sufficient to secure the desired CO₂-content at the top of a treated grain storage. This allows treatments not only in silo bins but also in flat storages sealed with gasproof plastic liners. The insecticidal effect of carbon dioxide fumigations does not depend solely on the replacement of oxygen. This allows for higher residual oxygen contents than in nitrogen treatments.

Grain temperatures have a major impact on the time needed for a successful disinfestation. The grain temperatures in an unclimatised grain store may vary considerably over the year and may range from around 0°C in late winter up to 35°C or even higher in late summer.

To study the influence of product temperature on the efficacy of atmospheres containing 60 % or 90 % of carbon dioxide in air, all developmental stages of the granary weevil *Sitophilus granarius* (L.) were exposed to these two gas mixtures at temperatures between 0°C and 40°C. Longest lethal exposure times of 49 days were measured at 5°C while probably the cold is responsible for a reduction to 35 days at 0°C. At 35°C lethal exposure times were reduced to 7 days and at 40°C to less than 2 days. Over the whole temperature range no significant deviations could be found in the efficacy of 60 % and 90 % CO₂. The results are compared to data of experiments using different species.

18-032

Biogeneration of modified atmosphere in small grain bins for the control of storage insects.

M. Calderon, N. Paster and Miguel Mora

Abstract

The principle of his method is to use a deterioration of waste plant material in small containers (biogenerators) for the production of high CO₂ concentrations and the consumption of O₂ (resulting on low O₂ contents). The produced, in the biogenerator, lethal to the insects modified atmosphere is transferred in the grain bin in which insect infestation takes place. The three parameters of the system were investigated and the following findings were noted: The Biogenerator may be of any volume depending on the quantity and the type of the waste plant material (the substratum) and the size of the grain bin. The substratum. It was concluded that wet substrata (orange peels, bananas, etc) under anaerobic conditions, produced markedly more CO₂ than dry materials (like wheat bran). The CO₂ production was notably large in the case of sugar cane. The grain bins were of capacity of 200 - 1000 kg of grain. It should be noted that this method was successfully demonstrated in Costa Rica (Central America).

RESISTANCE TO PHOSPHINE IN STORED PRODUCT INSECTS AND A STRATEGY TO PREVENT ITS INCREASE.

K. A. Mills, and I.A. Pacheco,¹

Ministry of Agriculture, Fisheries and Food, Central Science Laboratory, London Road, Slough, SL3 7HJ, U.K.
- 1 Instituto de Tecnologia de Alimentos, Av. Brasil, 2880, C.P. 139, Campinas-SP, 13073-001, Brazil.

The threat to the current availability of methyl bromide due to it being listed as an ozone-depleting substance under the UNEP Montreal Protocol means that there will be an increased use and mis-use of phosphine for the disinfection of stored products from insect pests. Phosphine resistance is a major problem in the control of some species due to inadequate attention to fumigation standards. The situation will only deteriorate unless a pro-active strategy for dealing with the resistance is implemented. In five stored product beetle species studied to date, the resistance is partly controlled by a major semi-recessive gene which controls uptake together with a modifier gene(s). For four species, a rapid resistance test based on the immobilisation of adults, rather than on mortality, has been developed which enables heterozygotes and homozygotes to be rapidly detected in populations before fumigation. The development of such tests is recommended for all species for rapid resistance diagnosis. They are also invaluable tools for the rapid generation of sufficient data for an accurate study of the genetics of the resistance in species where this is lacking. Heterozygotes can be controlled by modest increases in dose over those required for the control of susceptible insects. This should be achievable in carefully executed fumigations using current fumigation standards. Where the genes have already been selected, the doses for practical control should be re-defined from strains carefully selected in the laboratory to be homozygous for all the genes for resistance and fumigation standards adapted accordingly. The availability of information on the resistant genotypes present in a population coupled with a knowledge of accurately determined doses necessary to control all life stages of each genotype enables a decision to be made, before fumigation, on the appropriate dose to be applied taking the gas-tightness of the situation into account. These will prevent the selection of the resistance gene(s) or will eliminate homozygotes where they are produced. The careful application of these principles means that phosphine itself can be used to control resistant populations without producing unacceptable residues in commodities.

FUMIGANT PROPERTIES OF MOUNTAIN BIG SAGEBRUSH, *ARTEMISIA TRIDENTATA* NUTT. SSP. *VASEYANA* (RYDB) FOR STORED GRAIN INSECTS

F. Dunkel, J. Sears¹, F. Djibode, H. Christiansen¹

Department of Entomology, Montana State University, Bozeman, MT USA - ¹ Department of Chemistry, Montana State University, Bozeman, MT USA

Vapors released by a patented process (Dunkel et al. 1994) that utilized mountain big sagebrush, *Artemisia tridentata* ssp. *vaseyana*, were hypothesized to have insecticidal properties similar to the fumigant methyl bromide. Bioassays with the lesser grain borer, *Rhyzopertha dominica* (F.), 0-3 days after adult emergence indicated an LT₅₀ of 6.93±1.16 hours (hrs) from the volatiles generated from only 0.029 g dry processed plant material per cc headspace. Hatching of eggs of the Indianmeal moth, *Plodia interpunctella* Huebner, was completely suppressed when exposed 4-20 hrs after oviposition to 0.0073 g processed plant material per cc headspace in a container that allowed passive diffusion and in which the terpenes disappeared by 48 hrs. Adult red flour beetles, *Tribolium castaneum* Herbst were also tested. Gas chromatography/mass spectrometry (GC/MS) analyses of the headspace above this processed plant material indicated in an airtight container, there were 7 detectable compounds. The two main components of the headspace were in a mean ratio of 1:3.2, initially, but over 24 hrs, gradually shifted to 1:2.4. The ug/cc headspace of each detectable compound in a sealed container was followed intensively for 72 hrs, and less frequently 120 days. Active compounds released by the plant material in a closed, but not airtight container, were not detectable after 24 hrs with GC/MS analysis of the headspace. Fumigative studies with the same ratio of the two main compounds generated synthetically indicated embryos of *P. interpunctella* and adults of *R. dominica* were as sensitive to the synthetic mixture as they were to the processed natural material. Although one could apply the precise commercial terpenes in the same ratio, the plant material provides a natural formulation that is automatically diluted (formulated) to levels safe for handling. Therefore, this preparation method with this plant material shows good potential as an alternative to methyl bromide in stored grain and commodity fumigations.

18-035

CONTROL OF THE IMMATURE STAGES OF *Sitophilus oryzae* (L.) SUSCEPTIBLE AND RESISTANT TO PHOSPHINE BY PHOSPHINE FUMIGATION.

I.A. Pacheco and K.A. Mills¹

Instituto de Tecnologia de Alimentos, Av. Brasil, 2880, C.P. 139, Campinas-SP, 13073-001, Brazil.
-1 Ministry of Agriculture, Fisheries and Food, Central Science Laboratory, London Road, Slough, SL3 7HJ, U.K.

The objective of the present work is the determination of the dosages of phosphine required for the control of the immature stages of *Sitophilus oryzae* (L.) at 25°C and 60% R.H. A susceptible strain and resistant strains with different genetic backgrounds were tested. Cultures containing the naturally tolerant eggs and pupae of a susceptible reference strain a laboratory strain (476) selected to be homozygous for the major resistance gene and a resistant strain maintained in the laboratory without selection (Maringa, Brazil) were fumigated in laboratory chambers. Heterozygous resistant pupae produced from single pair crosses between the susceptible strain and strain 476 were also fumigated. The eggs of the susceptible strain were controlled by a 72 h exposure to a concentration-time product (CTP) of 36.55 ghm⁻³ whilst eggs of strains 476 and Maringa survived an exposure of 120 h to a CTP of 57.31 ghm⁻³ but not 168 h to a CTP of 75.87 ghm⁻³. For all strains tested the pupae were more tolerant than the eggs. Pupae of the susceptible strain were controlled by a 96 h exposure to a CTP of 47.38 ghm⁻³. Pupae of strain 476 survived an exposure of 120 h to a CTP of 57.31 ghm⁻³ but not 168 h to a CTP of 75.87 ghm⁻³ which allowed survival of pupae of strain Maringa. Pupae of strain Maringa were controlled by exposures of 168 and 240 h to CTPs of 106.44 and 100.87 ghm⁻³ respectively. The higher tolerance of some pupae of strain Maringa is of concern since it shows that selection in the field can produce a very resistant strain with possibly an enhanced resistance mechanism(s) or an additional mechanism(s). It is encouraging that the heterozygous resistant pupae were controlled by a 96 h exposure to a CTP of 47.88 ghm⁻³, a similar dose to that which controlled susceptible pupae. This indicates that the resistance genes can be eliminated when they are in the heterozygous condition and therefore, if continuous attention is given to the quality of fumigations, these genes can be eliminated when they are at a low frequency in the population.

THE POSSIBLE USE OF PLANT VOLATILES AS SUBSTITUTES FOR METHYL BROMIDE

E. Shaaya¹, M. Kostjukovsky¹ and U. Ravid²

1- Department of Stored Product, The Volcani Center, Bet Dagan,

2- Department of Aromatic Plants, Neve Yaa'r Research Center, Haifa,
Israel.

The fumigant toxicity of a large number of essential oils extracted from various spices and herb plants against five major stored-product insects was assessed. Eggs and pupae were found most resistant to the essential oils compared to adult and larvae. In the case of the most active compounds a concentration of 1.5 - 3 $\mu\text{l/l}$ air and exposure time of 24 h was enough to obtain 100% mortality of all adult insects tested. In columns filled with 70% wheat a higher concentration of around 50 and 70 $\mu\text{l/l}$ and a 7 - day and 4 - day exposure time respectively are needed to obtain 100% mortality of the adult insects tested. The rate of sorption and residues of the active compound in grain was also assessed. Studies to elucidate the effect of monoterpenes on the enzyme acetylcholinesterase in two stored-product insects showed that this enzyme is not the main site of action of these compounds.

18-038

INTERACTIONS OF MICROFLORA AND ARTHROPODS IN STORED GRAIN

D. T. WicklowMycotoxin Research, National Center for Agricultural Utilization
Research, USDA, Agricultural Research Service, Peoria, IL

Mycologists and entomologists have separately studied the interaction of temperature and moisture on the colonization patterns of fungi and arthropods in stored grain. Knowledge of the secondary metabolites produced by fungal taxa common to grain stores can suggest sources of mycotoxin/entomotoxin contamination and point to volatile fungal metabolites that may attract or repel certain arthropods. Investigations of interactions between grainary arthropods and fungi should recognize the trophic relationships of species, initially focusing on fungi and arthropods that share the same optima for growth and reproduction. Sap beetles (*Carpophilus* spp.) can influence the initial fungal colonization of maize grain before it is harvested. Primary grain feeding insects damage intact grains providing routes of entry for fungi, secondary insects, and mites. The latter include detritivores and fungivores that selectively consume fungi, choosing among a mosaic of fungal 'patches.' Arthropod grazing can stimulate or suppress fungal sporulation, while some adult beetles such as *Tribolium* spp. produce benzoquinones which inhibit fungal growth. Detritivorous insects are better able to tolerate molded and mycotoxin-contaminated resources than are herbivorous insects. Fungivores and secondary feeders may benefit from fungal toxins 'antibiotics' that cure parasitic infections.

18-037

THE CURRENT STATE OF SELF-MARKING MODELS

E. Paul WilevtoSchool of Veterinary Medicine, University of Pennsylvania, New
Bolton Center, Kennett Square, Pennsylvania, USA.

Self-marking models allow a mark-recapture type of population estimate from insect trapping. The estimates may be biased if certain model assumptions are violated. Violations of the original model are described by more complex models with larger numbers of parameters. Recent development has centered on model identification and selection, and alternative means for estimating the confidence interval. Results indicate that capture probabilities for more complex models are best determined numerically, using a general solution for the system of linear differential equations that describes self-marking and capture. Many alternative models can be identified in self-marking data, and likelihood-ratio tests do a reasonable job of selecting models. Finally, the bootstrap is now the best means of estimating a confidence interval. Bootstrap estimates allow us to incorporate model-uncertainty into the estimate, and perform significance tests using self-marking experiments.

COMPREHENDING STORED-GRAIN ECOSYSTEMS

R. T. ArbogastInsect Attractants, Behavior and Basic Biology
Research Laboratory, ARS-USDA, Gainesville, FL
USA

Understanding the dynamics of stored-grain ecosystems is essential to developing rational strategies for maintaining grain quality. Despite their apparent simplicity relative to many other ecosystems, stored-grain ecosystems are nevertheless quite complex, and their characteristics vary with geographic location, type of grain, and type of storage structure. Conceptual models developed over the past thirty years provide a useful framework for characterization and investigation of dynamics. Progress now depends upon our ability to identify, measure and analyze the key factors that drive these systems and then develop valid mathematical abstractions. The purpose of this workshop is to review progress in these areas.

18-040

THE IMPACT OF VARIABILITY IN LIFE HISTORY PARAMETERS ON MODELLING INSECT POPULATION GROWTH BASED ON DATA FOR *Sitotroga cerealella* IN STORED CORN

D. K. Weaver and J. E. Throne¹

USDA Insect Attractants, Behavior, and Basic Biology Research Laboratory, Gainesville, FL USA
- 1 USDA U. S. Grain Marketing Research Laboratory, Manhattan, KS USA

A computer model is presented for the population dynamics of *Sitotroga cerealella* on stored corn. The model is used to test assumptions regarding the impact of variability in life history parameters across strains or biotypes of this species. The model is also used to evaluate the impact of the completeness of life history data collection on the accuracy of resulting models. Specific questions asked are: 1) How does life history data collected over a full range of conditions that support growth compare with data collected at more optimal temperatures only? and 2) Can extrapolation compensate for this missing data? The model assesses these questions for all population growth and development parameters including fecundity, fertility, and longevity of adults, as well as for immature development and survival. We also compare the resolution of these various forms of the model with our validation data to determine the significance of any predicted differences in terms of measured population growth.

SPATIAL DISTRIBUTION AND MOVEMENT OF INSECTS IN BULK WHEAT IN RESPONSE TO AERATION

E. J. Wright, A.C.M. van Gerwen, W. A. Whitby

CSIRO Division of Entomology, Canberra, ACT, Australia

The study of the spatial distribution and movement of insects in bulk grain is technically very challenging, and historically has been done in small volumes of grain. The behaviour in large grain bulks with low density populations has remained an important but relatively unstudied issue. This paper describes a project that links large scale field studies with small scale laboratory studies to analyse the movement of insects in bulk grain that is subjected to cooling by aeration.

Using probe traps and equipment to set and retrieve these from depth, we tracked the movement of several species of beetles in a 6000 tonne aerated bulk of wheat and correlated these to the temperature gradients in the grain. Some species showed distinct responses to the temperature front, whereas others did not.

In order to investigate the spatial distribution and movement of the 5 most common species of stored product Coleoptera in Australia in detail, a laboratory apparatus was constructed that uses small enough amounts of grain and insects to be tractable, but which reflects the temperature and humidity relationships of a full-sized bulk. The apparatus consists of vertical columns of grain each comprising 10 sections that can be disassembled, plus all the equipment necessary to condition the input air.

Using this apparatus, beetles were exposed to upwards or downwards aeration, at 3 rates of air flow and to different gradients of temperature. From these experiments, the gravity response in non-aerated grain, the effect of aeration with warm air and of aeration with cooling air on the movement and distribution of beetles were determined and these were generally consistent with the field observations.

PRINCIPLES OF TRAP DESIGN FOR STORED-PRODUCT INSECTS

M.A. MULLEN

Grain Marketing and Production Research Center
U.S. Grain Marketing Research Laboratory
Manhattan, Kansas, USA

To develop an effective pheromone baited trap for stored-product insects, several factors must be considered. These factors include the target species and the environment in which the trap will be used. An effective trap exploits behavior characteristics of the target species that may increase the likelihood of being trapped. Behavior patterns that might be considered are the insects tendency to climb or enter tight dark places. Environmental concerns include how dusty, moist, or the amount of space available for the trap. Other considerations are the ease of counting trapped insects, type of pheromone dispenser used, and the durability of the trap. To illustrate the development of a pheromone baited trap, the evolution of the FLIT-TRAK M² will be discussed. The FLIT-TRAK M² is a pitfall trap that has been successfully used to trap a variety of stored-product Coleoptera.

18-043

MODELLING POPULATION DYNAMICS OF THE MAIZE WEEVIL *SITOPHILUS ZEAMAI* MOTSCHULSKY (COLEOPTERA: CURCULIONIDAE) AND ITS HYMENOPTERAN PARASITOID *ANISOPTEROMALUS CALANDRAE* (HOWARD) (HYMENOPTERA: PTEROMALIDAE)

L. Smith

Stored-Product Insects Research and Development Laboratory, USDA-ARS, Savannah, Georgia, USA

A temperature-driven age-structured computer simulation model was developed to help evaluate different strategies for augmentative biological control of the maize weevil *Sitophilus zeamais* in stored maize by the parasitic wasp, *Anisopteromalus calandrae*. Parameters of the model were based on detailed laboratory life history and functional response studies conducted at 20, 25, 30 and 35°C.

Establishment of a sufficiently large parasitoid population during the first host generation is critical to the success of biological control in this system. Simulation was used to explore the efficacy of various release strategies including time of first parasitoid release, numbers per release, time between consecutive releases, and number of consecutive releases. An optimal strategy at 25°C includes two or three sequential releases, using about ten times as many parasitoids as adult weevils, at 9 day intervals as soon as the first hosts of suitable size (≥ 15 days old) are available.

Temperature affects population growth rate of the two species differently. Growth rate of the parasitoid is greater than that of the weevil above 21°C, and this difference increases dramatically above 29°C. This indicates that the parasitoid may be particularly useful for warm storage conditions.

THE ROLE OF GRAIN LIPIDS IN STORED
PRODUCT INSECT LIFEZ. Winiecki¹, J. Nawrot¹, J. Szafraniek²,
E. Maliński²¹ Institute for Plant Protection, Poznań, Poland² Gdańsk University, Gdańsk, Poland

The main function of grain and insect surface lipids is to minimise the losses of body water through the cuticle. In plants and their seeds the lipid layer is the first element that the insect comes in contact during searching for food or place for egg-laying. The results of investigation on another properties of grain cuticular lipids in food recovery and food utilisation by storage insects and differences in chemical composition of lipids in development stages and different sexes of insects are also presented. The composition of substances found in cuticular lipids of grain and grain feeding insects is very diversified. Only n-alkanes occurred in all examined insect species and wheat grain showed the high correlation in the proportion of main components.

CHEMOSENSORY AND TACTILE REGULATION OF COPULATION
AND OVIPOSITION BY *CALLOSOBRUCHUS CHINENSIS* L.
AND *C. MACULATUS* FABRICIUS (COLEOPTERA, BRUCHIDAE)I. Yamamoto, H. Honda, T. Miyamoto, K. Ohsawa¹
Department of Agricultural Chemistry -1 NODAI Research
Institute, Tokyo University of Agriculture, Setagaya, Tokyo,
Japan

C. chinensis deposits eggs not only on beans but also on surface of certain curvature, while *C. maculatus* oviposits mainly by responding to chemical stimuli in the seed coat. There are two prominent phenomena that are associated with the oviposition behavior of both weevils. Under low population density conditions, the females oviposit evenly among beans, being guided by a marking pheromone. Under high density conditions, the number of eggs on each bean becomes high and egg distribution becomes random, but only a few eggs can hatch and grow normally inside a bean, leaving the remaining eggs to die by the ovidical action of higher doses of the marking pheromone. These weevils thus have developed a strategy to reduce competition among larvae and to maximally utilize the host beans by using the same substance at different levels. The two weevils can grow in many beans, but not in kidney bean due to the growth inhibitor in the bean. Immediately after emerging from beans, the adults make copulation. The sex attractant released from the female attracts the nearby male. When they are in close proximity, the second sex pheromone having no attractancy functions to induce erection and insertion of male genital organ and ejaculation. The ecochemicals involved in the above behaviors were partially or completely identified from the two weevils. They have some application for the pest control.

18-047

ANALYSIS OF SPECIFIC PROTEINS OF SYMBIOSIS IN THE WEEVIL *SITOPHILUS*

H. Charles and P. Nardon

Institut National des Sciences Appliquées, UA-INRA 203, SDI-CNRS 5128, Lyon, France

The weevil *Sitophilus* harbours intracellular symbiotic bacteria into specialized cells (bacteriocytes), which interfere with the host metabolism and supply the weevil with 5 vitamins. As a consequence, these bacteria increase the fertility and the rate of development of their host and are therefore responsible of the harmfulness of *Sitophilus* against stored cereals. Despite the fact that the symbiotic bacteria are highly integrated to the insect physiology, symbiosis can be disrupted by heat treatment and aposymbiotic weevils can be obtained. On a more fundamental point of view, this model allows us to study genetic interactive factors that are needed to maintain the symbiotic association.

Pulse field electrophoresis experiments have shown that the symbiotic bacteria chromosome is about half smaller than that of *E. coli* (the closest free living bacteria), indicating that some prokaryotic genes have probably been deleted or exported to the nucleus of the bacteriocytes during the coevolution of both partners.

We have also compared the protein patterns of two strains of *Sitophilus oryzae* (symbiotic and aposymbiotic) in order to detect some proteins synthesized by the host in response to the presence of the endocytobiont. Among the five detected proteins, we paid more attention on one (60kDa, pI=6) which belongs to the chaperonin family. This protein was called symbionin, the term being firstly used in 1982 by Ishikawa about the endocytobiosis of the aphid *Acyrtosiphon pisum*.

The endocytobionts synthesize more than one hundred proteins *in vitro*, and preferentially three of them *in vivo*. Western and northern blot analysis show that one of these proteins is the symbionin. The gene encoding the symbionin have been cloned and sequenced.

Chaperonins are ubiquitous proteins found in all cellular types, especially in parasitic bacteria. Considering that endocytobionts could have evolved from parasitic bacteria, it is thus not very surprising to find that they contain a chaperonin. But the most interesting questions are to know why this chaperonin is produced in such a great quantity by the endocytobionts, and whether the presence of symbionin is a general process of endocytobiosis conserved during evolution. The most conceivable hypothesis for the biological role of symbionin is that it might be produced for the endocytobiont own safe, and could act as a host protein pumping and assembling machinery.

COCKROACH NUTRITION: A GUIDE TO BETTER PEST CONTROL

C. Schal, R.J. Kopanic and H.P. Young
Department of Entomology, North Carolina State University,
Raleigh, NC USA

Nutrient intake is critical for development, growth, and reproduction of the German cockroach, *Blattella germanica*. Development of nymphs is tightly linked to availability of food and its quality. Adult females are also highly dependent on food during each gonotrophic cycle. At each stadium and in the adult female, a cycle of feeding corresponds to specific physiological events. In nymphs and adults, the synthesis of cuticular lipids is linked to availability of food and in adult females, juvenile hormone biosynthesis is linked to a gonadotrophic cycle. Clearly, these links are central to strategies and tactics that rely on insecticidal baits for cockroach control.

Nutrient characteristics of chemically defined baits ("bait base") significantly affect rates of food intake by different life stages of the German cockroach. Moreover, the nutrient status of feral cockroaches affects the amount of food removed from such baits in homes. Coprophagy plays an important role in vectoring active ingredient to non-feeding life stages and the nutrient characteristics of baits can affect the efficacy of their secondary effects. Strategies for targeting non-feeding stages with insecticidal baits will also be discussed.

INSECT SPECIES OCCURRING ON DATE PALM TREES AND STORED DATES IN THE SIWA OASIS, EGYPT

H.A. MESBAH, EL-KADY, B. MAGDA AND S.M. HAMMAD
University of Alexandria, Faculty of Agriculture,
Saba Bacha, Egypt

Field investigation and sample identification during the period from July 1994 until June 1995 were carried out in orchards of different regions of the Siwa Oasis. The occurrence of 18 insect species was recorded on date palm trees and/or date fruits.

Among the most injurious insect pests found, were *Cadra calidella* (Guen.), *Myelois ceratoniae* (Zeller), *Arenipses sabella* (Hamps.) and *Parlatoria blanchardi* (Targ.). Two hymenopterous parasitoids, i.e. *Phanerotoma flantestacea* (Fisher) and *Bracon hebetor* (Say) are common on the larvae of date moths.

The results include records of infestation levels by pest species on growing date palms and stored date fruits. Percentage of infestation found on dried fruits in open air storage were calculated. The fruits of different varieties of palm trees differ widely in their rate of infestation. The highest rate of infestation was recorded for the variety saeydi.

The occurrence of both date fruit moths *C. calidella* and *M. ceratoniae* was recorded for the first time on fruits of the Napk tree (*Ziziphus* sp.).

ASSESSMENT OF THE INHIBITORY EFFECTS OF BIOLOGICALLY ORIGINATED SUBSTANCES ON THE DEVELOPMENT OF THE MAIZE WEEVIL, *SITOPHILUS ZEAMAI* MOTCH. (COLEOPTERA : CURCULIONIDAE)

H. Nakakita, H. Fujii¹, P. Visaratanonth², H. Ikenaga and E. Shaaya³
National Food Research Institute, MAFF, Tsukuba, Ibaraki, 305 Japan
-1 Fruit Tree Research Institute, MAFF, Okitsu, Sizuoka, 424-02 Japan
-2 Division of Entomology and Zoology, DOA, Chatuchak, Bangkok 10900, Thailand-3 The Volcani Center, Bet Dagan, Israel

The recent progress in plant transgenic technology, make it possible, in the near future to introduce a new variety of rice resistant to *Sitophilus zeamais*, an insect most destructive to stored rice. However, basic knowledge of genetically regulated substances having inhibitory or regulatory effects on growth and development of this insect is still lacking. We developed an artificial diet method to evaluate the inhibitory action of biologically originated substances or materials for the weevil. In the search for such compounds, we found that soybean showed the strongest inhibitory action on the growth and development of *S. zeamais* among the materials tested, such as "oryzacystatin", a proteinase inhibitor of rice and "CB1", a chitin binding inhibitor obtained from *Bacillus licheniformis* and also a number of legumes. Our studies also show that "saponins" found in a concentration of about 0.5% in soybean play an important role in the inhibition of development of immature stages of *S. zeamais*.

INFESTATION OF TWO DATE-FRUIT VARIETIES WITH SOME NITIDULID BEETLES (COLEOPTERA: NITIDULIDAE).

BY

Ahmed Kamal Mourad

Faculty of Agriculture, Saba Bacha, Alexandria

University(Egypt) .

ABSTRACT

A study of the infestation of two date-fruit varieties with the nitidulid beetles, *Carpophilus humeralis*(F.), *C. dimidiatus*(F.), *C. hemipterus*(L.) and *Haptoncus luteolus*(Erich.) was carried out from August 1994 till January 1995. This investigation was fulfilled on the fallen fruits of Zaghloul and Semmany dates in the North Eastern Coast of Delta of Egypt.

The results indicated that the degree of infestation in summer was generally higher with *Carpophilus hemipterus* than the other nitidulid beetles .

Also, the degree of infestation of Zaghloul and Semmany in winter with the dried-fruit beetles was generally in high rate , except for *carpophilus hemipterus* which was more abundant on Zaghloul variety. The results also showed that the degree of infestation of Zaghloul and Semmany with *Haptoncus luteolus* and *Carpophilus humeralis* was higher in winter than in summer.

Chemistry of Methyl Neodecanamide (MNDA) - A New Insect Repellent**R. J. Steltenkamp¹****Colgate-Palmolive Company, 909 River Road,
Piscataway, New Jersey, USA-1**

Methyl Neodecanamide (MNDA) is a new chemical that is highly effective in repelling a variety of household pests including cockroaches and ants. MNDA is a member of a class of branched secondary neoalkanamides that are most effective within a specific molecular weight range with a total carbon number between 11 and 14.

MNDA is a safe compound that has strong affinity to surfaces and has excellent stability and aesthetics. As a result, MNDA can be incorporated into a home cleaning product where it can provide benefits as a repellent of nuisance pests having public health importance.

18-054

An Evaluation of MNDA Repellency to Household Pests Found in India**T. N. Ananthakrishnan¹****Entomology Research Institute Loyola College,
Madras, India - 1**

Evaluation of MNDA repellency against native Indian household pests has shown its significance as a useful repellent. Test protocols were developed to assess repellency to a wide variety of native pests. These pests included numerous species of ants, silverfish, beetles and local species of cockroaches. MNDA has been shown to be a more effective repellent than the standard Diethyltoluamide (DEET) in these protocols. These test protocols and repellency results will be presented along with their significance in controlling household pests.

18-053

Insect repellent effects of alkyl neoalkanamides: A new tool for indoor IPM**Coby Schal¹****Department of Entomology****Box 7613****North Carolina State University****Raleigh, NC, USA-1**

Control of pests in structures relies heavily on habitat modification, insecticides, and traps. Physical modification of the indoor environment, including sanitation and resource elimination, usually enhances the effects of other control measures against cockroaches. By reducing limiting resources for population growth and by facilitating movement of insects, physical changes can increase the probability that pests will contact residual insecticides and they can reduce areas which otherwise would require insecticide treatment. Repellents can be used in efforts to alter existing structures in order to reduce these resources. This paper will review data on the efficacy of new secondary amides as cockroach repellents, including structure activity relationships, dose-response studies, results with other cockroaches, repellency to other insect species, and comparisons with other repellents. These secondary neoalkanamides may constitute a new tool in reduced-risk integrated pest management of indoor pests.

18-055

Measuring Spatial Displacement of German Cockroach Populations Pressured by Repellent-treated Harborage**Dr. Richard J. Brenner¹****USDA, Agricultural Research Service, Medical &
Veterinary Entomology Research Laboratory,
Gainesville, Florida - 1**

The use of a cockroach repellent as a tool in integrated pest management strategies would represent a novel and significant departure from traditional reliance on toxicants. The research and development process requires radically different analysis techniques; whereas toxicants impact mortality, repellents impact spatial distributions. This paper describes spatial statistical analysis techniques developed to measure the potential of N-Methyl Neodecanamide (MNDA) to manipulate cockroach populations. The technique was used to document dramatic shifts in population distribution following treatment with 2% MNDA of 50% of cockroach harborage that cumulatively encompassed 85% of the population. Subsequent research in specially constructed and electronically monitored environments is focusing on the repellent's effectiveness (1) in preventing infestation of selected areas, and (2) in "herding" pests toward strategically placed toxic baits. Proposed field trials in cooperation with the US. Department of Defense and the US. Environmental Protection Agency will be discussed in which this repellent will be used in a reduced-risk integrated pest management program.

18-056

Surfactant Based Delivery System for the Insect Repellent N-Methyl Neodecanamide (MNDA)

T.F. Connors¹, K.M. Kinscherf¹

Colgate-Palmolive Company, 909 River Road, Piscataway, New Jersey, USA-1

Solutions of MNDA used to wash surfaces were found by extraction and analysis to deposit MNDA at efficacious levels. The strategy of modifying and “manipulating” insect behavior is promising. Solutions containing MNDA could be used to render areas “inhospitable”, and “move” insects away from indoor areas where insecticide use is discouraged. In conjunction with judicious use of appropriate insecticides, repellents solubilized in a surfactant base could also be used in an integrated approach to manage insect populations by providing sanitation and creating “pest exclusion zones”; thereby increasing the frequency and duration that insects are in contact with insecticides. This paper will review clinical studies done in homes to determine the efficacy of MNDA containing surfactant solutions against household pests such as cockroaches and ants.

18-058

AGGREGATION PHEROMONES OF WEEVILS ASSOCIATED WITH STORED PRODUCTS IN THE GENUS SITOPHILUS - THEORETICAL AND APPLIED ASPECTS

R. Plarre

Stored Product Insect Research Unit, USDA-ARS, Department of Entomology, University of Wisconsin, Madison WI USA

The maize weevil, the rice weevil and the granary weevil are closely related species in the genus *Sitophilus*. All are associated with stored grain of all kinds and cause severe damage in post harvest systems worldwide. Sitophilone the aggregation pheromone of *Sitophilus zeamais* and *S. oryzae* as well as sitophilate of *S. granarius* have been identified. Behavior studies on *S. zeamais* and *S. oryzae* towards natural and synthetic pheromone sources will be reviewed and compared to recent studies on *S. granarius*. Orientation towards the pheromone can best be described as orthokinesis where weevils of both sexes show arrestant behavior near the odor sources. This might lead to a modified trapping strategy combining baited and unbaited traps.

18-057

APPLYING PHEROMONES IN STORED PRODUCT PROTECTION - A REVIEW AND PROSPECTIVE NEEDS

R. Plarre, W.E. Burkholder

Stored Product Insect Research Unit, USDA-ARS, Department of Entomology, University of Wisconsin, Madison WI USA

Most pheromone components of post harvest pest arthropods of major economic importance have been identified successfully during the past 25 years. Many of the pheromones are available for both lepidopteran and beetle species. Sex and aggregation pheromones for beetles and weevils are often multiple compound complexes with optically active enantiomers, which physical characters are often very similar but their physiological effects are generally different.

Twenty-five years of applied pheromone research and field data will be reviewed.

This will include successful monitoring of pest insects and proper timing of control, mass trapping and the strategy of attract and kill. The technique of mating disruption will be discussed.

Pheromones act as attractants, arrestants or repellents, thus regulating population dynamics. Their successful application depends on the optimal concentration, suitable dispensers and effective trap design. Pheromones are generally regarded as intraspecific active semiochemicals, but they very often also function interspecifically as allomones or kairomones. In biological pest control kairomones are becoming more important for monitoring the presence and abundance of predators and parasitoids.

The identification of a pheromone's chemical structure can only be the beginning in understanding an odor based communication system.

While much has been learned in field trapping research, many questions remain. Some of them will be addressed.

18-059

SEX PHEROMONE BIOLOGY OF *CALLOSOBRUCHUS SUBINNOTATUS* AND *C. MACULATUS*: SITES OF PRODUCTION, CHEMISTRY, AND PHYSIOLOGICAL AND BEHAVIORAL RESPONSES

S. B. Ramaswamy, S. Shu, G. N. Mbata

Department of Entomology & Plant Pathology, Mississippi State University, Mississippi State, MS, USA.

This paper discusses several aspects of the sex pheromone biology of *Callosobruchus maculatus* and *C. subinnotatus*, including ultrastructure, chemistry, behavior, and electrophysiological responses. Type 3 secretory cells on pygidium of females have been localized as the source of the sex pheromone in these two species. These cells open to the exterior via cuticular pores, which appear to be more numerous on the pygidium. Secretory cells and pores are present in both females and males; however, we have not been able to ascribe a function to the male structures. Organic solvent extracts and entrained volatiles from females only elicit behavioral and electroantennographic (EAG) responses from males. Both species appear to utilize mixtures of volatile, short chain fatty acids as sex pheromone, characteristic of several species of bruchids. *C. maculatus* are sexually active throughout photophase, but virgin females entrained to a 16:8 L:D light cycle emit more sex pheromone during the first half of photophase than during the second half of photophase or during scotophase. Sex pheromone production is affected by age and mating status, but is not affected by the presence of oviposition hosts. Males respond with upwind orientation to and attempt to copulate with substrates containing pheromone. The potential use of sex pheromones and other behavior modifying substances in the management of bruchids will also be discussed.

PHYSICAL CONSTRAINTS ON PHEROMONE DISPERSAL IN STORAGE ENVIRONMENTS: EFFECTS ON ORIENTATION BEHAVIOR

R. W. Mankin and D. W. Hagstrum¹

USDA Insect Attractants, Behavior, and Basic Biology Research Laboratory, Gainesville, FL USA - 1 USDA Grain Marketing Research Laboratory, Manhattan, KS USA

Orientation of flying insects to pheromone in a closed, warehouse environment is not as efficient as that in a field environment where wind direction and plume intermittency provide additional cues about the location of a pheromone source. The effects of adsorption and re-emission of pheromone from nearby surfaces also are relatively more important in a storage than in a field environment. In this report, the alterations in searching behavior that result from such constraints are considered by three dimensional analysis of searching behavior flights by male *Cadra cautella* (Lepidoptera: Pyralidae). The shape of the plume around a pheromone-emitting female is inferred from comparisons with published descriptions of flights in a wind tunnel.

BEHAVIORAL AND PHYSIOLOGICAL MECHANISMS UNDERLYING MATING DISRUPTION IN ALMOND MOTHS USING A NOVEL SEMIOCHEMICAL RELEASE DEVICE

A. Mafra-Neto and T.C. Baker, Department of Entomology, Iowa State University, Ames, IA 50011, USA

A novel, truly controlled release system for long term storage and intermittent delivery of semiochemicals over long periods of time, at specified release rates, was developed and tested for use in the field as mating disruptant or attract-and-kill bait for *Cadra cautella* (Walker) (Lepidoptera: Phycitinae). There were no signs of degradation or reduction of biological activity of pheromone stored in the aerosol canisters of timed, metered, semiochemical release (TMSR) devices that were kept at ambient temperatures in the field throughout the summer. Pheromone released upon demand from those cans disrupted all mating of freely flying virgin *C. cautella* males and females at a 2:1 ratio kept for 24 h in storage rooms, and up to 92% mating for 72 h. Mating disruption was measured directly by examination of the bursa copulatrix of recaptured females for spermatophores, indicators of successful mating encounters. TMSR devices delivering 50 µg pheromone spray⁻¹ 15 min⁻¹ disrupted mating by more than 90%, independent of either moth population density or of number of TMSR devices used per room. TMSR devices delivering 5 µg spray⁻¹ 15 min⁻¹ disrupted at least 60% of mating. Addition of 1% natural pyrethrin extract to the 5 µg pheromone sprays enhanced disruption (to more than 80%) by exterminating 96% of the male population in 24 h. Observation of the moths in the field experiments, and complementary laboratory experimentation, indicates that elevation of pheromone response threshold of males pre-exposed to pheromone from TMSR devices plays a major part in disruption of *C. cautella*. The antennae of pre-exposed males produced smaller electroantennographic responses to pheromone than did the antennae from naive males. Furthermore, competition between synthetic sources and calling females, as well as false trail following were implicated in our observations as mechanisms that enhance mating disruption of *C. cautella*. We will discuss the new applications (and possible limitations) of the use of TMSR devices to deliver semiochemicals for the management and control of storage and urban insect pests.

18-061

EFFECTS OF PHEROMONE PLUME STRUCTURE ON UPWIND FLIGHT AND CASTING RESPONSES OF THE ALMOND MOTH

T.C. Baker and A. Mafra-Neto Department of Entomology, Iowa State University, Ames, Iowa 50011 USA.

The upwind flight of male moths to conspecific females is mediated by the chemical and structural characteristics of a pheromone plume. The reaction of male *Cadra cautella*, the almond moth, to the brief interception of single pulses of sex-pheromone, the smallest structural units of odour plumes, is to interrupt casting flight by suppressing counterturning and briefly adopting a straighter upwind heading before reverting to casting flight. These behavioral reactions to pheromone contact and loss support the phasic-tonic model of odour-modulated flight, in which an underlying tonic counterturning rhythm, expressed upon pheromone loss, is briefly overridden by phasic upwind surges, expressed upon pheromone filament interception. *C. cautella* males fly increasingly faster and straighter as the duration of pheromone pulses, mechanically generated at a constant frequency of 2Hz, increases from 20 to 300 ms, culminating with the highest levels of such flight at 400 ms and continuously generated plumes. Surprisingly, the shape and form of the flight tracks of males exhibiting casting flight following the loss of pheromone likewise was correlated with the structural differences of the odour plumes in which males had recently flown. Moths that had flown upwind fast, in nearly straight tracks along rapidly-pulsed or continuous plumes, exhibited downwind casting flight soon after pheromone removal. On the other hand, males that had flown upwind slowly in wide zigzagging tracks in response to slowly-pulsed plumes exhibited long, stationary zigzag flights during casting in clean air following plume loss. Such males took three times as long to drift downwind away from the field of view than those that had flown upwind in response to either rapidly-pulsed or continuous plumes. The after-effects of contact with plumes of various structures are thus long-lasting and may indicate that the pheromone-mediated programs of anemotaxis and counterturning are constructed to respond to either rapidly or slowly shifting air-currents and wind-fields.

ENDOGENOUS REGULATION OF PHEROMONE BIOSYNTHESIS IN *Plodia interpunctella*

A. Rafaeli C. Gileadi

Department of Stored Products, ARO, The Volcani Center, Institute for Technology & Storage of Agricultural Products, P.O. Box 6, Bet Dagan, Israel.

Plodia interpunctella female moths attract conspecific males by emitting pheromone during a defined period of the night. The main pheromone component was identified as Z,E, 9, 12 tetradecadienyl acetate (ZETA). In this study the mechanism of control of pheromone production was studied¹. Brain-subesophageal (Br-SOG) extracts of *P. interpunctella* possessed pheromonotropic activity when tested on the pheromone production of *Helicoverpa armigera* females. A significant stimulation of pheromone production by *H. armigera* females was observed when they were injected with 1 Br-SOG equivalent from *P. interpunctella* as well as the related moth *Ephestia cautella*. Decapitation of *P. interpunctella* females for 24 hours prevented normal production of ZETA. This was reversed by injections of synthetic pheromone biosynthesis activating neuropeptide (Hez-PBAN) as well as Br-SOG extracts. In addition, Hez-PBAN, injected to *P. interpunctella* during the photophase induced a large increase in ZETA production. Mating caused a sharp decline 3 hours afterwards. Using isolated pheromone glands, Hez-PBAN was also shown to stimulate pheromone production *de novo*. This stimulation was significantly inhibited by the neurotransmitter, octopamine, in a dose-dependent manner thereby implicating its modulatory role in pheromone production as was observed in *H. armigera*².

SOME ASPECTS OF THE SEXUAL BEHAVIOUR OF THE LEPIDOPTERA PYRALIDAE INFESTING STORED-PRODUCTS

P. Trematerra

Dipartimento di Scienze Animali, Vegetali e dell'Ambiente, Università degli Studi del Molise, Campobasso, Italy

Research on moth sexual behaviour has focused primarily on female pheromones and male behavioural responses to them. Although several researches on moth sex pheromones have demonstrated that the complete sequence of courtship behaviour also involves male pheromones and other types of communication, relatively little work has been done on the connection between pheromones and extrusible organs or with sound production.

Many insects have airborne sound receptors, which function primarily in intraspecific communication whilst in others hearing serves to warn of the potential threat of a predator.

Certain pyralid moths infesting stored food, such as the Galleriinae *Achroia grisella* F., *Galleria mellonella* L. and *Corcyra cephalonica* (Staint.), and the Phycitinae *Ephestia cautella* (Walker), *Ephestia kuehniella* Zeller and *Plodia interpunctella* (Hübner) have acquired the additional ability to generate sounds by wing-fanning for intraspecific communication and pair forming.

The courtship of these Lepidoptera Pyralidae has been examined and several studies have been made on the male orientation to the pheromone produced by the calling female and also on the behaviour of the male after the female has been located.

The paper gives details on the role of ultrasound production in the courtship behaviour and discusses the role of other signals in pair forming.

18-066

SURVEILLANCE OF MOTH SPECIES (PHYCITINAE) ON STORED DATES IN MOROCCO BY MEANS OF PHEROMONE TRAPS

A. Boughdad, M.T. El Abbassi

Département de Zoologie Agricole, E.N.A. B.P.S/40 Meknès, Maroc

In an attempt to monitor the moth species (Phycitidae, Phycitinae) infesting stored dates, adhesive pheromone-baited (TDA) traps (Detia Ltd., Germany) were set up in a store comprising dates of the variety "Khalt" in Zagora (southern Morocco) from February through August 1992. Four species of Phycitinae were trapped: *Cadra cautella* (Walker), *C. calidella* (Guénéé), *Plodia interpunctella* (Huebner) and *Ectomyelois ceratoniae* (Zeller). Those species represent 22.2, 35.8, 38.3 and 3.6 % of 720 moths caught on pheromone traps, respectively. The pheromone traps caught 77.5 % of the total catch, being males only. The unbaited adhesive traps (control) merely caught 22.5 % of the total catch, i.e. 97 male and 65 female moths. There was a close correlation between moth trapping and ambient temperature (ranging from 15 to 36°C).

E. ceratoniae was more common in the field than indoors, whereas *C. cautella*, *C. calidella* and *P. interpunctella* were mainly caught indoors. Three successive generations of the latter occurred between March and July.

Observations made on laboratory cultures of the above species revealed a close correlation between the time of moth flight and onset of infestation, i.e. oviposition on stored dates. Appropriate periods of date protection against phycitid infestation are thus end of March, first decade of May and /or end of June, in accordance with the trapping data.

Since the consumer rejects any infested date, economic loss is equivalent to the infestation rate, regardless of the number of larvae per date.

18-065

PHEROMONES OF STORED-PRODUCT INSECTS AND THEIR POTENTIAL IN PEST MANAGEMENT

P. Trematerra

Dipartimento di Scienze Animali, Vegetali e dell'Ambiente, Università degli Studi del Molise, Campobasso, Italy

The use of pheromones, is one of several modern techniques that show promise in controlling stored-product insects, their utilization may lead to a drastic reduction of chemical treatments with consequent economic and qualitative advantages. Goods may be protected from possible pesticide residues and thus improve the image of the company's products.

Considerable progress has been made in recent years in monitoring and control of stored-product insects by using mass trapping, mating disruption and attracticide (lure and kill) methods.

Good results can be obtained by the use of the pheromones together with careful cleaning of the rooms, particularly in the corners and, above all, inside machinery. This procedure eliminates the possibility of insect reproduction in areas where food is present.

In the case of complex infestations, where more than one species of moth or beetle is involved, treatments which use only pheromones become complex and are not effective. Integrated treatments which use different technical means, not excluding chemicals achieve better results.

An important role should be assigned to all prevention techniques which effectively keep infested goods out of food-processing plants, mills, storehouses, etc..

18-067

EICOSANOIDS AS MEDIATORS OF CRITICAL PHYSIOLOGICAL FUNCTIONS IN INSECTS

R.W. Howard, D.W. Stanley-Samuelson¹

USDA-ARS, 1515 College Ave., Manhattan, KS 66502 USA

¹Insect Biochemistry/Physiology Laboratory, Department of Entomology, University of Nebraska, Lincoln, NE 68583-0816 USA

Eicosanoids are oxygenated metabolites of 20:4n-6 and two other C20 polyunsaturated fatty acids (PUFAs). These compounds are crucial mediators of many cellular events in humans and other vertebrates; their significance in insects and other invertebrates is now gaining increased recognition. Eicosanoids exert important actions in reproductive and thermoregulatory behavior of some insects. They also mediate cellular immune reactions and water and ion transport physiology in all insects so studied. Of particular interest in this symposium, we have identified two crucial eicosanoid actions in stored grain beetles.

First, eicosanoids mediate nodule formation in response to bacterial infections in larvae of the tenebrionid beetle, *Zophobas atratus*. Nodule formation is the major cellular immune reaction to bacterial infection in insects. We found that treating the insects with eicosanoid biosynthesis inhibitors prior to infections impaired the insects' ability to form nodules. Nodulation could be restored by subsequent treatment with eicosanoid-precursor PUFAs.

Second, we detected these PUFAs and prostaglandin E₂ in Malpighian tubules of the mealworm beetle, *Tenebrio molitor*. Based on findings in mosquitoes, prostaglandin E₂ probably regulates Malpighian tubule function in *T. molitor*. These results open wide the possibility of developing novel and insect-specific inhibitors that can impact insects during crucial stages of their life cycle.

18-068

JUVENILE HORMONE IN COCKROACHES: A MULTI-FUNCTIONAL TARGET SITE IN PEST CONTROL

C. Schal, G.L. Holbrook and V.L. Sevala

Department of Entomology, North Carolina State University, Raleigh, NC USA

Juvenile hormone analogs (JHAs) have proven to be effective materials for cockroach control. They disrupt development by interfering with the transformation of the last instar nymphs to adults, resulting in sterile adults. In addition to governing the molt cycle, JH also plays a central role in female reproduction, including vitellogenin synthesis and uptake by oocytes, pheromone production, sexual receptivity, ootheca production, and the pattern of feeding. Using *Blattella germanica*, we have studied environmental signals that affect corpora allata (CA) activity, including social interactions and food quality and quantity. Internal physiological factors, such as the ovaries and signals associated with copulation also affect JH synthesis by the CA. Pregnancy in *Blattella* requires a period of low JH titer. We reasoned that application of high levels of JHAs might increase the frequency of abortions in gravid females. Removal of feeding inhibition, caused by removal of the ootheca, together with high levels of JHA, should further stimulate the previously gravid female to feed. We thus hypothesized that this strategy might increase the fraction of feeding females in a cockroach population, and therefore should increase the efficacy of insecticidal baits.

This novel strategy was tested both in the laboratory and in the field (120 homes). JHAs effectively enhanced the efficacy of insecticidal baits in both situations. As the rate of development of new insecticides declines, enhancing the efficacy of available insecticides will become an important tactic in urban pest management. Research into the basic biology (ecology, physiology, behavior) of pest species will guide such new strategies.

18-070

DISTRIBUTION OF *DERMATOPHAGOIDES* MITE ANTIGENS IN HOMES AND PUBLIC FACILITIES IN JAPANE. Konishi¹, K. Uehara^{1,2}

1 Department of Medical Zoology, Kobe University School of Medicine, Kobe, Japan, 2 Chemicals Division, Shinto Paint Co., Ltd., Osaka, Japan

Study on contamination of *Dermatophagoides* mites in human environment is important for prevention of sensitization and therapy of mite allergic patients. In order to show the current hygienic situation in Japan, we have surveyed distribution of mites in homes of allergic patients and non-allergic people, as well as public facilities, such as hospitals, hotels, ryokans, offices and movie theaters. Dust samples were collected mainly from floors and bedclothes, and examined for mite antigen levels by an enzyme-linked immunosorbent assay. The antigen detected by this method is characterized as a protein with a molecular weight of 180 kDa and distributed in most parts of the mite body. The results of survey among homes indicated that patient homes had higher antigen levels than control homes in comforters and pillows but not in futons, carpets, tatamis, and wooden floors. Samples with antigen levels of ≥ 10 ug/m² were more frequent in and around summer than other seasons of the year in most materials. Wooden structures showed higher antigen levels than concrete structures in comforters, pillows, carpets and tatamis in patient homes. The results of survey among public facilities indicated that clinically important antigen levels of ≥ 50 ug/m² were detected in 71% of samples from seats in a movie theater and 42% of samples from tatamis of guest rooms in two ryokans, whereas such a serious mite contamination was not observed in samples from offices and a hotel. Sickrooms of hospitals had antigen levels of ≥ 50 ug/m² in 2% of mattresses and 6% of painted and tiled floors but not in comforters, futons and pillows. Different antigen levels in these facilities suggested that low humidity conditions, regular cleaning of floors, and regular exchange of sheets or covers for bedclothes are effective to keep mite levels low.

18-069

CROSS-ALLERGENICITY OF THE HOUSE DUST MITES *EUROGLYPHUS MAYNEI* AND *BLOMIA TROPICALIS*L.G. Arlian, M.S. Morgan, E. Fernandez-Caldas¹Department of Biological Sciences, Wright State University, Dayton, OH USA and ¹CBF Leti S.A., Madrid, Spain

The domestic mites *Euroglyphus maynei* (EM) and *Blomia tropicalis* (BT) frequently co-inhabit homes in subtropical/tropical regions around the world. Both species are the source of substances that cause allergic reactions in patients. The purpose of this study was to examine the immunologic cross-reactivity between EM and BT.

Sera of 19 mite-sensitive patients who were skin test positive to BT and/or RAST positive to EM were used to probe immunoblots or crossed radioimmuno-electrophoresis (CRIE) gels. Western blotting showed that individual sera had IgE that bound to 0-17 and 2-15 proteins in EM and BT extracts, respectively. Corresponding IgE-binding proteins of 105, 75, 57, 18 and 14 kD were detected in both EM and BT extracts. The majority of IgE-binding proteins did not show corresponding bands in both extracts. Heterologous CRIE showed IgE binding to 6 of the 9 EM antigens precipitated by anti-BT serum with individual sera recognizing 0-4 of the 6 allergens. In the reciprocal reaction, 10 of the 12 proteins of BT that were precipitated by anti-EM serum bound IgE with individual sera binding to 0-5 proteins.

This study indicated that EM and BT are the source of both species-specific and cross-reactive allergens, but most allergens in each extract were species-specific.

18-071

BRONCHIAL ASTHMA DUE TO SENSITISATION TO STORAGE MITES.

RESULTS OF A MULTICENTER STUDY IN GERMANY

Rolf F. Kroidl¹, E. Frank², in behave of the WATL³.

1 Stade, Germany 2 Allergopharma Joachim Ganzer KG, Reinbek, Germany 3 WATL Wissenschaftliche Arbeitsgemeinschaft für die Therapie von Lungenkrankheiten e.V. (Cooperative study group for therapy of lung diseases), Germany

This study describes clinical and allergological data from 90 patients, living in different regions of Germany. They were asthmatics, with relevant allergy to storage mites and / or house dust mites. Diagnosis based on clinical and allergological examinations, including bronchial challenge tests. Environmental conditions (at work places and in the homes) are described in detail. A total of 151 bronchial challenge tests were performed. The result is as follows

Allergen	Total no of pat.	No of positive	No of negative results.
Lepidoglyphus	43	31	12
Acarus siro	38	16	22
Tyrophagus	24	12	12
D. pteron.	46	22	24

The overall prevalence of allergy to storage mites in the general population is calculated with 5%, this is half of the estimated prevalence to house dust mites. 42 from the total of 90 patients were farmers, 5 patients worked with grain or flour, 7 with woods or with paper dust. 36 had not such work place. Thus, allergies to storage mites are also encountered in the „normal population“.

18-072

DENSITIES OF *LEPIDOGLYPHUS DESTRUCTOR* AND LEVELS OF ITS MAJOR ALLERGEN Lep d 1 IN GRAIN AND FLOUR

L. Stengård Hansen¹, C. Herling², C. Danielsen¹
1: Danish Pest Infestation Laboratory,
Ministry of Agriculture and Fisheries, Lyngby, Denmark.
2: Gentofte University Hospital, Gentofte, Denmark

Allergic Danish bakers display positive reactions in skin prick tests to several stored product pests even though no correlation to the development of allergic symptoms could be determined. The possibility of developing serious allergies following exposure to stored product pests is considered a potential risk to the health of workers involved in grain and flour handling.
The correlation between the presence of stored product pests and levels of a major pest allergen in samples of grain (wheat) and flour for human consumption was investigated. 1600 samples were collected from grain stores after different lengths of storage and from flour mills before and after the milling process. Extent of pest infestation was determined. The levels of the major allergen Lep d 1 deriving from the grain mite *Lepidoglyphus destructor* (Acarina: Glycyphagidae) was determined by means of ELISA; antibodies were supplied by Dr Ventas and Dr Polo, ALK-ABELLÓ, Spain.
In laboratory samples with mites added, the correlation between the mite density and the Lep d 1 level was good. Densities of *Lepidoglyphus destructor* were generally low in the collected samples, possibly due to warm and dry weather during harvest in 1994 and 1995. As a consequence, the Lep d 1 levels were also low, in most cases below the background level. Other mites species were more abundant; allergen levels deriving from these pests will be determined, if possible.

OCCUPATIONAL ALLERGIC PATHOLOGY INDUCED BY *TETRANYCHUS URTICAE* IN FARM WORKERS.

C. Astarita.
Laboratorio di Immunopatologia, Clinica Medica, Dipartimento di Internistica Clinica e Sperimentale "F. Magrassi" - Naples Second University Medical School - Naples - Italy.
Over the last 3 years a seasonal, occupational syndrome has been observed in a group of farm workers featuring rhinitis coupled mostly with bronchial asthma and urticaria or recurrent dermatitis on the hands (1,2). Since this syndrome had remained "undetermined" after standard and usual specific professional allergic diagnostic trial, the possible etiologic role of *Tetranychus Urticae* (TU), a macroscopic mite ubiquitous to warm climate commonly known as "red spider", has been investigated. Skin prick test, serum IgE dosage and different types of epicutaneous tests were performed with a TU-whole body extract prepared in our laboratory. This specific diagnostic trial allowed a definite diagnosis of TU-induced allergic or immune-mediated disease in 43 out of the 56 patients examined. Moreover, an epidemiological pilot study on unselected farm workers has shown a 2.5% cumulative prevalence of TU-induced sensitization and a 1.0% prevalence of TU-induced immune-mediated diseases.

DOMESTIC MITES AS A CAUSE OF ALLERGIC DISEASES; A METHOD FOR MANAGEMENT IN THE HOME ENVIRONMENT.

F.M. Knies¹, K.-U. Blank¹, E.R.C. Bischoff²
¹ Allergopharma J. Ganzer KG, Research-Prevention, Reinbek, Germany; ² Kirchheim-Boland, Germany.

Domestic mites such as *Dermatophagoides* spp. are major producers of allergens, which are responsible for mite allergic diseases, like asthma.
The first step in mite-management is detection of the source of these allergens. In the home environment the detection of a nitrogeous waste-product of the mites -guanine- with the aid of a dip-stick is the method of choice for the laymen. A good correlation exists between guanine and mite-allergens ($r=0.56$), but not between mites and guanine ($r=0.17$). Mite-infested objects should be treated in such a way that either the mites are killed and the old allergens are removed, or the mites as well as allergens are immobilized by the use of mite- and allergen-tight encasings.
The use of such methods in a double-blind placebo-controlled clinical study demonstrated that mite-reduction was near 100% and allergen-reduction was over 50% within 1 year after treatment. Subjective and objective data were showed significant improvements in the active group compared with the placebo-group (symptomscore 47%; $p=0.025$ and total IgE 38%; $p=0.0049$). A further treatment is necessary once or at most twice a year depending on the level of infestation. An expansion of this mite-management system with a method to prevent reinfestation of mites would optimize this already practical concept.

18-075

WATER BALANCE OF THE HOUSE DUST MITE *DERMATOPHAGOIDES PTERONYSSINUS* (ACARI; PYROGLYPHIDAE) IN DIURNALLY FLUCTUATING AIR HUMIDITY

R. de Boer & K. Kuller
University of Amsterdam, Section Population Biology
Kruislaan 320, 1098 SM Amsterdam, The Netherlands

House dust mites are able to extract water vapour from the air, but only if the relative humidity (RH) is above a certain minimum. This minimum RH-value is called the 'Critical Equilibrium Humidity (CEH)'. We studied the RH and temperature on carpeted floors and in the core of mattresses, where house dust mites live. In these microclimates the RH is commonly below the CEH during most of the day and above it for only a few hours. In a separate experiment we examined how many hours per day the RH must be above the CEH for the mites, to maintain water balance. It was found that a daily period of elevated humidity ($>CEH$) lasting 1 1/2 hours; strongly promotes the survival of a population and that 3 hours above the CEH enables the mites to produce some eggs.

18-076

HOUSE DUST MITES AND STORAGE MITES IN HOMES OF PEOPLE LIVING IN AGRICULTURAL SETTLEMENTS IN ISRAEL

K.Y. Mumcuoglu,¹ Z. Gat,² J. Miller,¹ T. Horovitz,² A. Ben-Zvi,³ Y. Naparstek³

¹Dept. of Parasitology, Hebrew University-Hadassah Medical School, Jerusalem, ²Israel Meteorological Services, Beit Dagan and ³Clinical Immunology and Allergy Unit, Hadassah Medical Center, Jerusalem, Israel. The correlation between climatic conditions and mite numbers in houses from rural areas was studied. Houses from 13 agricultural communities (kibbutzim and moshavim) in seven geo-climatic areas of Israel, i.e., the coastal region, Samaria-Judean foothills, high mountains, low mountains, Negev desert, northern valleys and central Jordan valley were randomly chosen for examination. A mattress, carpet and sofa were examined in each house. A total of 195 dust samples was collected with a vacuum cleaner during July and August 1995. In addition, two houses from Zova, a kibbutz in the mountains of Jerusalem, and two houses from Palmachim, a kibbutz in the coastal region, were chosen for monthly sampling throughout the year. Mites were present in 97% of the dust samples. The average number of mites per gram of dust in the different localities ranged between 84 and 2,053. Most of the mites were isolated from the carpets and sofas (37.0% and 33.7%, respectively), and less from the beds (29.3%). The maximum number of mites (7,440/g dust) was found from a carpet from Geva Carmel in the coastal region. The most prevalent species of mites were *Dermatophagoides pteronyssinus* and *Dermatophagoides farinae*, found in 85.6% and 71.3%, of the samples, respectively. The house dust mites (*D. pteronyssinus*, *D. farinae* and *Euroglyphus maynei*) constituted 94.8% of the mites. Storage mites of the sub-order Astigmata (*Blomia*, *Acarus*, *Gohieria*, *Tyrophagus*, and *Rhizoglyphus*), Mesostigmata, Cryptostigmata and Prostigmata constituted 5.2% of the mite fauna. These findings are not significantly different from those of an urban environment. The relationship between mite numbers and climatic conditions, in particular temperature and humidity, will be analysed statistically. The seasonality of the mites in the areas examined, will be discussed.

18-078

RECENT PROGRESS IN BIOLOGICAL CONTROL OF STORED FOOD MITES.

E.Žďárková

Department of Stored Product Pest Control, Research Institute of Crop Production, Prague, Czech Republic

Biological control which has been developed and proven effective against mites of stored grain and seed is the only biological control method practically used in the stores.

The predator used is *Cheyletus eruditus*, a predatory mite that is commonly found in stores.

Biological control can be used as a preventive measure in empty stores and to prevent or repress pest populations on grain or seed

The predator has lower susceptibility to insecticides than its prey. Differences in susceptibility to insecticides were also found among different strains of *Cheyletus eruditus*. A long-established laboratory strain was most susceptible. A strain, which survived exposure to of PH₃ most resistant. Low susceptibility was also found in strains from the field and from the grain stores. A population of *Cheyletus eruditus* resistant to low temperature was selected. The development of these predators at 12°C is 4 times longer than at 25°C.

RECENT PROGRESS ON RESEARCH CONCERNING SEX PHEROMONE IN ASTIGMATID MITES

Y. Kuwahara, N. Mori

Pesticide Research Institute, Faculty of Agriculture, Kyoto University, Sakyo-ku, Kyoto 606-01, Japan

The female sex pheromones (produced by females and functioning as con-specific male's sexual excitant) have been identified in following four species of genus *Caloglyphus*, including two unidentified; sp. 1, *C. polyphyllae*, *C. rodriguezi* and sp.2, as (2R, 3R)-epoxyneral, β-acaridial, undecane and rosefuran., respectively. These compounds were, however, commonly distributed not only in females, but also in con-specific males and, in extreme cases, also detectable in nymphal stages. In order to understand those phenomena rationally, contents among sexes and developmental stages, and male behavior against both sexes were compared among four species.

Content ratio of female to male varied from 1.4 (sp. 1), 3.4 (*C. polyphyllae*), 6.3 (*C. rodriguezi*) to 8.4 (sp. 2). In nymphal stages of the sp. 1 and *C. polyphyllae*, their pheromone were detectable as a major component, while trace amount in the other two species. Evaluation of male's ability to recognize conspecific females revealed that males of all three species except the sp. 1 could discriminate between females and males.

As a result, the mite sex pheromone was suggested to have evolved from a common compound functioning as male's sexual excitant into the sex linked specific one with biological activity.

18-079

MANAGEMENT OF TERMITE PROBLEMS IN BUILDINGS - CURRENT PRACTICES AND TRENDS IN AUSTRALIA

M. Lenz

CSIRO Division of Entomology, GPO Box 1700, Canberra ACT 2601, Australia

The ban on using organochlorines for termite control in Australia since 1 July 1995 has greatly enhanced the development of alternative strategies for the protection of buildings from subterranean termites. A greater diversity of control measures is now available or under development in Australia than in most other countries with termite problems.

Prevention of termite infestations is achieved with:

(1) Physical barriers: Two systems, using stainless steel mesh or graded stones, incorporated into the Australian Standard on termite control; a number of other materials is currently assessed for their suitability in forming effective physical barriers to termite entry.

(2) Chemical barriers: One organophosphate (chlorpyrifos) and one synthetic pyrethroid (bifenthrin) with various registered applications. Other chemicals, such as the novel compound imidachloprid, still under evaluation. Chemicals can either be applied directly to the soil or for slab-on-ground constructions also via a number of reticulation systems. Chemical barriers can also be formed by applying the compounds to other carriers than soil, such as a fibrous blanket or plastic materials.

Control of existing infestations can be achieved by locating and destroying termite nests; dusting termites and their workings with arsenic trioxide (often in conjunction with trap-and-treat systems); and by the establishment or re-establishment of chemical soil barriers. Under evaluation are alternative dusts, a range of bait-systems (matrix + slow-acting, non-repellent toxin) and the use of biological control agents (especially the fungus *Metarhizium anisopliae*). Developments in termite management in Australia focus increasingly on design of buildings and use of resistant materials ("building-out" termites), safer application of chemical barriers, trap-and-treat and bait systems, use of pathogens, and the integration of different control strategies.

18-081

RESPONSE OF DIFFERENT SPECIES OF INSECTS TO MIXTURES OF CARBON DIOXIDE AND/OR NITROGEN IN AIR

M.Y. Hashem¹ and Ch. Reishmuth²

¹ Dept. of Econ. Entomology, Fac. of Agric., Cairo Univ., Giza, Egypt.

² Institut für Vorratsschutz, Biologische Bundesanstalt für Land-und Forstwirtschaft, Berlin, BRD.

Exposure of different species of insects to 60% CO₂ in air and mixture of 98% nitrogen and 2% oxygen enables a quicker kill to adults (after 2 to 3 days) than does exposure to mixture contained 40% CO₂ in air.

These species are: *Oryzaephilus surinamensis*, which is more tolerant than *Q. mercator*, *Tribolium confusum* is slightly tolerant than *T. castaneum*, *Trogoderma inculsum* is tolerant than *T. grasmani*, *Dinoderus*

porcellus and *D. bitoveolatus* are very sensitive at 60% CO₂ in air and 98% N₂, but at 40% CO₂ in air needs more than 5 days to gain 100% kill of their adults.

These results are due to the relative order of susceptibilities of different insect species to the depletion of oxygen in the mixture.

18-080

METARHIZIUM ANISOPLIAE AS A MYCOTERMITICIDE - LABORATORY BEHAVIOURAL BIOASSAY

J.A. Staples, R.J. Milner, M. Lenz

CSIRO Division of Entomology, GPO Box 1700, Canberra ACT 2601, Australia

The insect pathogenic Hyphomycete fungus *Metarhizium anisopliae* is a promising biological insecticide for the major pest species of subterranean termites in Australia. The infectious green conidia are mass-produced by solid-state fermentation on rice and the pure dry conidial formulation can be used for control in a number of ways. One promising method is by direct application to kill colonies of mound and tree nesting termites. While inundative application directly to termite nest colonies in mounds or in trees has been shown to be highly effective, indirect control of colonies by treatment of termite feeding sites has been shown to have variable results due to the ability of termites to detect the fungal spores. A laboratory bioassay to measure the relative repellency/attractancy of different baits or bait matrices based on termite tunnelling activity is described. The assay also allows determination of the degree of inhibition of repellency by adding varying amounts of other behaviour-modifying components, or synergists. This assay has been used to study the effects of different strains or isolates of *Metarhizium*, different concentrations and age of conidia, and the addition of various bait matrix components, on tunnelling response of termites. Such data are important to development of baiting systems for termites, which may incorporate pathogens, insect growth regulators, slow toxicants, or combinations of any of these as the main control agent, together with attractants.

BOOTSTRAP SIGNIFICANCE TESTS FOR A BIOLOGICAL CONTROL EXPERIMENT USING THE MARKOV-RECAPTURE ESTIMATE

E.P. Wileyto¹, and D.K. Weaver².

¹ School of Veterinary Medicine, University of Pennsylvania, New Bolton Center, Kennett Square, Pennsylvania, USA - 2 USDA, ARS, Insect Behavior, Ecology, and Reproduction Research Laboratory, Gainesville, Florida, USA

This paper presents the development of a parametric bootstrap significance test used in the analysis of replicated Markov-Recapture results, which were used to monitor an experiment on augmented biological control of *Sitotroga cerealella* in bulk stored corn. Six 10,000 bushel grain bins were inoculated with *S. cerealella*, and three of those inoculated later with the parasitoid *Pteromalus cerealellae*. Markov-Recapture was used to estimate the host populations weekly. The test statistic was the difference between group averages. Population size was first estimated for the *i*th bin (\hat{N}_i), and empirical capture probabilities used to reassign each estimated population \hat{N}_i into capture categories to form each bootstrap replicate. Estimation was performed again using replicates from each bin, and the difference between the group averages noted. The test was considered significant when a difference of 0 fell into the tails of the distribution of group differences. Simulations were performed to examine the power of the significance test. The test was reasonably powerful for the range of data noted in the actual experiment.

18-083

TIME-COURSE MORTALITY AND RADIOSENSITIVITY INDICES IN IRRADIATED *TRIBOLIUM* SPP.

M. M. Hasan

Department of Agricultural and Environmental Science
University of Newcastle upon Tyne
NE1 7RU, United Kingdom

Effect of gamma irradiation (Cobalt⁶⁰) on the time-course mortality and radiosensitivity indices in adult (1- and 10-days old) *Tribolium* spp. (*T. anophe*, *T. brachycornis*, *T. castaneum*, *T. destructor*, *T. freemani*) was studied. Investigation showed that the longevity was always adversely affected as result of irradiation of 1- and 10-days old adults and was linearly dependent on the dose rate. It also showed that most of adults died within 12 weeks of irradiation at 4- and 5-krad except for 10-days old irradiated adults. In addition, *T. destructor* was markedly more radioresistant than were the other species at all dose levels and had a longer life expectancy. The mean survival times of adults were shorter in female than in the males in most cases for all the species. The radiosensitivity indices did not vary widely among the species and these values decreased as the dose increased in all the species which clearly indicate that the resistance of the species is dose-dependent.

18-084

CROSS-RESISTANCE IN STRAINS OF *RHYZOPERTHA DOMINICA* (F.) (COLEOPTERA: BOSTRYCHIDAE) AND CHANGES IN INSECTICIDE TOLERANCE WITH OR WITHOUT DELTAMETHRIN SELECTION.

I. Lorini & D.J. Galley

Department of Biology, Imperial College, University of London,
Silwood Park, Ascot, UK.

Cross-resistance in deltamethrin resistant strains of *Rhyzopertha dominica* was evaluated with three insecticides used also in stored grain to control pests, permethrin (pyrethroid), pirimiphos methyl and chlorpiriphos methyl (organophosphates). Deltamethrin was used as standard. Ten strains from Brazil (BR1, BR2, BR3, BR4, BR5, BR6, BR7, BR8, BR9 and BR10) were used and one laboratory strain from Imperial College at Silwood Park (UK1). BR4 and UK1 were susceptible and BR6 and BR7 had shown high resistance to deltamethrin. The other strains had intermediate resistance to that insecticide. Changes in tolerance in five of these strains (BR4, BR2, BR6, BR7 and UK1) when exposed or not to selection with deltamethrin at each generation were investigated. The selection like the bioassays was carried out on filter paper, the survivors were cultured and selected again at the next generation. At every third generation adults were bioassayed against deltamethrin. The LD₅₀ of each strain was determined and resistance ratios calculated. The results showed that cross-resistance to permethrin existed in strains BR6 and BR7 strains, but no clear evidence of cross-resistance to pirimiphos methyl or chlorpiriphos methyl was found in any of the strains tested. In the selection experiments, resistant strains reared without selection decreased in their susceptibility while susceptible ones were not changed. Also selected strains changed in their tolerance to this insecticide.

18-085

INSECTICIDE RESISTANCE IN *RHYZOPERTHA DOMINICA* (F.) (COLEOPTERA: BOSTRYCHIDAE) INFESTING STORED GRAINS IN BRAZIL.

I. Lorini & D.J. Galley

Department of Biology, Imperial College, University of London,
Silwood Park, Ascot, UK.

The failure to control *Rhyzopertha dominica* (F.) in Brazil was recorded by the first author in many storage units where the insecticide deltamethrin was used repeatedly to protect grains. Samples from these and other pest-populations were taken to investigate their tolerance. Ten strains from Brazil (BR1, BR2, BR3, BR4, BR5, BR6, BR7, BR8, BR9 and BR10) and one laboratory strain from Imperial College at Silwood Park (UK1), were bioassayed on filter paper against deltamethrin (K-otec 25 EC). Another series of bioassays were carried out on some of the strains (BR4, BR2, BR6 and BR7 and UK1) where adults were bioassayed in each one of four age ranges (1-10, 11-20, 21-30 and 31-40 days after emergence). Eggs collected from untreated individuals in each group were reared through to adulthood and these assayed also 10 days after emergence. The LD₅₀s were determined and resistance ratios calculated. The results showed two strains, BR4 and UK1, were the most susceptible and these were taken to represent the normal tolerance level of this species to deltamethrin. Two strains, BR6 and BR7, showed high resistance factors of 105 and 700 respectively. The other strains, BR1, BR10, BR5, BR8, BR2, BR9 and BR3 exhibited a range of resistance factors up to 74 times greater than the most susceptible strain. There were no statistical differences among the age groups in all the strains tested and also no significant differences between the progeny from each age group. These results mean that comparable data may be achieved with populations of differing age structure and that the susceptibility of the progeny was also independent of parental age.

18-086

POTENTIAL BIOLOGICAL CONTROL OF BRUCHIDS INFESTING STORED DRIED LEGUMES WITH THE GENERALIST PREDATOR *XYLOCORIS FLAVIPES* (REUTER) (HEMIPTERA: ANTHOCORIDAE)S. Sing^{1,2}, R.T. Arbogast¹, J.H. Brower³, R.K. Stewart²

1 USDA-ARS, Insect Attractants, Behavior and Basic Biology Research Laboratory, Gainesville, FL USA -2 Department of Natural Resource Sciences, McGill University, Montreal, PQ, Canada -3 USDA-ARS, U.S. Grain Marketing Research Laboratory, Manhattan, KS, USA

F₁ emergence of the pest Bruchidae *Callosobruchus maculatus* (Fabricius), *Callosobruchus chinensis* (Linnaeus), *Callosobruchus analis* (Fabricius), *Zabrotes subfasciatus* (Boheman), and *Acanthoscelides obtectus* (Say) infesting the common bean *Phaseolus vulgaris* (L.), chickpea *Cicer arietinum* (L.), and cowpea *Vigna unguiculata* (L.) Walp. was significantly reduced by the presence of *Xylocoris flavipes* (Reuter) in test arenas. Both predator density and predator introduction time impacted the number of emerging F₁ bruchids.

Suppression of pest bruchids was enhanced by the combined treatment of *Xylocoris flavipes* and various strains and species of the pesticide-resistant and pesticide-susceptible hymenopteran larval parasitoids *Anisopteromalus calandrae* (Howard), *Pteromalus cerealellae* (Ashmead), and *Choetospila elegans* Westwood. Biocontrol efficacy of a pesticide-susceptible laboratory strain of *Xylocoris flavipes* was not significantly different from that of the pesticide-resistant field strain of the predator.

18-087

STUDY ON A NEW METHOD CONTROL RETICULITERMES DAMAGES BUILDING

Liu Xuanjun, Li Weizhong

Yichang Institute of Termite Control, Yichang 443000, China

The method of drilling and putting baits is a new method in control *Reticulitermes* damaging building. The result of control showed 96.58% on yellow chest termite and 100% on black chest termite. The operation process is simple. It can be used in the four seasons of the year. It damages buildings slightly and doesn't make environmental pollution

Key Words:

Reticulitermes, the method of drilling and putting baits

ANTI-INVADING METHODS AGAINST GREGARIOUSLY OVER-WINTERING STINK BUGS IN JAPANESE HOUSES

M. Watanabe¹, R. Arakawa² and Y. Shinagawa¹¹ Toyama Institute of Health, Kosugi, Toyama, Japan² Laboratory of Applied Entomology, Faculty of Agriculture, Kouchi University, Nankoku, Kouchi, Japan

A great number of stink bugs, mainly *Halyomorpha halys* and *Menida scotti*, gathered to invade the buildings at the many mountainous areas of Japan in every year. For their bad smell giving out they are disliked as nuisance at the hotels, schools, offices and dwelling houses. From 1988 we have been studying the biology of coming-fly and control of these house-invading stink bugs at some mountainous areas in Toyama Prefecture, central part of Japan.

House-invading activities of *H. halys* began in late September and ended in late November. The peak flight activity of *H. halys* was observed on mid-October at the altitude of 300 m. *M. scotti* gathered around the buildings later than *H. halys* and the peak activity was observed on early November at the altitude of 600 m. The "slit-trap" was proved to be effective as an attractant for these bugs. The application of concentrated cyphenothrin or repellent (deet) to window frames was effective to prevent the invasion of these bugs. Covering by cyphenothrin-treated nets over the wooden houses was also effective.

18-089

THE PESTICIDAL EFFECT OF SOME SELECTED BOTANICALS ON REDUCING INFESTATIONS BY CALLOSOPRUCHUS SPECIES

Rohan Rajapakse

Department of Agricultural Biology

University of Ruhuna, Mapalana, Kamburupitiya

Sri Lanka.

Callosobruchus maculatus (bruchid beetle) is a serious insect pest of grain legumes in Sri Lanka along with *Callosobruchus chinensis*. In an investigation to explore the possibility of using botanicals, it was found that *Cymbopogon citratus* (L.), *Cinnamomum camphora* (L.) and *Monodora myristica* (L) significantly lowered egg hatchability of two *Callosobruchus* species. No Plant powder was effective in controlling the adults. The current status of affairs of using botanicals to manage *Callosobruchus* is reviewed.

18-090

BIOACTIVITY OF POWDERS FROM SOME PLANTS ON *ZABROTES SUBFASCIATUS* (BOH.) (COLEOPTERA: BRUCHIDAE)

J.D. Vendramim, S.O. Procópio

Departamento de Entomologia, ESALQ, Universidade de São Paulo, Piracicaba-SP, Brasil.

The repellency, oviposition and survival of the Mexican bean weevil, *Zabrotes subfasciatus* (Boh.) were evaluated under laboratory conditions with bean grains treated with powders obtained from fruits of neem (*Azadirachta indica*) and pepper (*Capsicum frutescens*); from leaves of eucalyptus (*Eucalyptus citriodora*), chinaberry (*Melia azedarach*) and castor bean (*Ricinus communis*); and from a mixture of leaves, flowers and fruits of the Mexican tea (*Chenopodium ambrosioides*). Each powder was mixed with bean grains and kept in a small plastic box (6 cm diameter). The repellency of the powders was determined in a double choice experiment between treated (0.3 g of powder per 10 g of bean) and untreated boxes (only beans) kept in an arena. The number of individuals in each treatment was evaluated 24 h of insect release. The oviposition and survival were evaluated by infesting 5 couples of *Z. subfasciatus* (1-day old) per recipient (0.6 g of powder per 20 g of bean) for 5 days. Boxes containing only beans were used as controls. The number of live insects and eggs per recipient were counted daily. The most repellent plant species were *E. citriodora* and *C. ambrosioides*, followed by *M. azedarach*. The only treatment that showed significant effect on survival and oviposition of *Z. subfasciatus* was *C. ambrosioides* which caused 100% mortality one day after infestation. The insecticide activity threshold was determined for this plant species; data showed that the bruchid mortality was higher than 90% even at the concentration of 0.075 g of powder per 20 g of bean.

18-091

BUILDING MEASURES AGAINST COCKROACHES

F.E. van Boven, B.G. Wolfs¹, J.E.M.H. van Bronswijk¹, H.L. Schellen¹ and J.B. Dijkstra¹

¹ Eindhoven University of Technology, Eindhoven, the Netherlands

Cockroaches are common pests in buildings around the world. Because of restricted use of insecticides and resistance of cockroaches, building (preventive) measures are becoming more important. A study has been done on building measures to reduce transport and reproduction of cockroaches in bakeries in the Netherlands. The study was limited to the cockroach species *Blattella germanica*, *Blatta orientalis* and *Periplaneta americana*. This study involved a literature investigation and a case study. Dispersal of cockroaches can take place through cracks of 0.5*1 mm². Reproduction is dependent on temperature and relative humidity of the air. Cracks and presence of niches can be reduced by building technology. The reproduction of cockroaches is influenced by physical measures. A statistical model was constructed to relate reproduction from *B.orientalis* to physical variables ($\alpha = 0.05$) and that may be used to evaluate a physical measure. Three bakeries in the Netherlands were investigated. All were infested. The hypothesis based on the investigation reads that infestations take place in the stocks of goods via incoming goods and means of transport. From there, transport take place within the bakery. Building measures based on this hypothesis are:

1. Stocks of goods must be cooled and dried. Transport of cockroaches can be reduced by closing cracks and crevices.
2. In bakeries the presence of niches must be prevented first. Remaining niches must be made accesible for pest control or can be made unsuitable for reproduction by building physical measures. But first cause and development of infestations need to be studied.

A NEW MICROSPORIDIAN PATHOGEN OF *TROGODERMA VARIABLE* (COLEOPTERA: DERMESTIDAE)

R.J. Milner¹, E.J. Wright¹, A. van Leest², A. P. Cartledge¹

¹ CSIRO Division of Entomology, Canberra, ACT, Australia - ² Department of Zoology, Agricultural University, Wageningen, The Netherlands.

Protozoan diseases are commonly found in stored product beetle pests. *Trogoderma* spp. are known to harbour protozoans from the genera *Mattesia*, *Adelina* and *Pyxinia*. A single incidence of an unidentified microsporidan was reported from *T. simplex* in California. No microsporidan pathogen has previously reported from *T. variable*.

Laboratory cultures of *T. variable* that were initiated by insects collected in New South Wales and Western Australia were found to be infected with a microsporidan pathogen. Here we report on a study of its taxonomic status and potential value in biological control.

Features of the life-cycle and the ultrastructure place the organism in the genus *Nosema*. On the basis of host and tissue specificity and features of the spores such as the size, polar filament length and arrangement as seen in thin sections, it was concluded that the present species has not been described previously.

This *Nosema* pathogen is infectious per os, attacks the larval fat body and can substantially reduce the rate of increase of the population. It causes little direct mortality even at doses as high as 10⁷ per g of medium. Sublethally infected adults are readily produced and the infection reduces their fecundity. No evidence of transmission in or on the egg was found.

The fact that the disease can substantially reduce the rate of population increase in *T. variable* suggests a possible role for *Nosema* in biological control. The disease is too slow acting and not sufficiently lethal to be a good microbial insecticide. However, introducing the disease into the general population may be effective in reducing the abundance of the pest within the general environment.

18-092

EFFECTIVENESS OF FOUR ESSENTIAL OILS AGAINST *CORCYRA CEPHALONICA* (St.) (LEPIDOPTERA : PYRALIDAE)

M.C. Bhargava

Department of Entomology, S.K.N. College of Agriculture, Rajasthan Agricultural University, Campus : JOBNER-303329 Distt. Jaipur, Rajasthan, INDIA.

Different concentration of four essential oils viz., geranium oil (*Palogonium graveolens*), palmarosa oil (*Cymbopogon martini*), citronella oil (*C. winterianus*) and lemongrass oil (*C. flexuosus*) were tested against rice moth, *Corcyra cephalonia* Stainton. The toxicity of essential oils against eggs was as lemongrass citronella palmarosa geranium. The calculated LC₅₀ values of different oils for eggs ranged from 0.4741 to 1.9529 per cent. Significant reduction in adult emergence was recorded when newly hatched larvae were developed on treated food with oils. The essential oils had feeding deterrent activity. The weight of food ingested and digested and the weight gained by the test insects were reduced when fed on treated food. The approximately digestibility (AD), efficiency of conversion of ingested food to body substances (ECI) and efficiency of conversion of digested food to body substances (ECD) were also decreased.

18-094

INFESTATION EFFECT OF *Tenebrio molitor* (COLEOPTERA: TENEBRIONIDAE) ON AMINOACIDS CONTENT OF MEAT AND BONE MEAL

R. Q. Vasconcelos¹, M. W. dos Santos¹, S. Favero² & A. E. Eiras².

¹ Lab. de Zootecnia e Nutrição Animal - CCTA/UENF, Campos/RJ, Brasil; ² Lab. de Proteção de Plantas - CCTA/UENF, Campos/RJ, Brasil.

Tenebrio molitor infestation alters the chemical composition and nutritional value of stored products. The present work was aimed to verify the essential aminoacid levels of meat and bone meal submitted to several *T. molitor* infestation levels. Five infestation levels were tested (0, 10, 20, 30 and 40 larvae/ 100g of meat and bone meal), with four replicates each treatment. Two samples of each treatment had aminoacids compositions analysed at the 1st, 30th and 60th day after infestation. The first sample consisted of grounded larvae and meat and bone meal whereas the second sample had the larvae removed from it. The aminoacids studied was methionine, cysteine, lysine, tryptophan, arginine, histidine, phenylalanine, leucine, isoleucine, valine, and threonine. The results showed that the infestation of *T. molitor* changed the aminoacids meat and bone meal content, mainly on the samples with larvae present.

18-095

ACTION OF *Tenebrio molitor* (COLEOPTERA: TENEBRIONIDAE) ON THE MEAT AND BONE MEAL MINERAL CONTENT.

S. Favero¹, R. Q. Vasconcelos², M. W. dos Santos², A. E. Eiras¹ & C. A. da Cruz³. ¹ Lab. de Proteção de Plantas - CCTA/UENF, Campos/RJ, Brasil; ² Lab. Zootecnia e Nutrição Animal - CCTA/UENF, Campos/RJ, Brasil. ³ PESAGRO-RIO, Niteroi/RJ, Brasil.

The present work was aimed to verify the changes on the mineral content of meat and bone meal submitted to several infestation levels of *Tenebrio molitor* larvae. The experiment was carried out with 0, 10, 20, 30 and 40 larvae/ 100g of meat and bone meal with four replicates for each treatment. Calcium, phosphorus and sodium levels were analysed of samples of each treatment at the 1st, 30th and 60th day after infestation. The first sample consisted of grounded larvae and meat and bone meal whereas the second one had the larvae removed from the meat and bone meal. The results showed that the infestation of *T. molitor* changed the meat and bone meal chemical composition, mainly on the mineral value of the highest infestation level.

18-097

THE VARIETAL CHARACTERISTICS OF WHEAT INFLUENCING POST-HARVEST INFESTATION BY *SITOPHILUS GRANARIUS* (COLEOPTERA: CURCULIONIDAE) AND CAUSED LOSSES

Z.Kučerová, V.Stejskal

Department of Stored Product Pest Control, Research Institute of Crop Production, Praguc, Czech Republic

Twenty-eight wheat varieties registered in the Czech Republic were tested under laboratory conditions for their susceptibility to post-harvest infestation by *Sitophilus granarius*. The criteria used were: the number of the F₁ progeny, the duration of development, the dynamics of adult emergence and the weight losses of grain caused by infestation. The factors affecting cultivar susceptibility were studied.

Varieties of best technological qualities were least susceptible to *S. granarius*. The higher tolerance of these cultivars to infestation appears to be connected with their physical and chemical characteristics. Negative correlations between pest progeny production and protein content, vitreousness and hardness of kernels were found. In all varieties, the results fluctuated depending on the year of the harvest.

18-096

INFESTATION EFFECT OF *Tenebrio molitor* (COLEOPTERA: TENEBRIONIDAE) ON NUTRITIONAL VALUE OF MEAT AND BONE MEAL

M. W. dos Santos¹, R. Q. Vasconcelos¹, S. Favero² & A. E. Eiras². ¹ Lab. de Zootecnia e Nutrição Animal - CCTA/UENF, Campos/RJ, Brasil; ² Lab. de Proteção de Plantas - CCTA/UENF, Campos/RJ, Brasil.

The beetle *Tenebrio molitor* is an important pest on stored animal feed such as poultry and swine. The present work was aimed to verify the energy and protein contents of meat and bone meal submitted to several beetle infestation levels. Five infestation were tested (0, 10, 20, 30 and 40 larvae/ 100g of meat and bone meal), with four replicates for each treatment. Energy and protein crude compositions of sample of each treatment were analysed at the 1st, 30th and 60th day after infestation. A sample consisted of grounded larvae and meat and bone meal whereas other one had the larvae removed from it. The results showed that the infestation of *T. molitor* changed the chemical composition and the nutritional value, of the feed. Therefore, the results suggest that infestation of *T. molitor* could be used to increase the protein value of the stored animal feed.

18-098

TRAPPING RESPONSE OF THREE SPECIES OF *TRIBOLIUM* TO VARIOUS WINDOW TRAPS

V. Stejskal, Z. Kučerová

Department of Stored Product Pest Control, Research Institute of Crop Production, Prague, Czech Republic.

The trapping experiments were conducted on *Tribolium castaneum*, *T. confusum* and *T. destructor*, which are the most important tenebrionid pests in stores and households in the Czech Republic. Three commercial types of window traps (Agrisense), i.e. box-shaped sticky traps lured with aggregation pheromone, were tested. Two of these had narrow entry channels.

The traps were more efficient for *T. confusum* than for *T. castaneum*, whereas they were completely ineffective for *T. destructor*. Their efficiency was strongly affected by the competing factors of surrounding environment, alternative food being most important. Two types of trapping rate were observed which were triggered by the presence (linear response) or absence (exponential response) of food in the arena.

18-099

INSECTICIDE RESISTANCE IN *TRIBOLIUM CASTANEUM* AND *TRIBOLIUM CONFUSUM* (COLEOPTERA: TENEBRIONIDAE) IN THE CZECH REPUBLIC

P. Werner

Department of Stored Product Pest Control, Research Institute of Crop Production, Prague, Czech Republic

Field strains of *Tribolium castaneum* (8 samples) and *T. confusum* (3 samples), collected from various storages, bakeries and flour mills in the Czech Republic, were surveyed for resistance to malathion, pirimiphos-methyl, fenitrothion and chlorpyrifos-methyl.

Dose-response test procedure was used (FAO method No. 15, slightly modified). Adult beetles (mostly F₃ generation, 20-30 days old) were confined to an insecticide-impregnated filter paper placed in a Petri dish for 24 hours.

Low-level resistance to four organophosphates was found in almost all field strains of *T. castaneum* (resistance factor >2). The highest resistance observed was the response to pirimiphos-methyl (resistance factor 5 to 23), which is well corresponding with a frequent and long-term usage of pirimiphos-methyl in the Czech Republic. The highest susceptibility was found to chlorpyrifos-methyl: insecticides containing chlorpyrifos-methyl are only used within a few recent years in the Czech Republic.

Low-level resistance to pirimiphos-methyl and to malathion (slightly lower than to pirimiphos-methyl) was found in all three field strains of *T. confusum*, while resistance to fenitrothion and chlorpyrifos-methyl in field strains of *T. confusum* was not significantly higher than in the susceptible laboratory strain.

The results of this study have shown that low-level resistance to various organophosphates, especially to pirimiphos-methyl, is present and widespread in the populations of *T. castaneum* in the Czech Republic.

18-101

DIFFERENCE OF MITE NUMBER AND ALLERGEN IN SUMMER AND WINTER BETWEEN WITH AND WITHOUT PETS (CAT AND DOG) IN A HOUSE

M.Yoshikawa, M.Ogawa¹, K.Kaneko¹, H.Hayashitani¹

Department of Environmental Health, Tokyo Metropolitan Research Laboratory of Public Health, Tokyo Japan
-1 Department of Agriculture, Tokyo University of Agriculture and Technology, Tokyo Japan

Mite numbers and allergens (Der1: allergens derived from feces of *Dermatophagoides pteronyssinus* (Derp1) + *D. farinae* (Derf1)) were compared in houses in Tokyo in summer and winter in which non-pet (A), single pet (cat or dog: B) and plural pets (cats or dogs or both: C) were kept.

In winter, 1994, 30 houses (10A, 10B, 10C) were selected for collecting house dust using a vacuum cleaner. The dust was sieved through 16 and 200 mesh and 0.5g fine dust on 200 mesh was examined by a centrifuging method using saturated NaCl for mite research, while dust was sieved through 48 mesh and 0.1g of fine dust was analyzed for Der1 amounts by an enzyme-linked immunosorbent assay.

There were no significant differences in mite numbers and Der1 amounts between those in houses A and B-C with average mite numbers/0.5g-dust of 980.2 (A), 845.8 (B) and 424.2 (C), and average Der1 amounts of 21.4 µg/g-dust (A), 27.2 (B) and 16.7 (C). Pyroglyphidae occupied 76.3-94.6% of the total mites in houses A-C, although Derp1 had 50.9-84.4% of Der1.

In summer, 1995, 39 houses (14A, 17B, 8C) were examined for mite numbers and Der1 amounts in the same way as in winter. There were no significant differences between those in A and B-C. The average mite number/0.5g-dust was 881.4 (A), 961.1 (B) and 408.9 (C), while average Der1 amount 27.1 µg/g-dust (A), 23.5 (B) and 23.3 (C). Pyroglyphidae and Derp1 accounted for 83.4-93.4% and 67.2-89.7%, respectively.

18-100

TOXICITY AND PROTECTANT POTENTIAL OF MAJOR COMPONENTS OF ESSENTIAL OIL OF THREE *OCIMUM* SPECIES AGAINST STORED PRODUCT COLEOPTERAD. Obeng-Ofori, Ch. Reichmuth, A.J. Bekele¹ and A. Hassanali¹

Federal Biological Research Centre for Agriculture and Forestry, Institute for Stored Product Protection, Berlin, Germany - 1
International Centre of Insect Physiology and Ecology, Nairobi, Kenya

The use of locally-available plant materials to limit insect damage in stored foodstuffs is common practice in traditional farm storage in developing countries. *Ocimum* plants grow widely in India and parts of East Africa and have traditionally been used as insect repellents against mosquitoes. Local farmers also mix stored foodstuffs with dry leaves of these plants for protection against insect pest damage in storage. Essential oil extract was isolated by steam distillation from leaves, inflorescences and succulent stems of *Ocimum kenyense*, *O. suave* and *O. kilimandscharicum* (Labiatae) and analysed by GC-MS techniques and spectral comparison with synthetic standards. 1,8 cineole, eugenol and camphor were identified as the major components comprising 40, 60 and 70% of the total collection, respectively.

The bioactivity of each compound against *Sitophilus granarius*, *S. zeamais* and *P. truncatus* was evaluated in the laboratory by contact toxicity, grain treatment and repellency assays. Each compound applied topically or impregnated on whole wheat and maize grains was highly toxic to the three species. Development of eggs and immature stages of the beetles within grain kernels as well as progeny emergence was completely inhibited in treated grain. Eugenol and camphor were also highly repellent to the beetles with overall repellency in the range of 80-100%. There was, however, highly significant loss of toxicity after only 24 h following treatment.

18-102

VEGETABLE OILS FOR PROTECTION OF PIGEONPEA, *CAJANUS CAJAN* (L.) MILLSP. AGAINST *CALLOSBRUCHUS CHINENSIS* (L.) IN STORAGE ECOSYSTEMS

Shiv K. Singal and J.C. Mahla

Department of Entomology, CCS Haryana Agricultural University, Hisar-125 004, Haryana, INDIA.

Effectiveness of vegetable oils coconut, groundnut, mustard and soybean used at two doses of 5 and 7.5 ml/kg seed as surface protectants of pigeonpea, *Cajanus cajan* (L.) Millsp. against *Callosobruchus chinensis* (L.) was investigated for two years. During both the years pigeonpea seed treated with both doses of all the tested oils resulted in reduced mean per cent seed damage and weight loss at all the testing levels of 2, 4, 6 and 8 months as compared to control. The level of mean per cent damage in the pooled data in coconut, groundnut, mustard and soybean oils was upto the tune of 0.0 to 0.0, 0.0 to 0.0, 0.0 to 0.0 to 2.15 and 0.0 to 8.83% as compared to 30.34, 67.23, 97.83 and 94.40% in control after 2, 4, 6 and 8 months of storage, respectively. After 2 and 4 months of storage interval, practically no weight loss was observed in the treated seeds at both the oil doses. After 6 months of storage in the pooled data, higher doses of coconut (0.0% weight loss), groundnut (0.0%), mustard (0.0%), soybean (0.0%) and lower dose of coconut (0.18%) and groundnut (0.0%) proved superior and equieffective and in reducing seed weight less than lower dose of mustard (0.97%) and soybean (1.82%). After 8 months, seed treatment with both higher and lower doses of all oils (0.0 to 0.91%) except lower dose of soybean (7.44%) were at par and proved superior in reducing mean per cent weight loss.

18-103

EFFECTIVENESS OF BENZYL ALCOHOL IN THE CONTROL OF HOUSE DUST AND STORED CROPS MITES (ACARI ASTIGMATA)

M. Castagnoli, M. Liguori, R. Nannelli, S. Simoni
Istituto Sperimentale Zoologia Agraria, Sez. Acarologia, Firenze - Italy

Benzyl Alcohol (BA) is recognized as pharmaceutic aid on account of its bacteriostatic properties and considered non-toxic for man at low concentration (oral LD₅₀ : 500mg/Kg). Its acaricide effects were tested on the house dust and storage mites *Dermatophagoides pteronyssinus* (Trouessart), *D. farinae* Hughes, *Euroglyphus maynei* (Cooreman), *Tyrophagus putrescentiae* (Schränk), which are pests of stored crops and are responsible for atopic allergy.

For each species from stock cultures in optimal growth conditions 150 eggs and 1100-1500 motile stages (7-9 replications of about 150 specimens) were uniformly nebulized (80 µl on about 100 cm²) with a 3.25 % water solution of BA. The effect on motile stages was evaluated at room temperature (15°-19°C) in the first 24 hours after the treatment. The eggs were kept in a climatic cabinet at about 22°C for a period longer than that necessary for their hatching and observed once a day. The humidity was always high (> 80%) because the tests were carried out on units surrounded by wetted cottonwool to prevent the mites escaping.

Immediately after spraying almost all the mites appeared immobilized. The highest mortality on motile stages was recorded after 24 hours and was about 83% for *E. maynei* and *D. farinae*, 84% for *D. pteronyssinus* and 87% for *T. putrescentiae*. The effectiveness of BA was lower on the eggs with a 56% of hatchability for *T. putrescentiae* and 25-30% for the other species. However, the natural mortality under the tested conditions of *T. putrescentiae* was 1%, while for the others 8-9%. BA also appeared to exert a repellent effect and the treated surface were less colonized by mites. Our similar previous experiment on *D. farinae* at 20°-25°C recorded a 96% mortality.

These results suggest a promising use of BA to control mite populations in the home and in storage environments.

18-105

EVALUATION OF A METHOD OF FILTH-TEST USED FOR DETECTION OF SOLID MATTER IN MEAL

G. Loi, M. Pinzauti
Dipartimento di Coltivazione e Difesa delle Specie Legnose, Sezione di Entomologia Agraria, Università degli Studi di Pisa, Pisa, Italy.

This method involves "chemical digestion" of meal by nitric acetate solution, flotation of solid matter with ethyl alcohol and benzene, trapping in a Wildman flask and vacuum filtration.

Results showed a mean detection rate of 96% of insect fragments counted and introduced in 15 programmed repetitions. Possible causes of error at different stages of the procedure are discussed.

The same method was also evaluated on chestnut meal, giving good results.

18-104

TERMITES AND WOODEN STRUCTURES IN MONREALE CATHEDRAL

G. Liotta
Istituto di Entomologia agraria, Università degli studi, Palermo, Italy
The wooden structures in the roofs at Monreale Cathedral have suffered serious attacks by the termite species *Reticulitermes lucifugus* (Rossi) (Isoptera, Rhinotermitidae).

The first hotbeds of termites were found in 1978 under the mosaic surface resting on mortar made up of chalk "reinforced" with barley straw.

Subsequently, after oriented sampling, infestations were found on almost all the structures, especially the north-facing ones, mainly in the ends of the trusses in the nave and in the beams in the aisles and transept. The damage was extensive.

Termite nests were found near the baptistery, on one side, and in the vicinity of the north portico and the Angels' Arch on the other.

Two methods were used for the safeguarding of the monument: one tending to drive termites away from the infestation area and to create environmental conditions unfavourable to their survival, the other aiming to destroy the termite populations present. The work to achieve these aims was decided in cooperation with the planners of restoration work and carried out in cooperation with the director of works.

Among the main operations for disinfestation and tutelage we can mention:

1. Separation of the main structures of the roof from those of the ceiling.
2. Creation of an air gap between the two structures.
3. Aeration of ends of the trusses and beams by means of appropriate niches.
4. Aeration between the tiles and the roof planks.
5. Curative and preventive treatment of all wooden material with appropriate insecticides.
6. Creation of a trench under the north portico, to interrupt movement of termites from the nests to the "grazing" areas and to reduce rising damp in the building and isolate the town drain.

18-106

DISTRIBUTION AND DENSITY OF HOUSE DUST-MITES *DERMATOPHAGOIDES* SPP. (ACARINA: PYROGLYPHIDAE) IN THE MATTRESSES OF TWO DISTRICTS IN ROME, ITALY

M. Maroli, F. Bigliocchi, L. Frusteri.

Department of Parasitology, Istituto Superiore di Sanità, Viale R. Elena, 299 - 00161 Rome, Italy.

House-dust mite infestation was studied for the first time in Rome by Bigliocchi & Maroli (*Aerobiologia* 11: 35-40, 1995): 87.8% of the sampled houses were positive for dust-mites. The mattress was significantly the most infested (71.1%) of the tested sites. *Dermatophagoides farinae* was the most abundant species (53.1%), followed by *Glycyphagus domesticus* (34.5%), *D. pteronyssinus* (5.2%), and *Euroglyphus maynei* (0.2%).

The present study deals with the distribution and density of *D. farinae* and *D. pteronyssinus* in the mattresses of two districts in the city of Rome. Weekly samples of dust were collected during the period of high mite density. A total of 4,179 live and dead mites was collected. In the two examined areas, a difference in species distribution was observed. *D. farinae* was always the prevalent species, it was 94.7% in area A and 64.1% in area B; only in the two out of 10 houses was *D. pteronyssinus* the most abundant species (71.4% and 45.8%). Housekeeping practices were investigated by interviewing the tenants; correlation analysis revealed a significant relationship between these practices and mite density. The poorest housekeeping practices produced the heaviest mite infestations, while the good ones were associated with low densities.

Key words: *Dermatophagoides pteronyssinus*, *D. farinae*, house-dust mites, distribution, relative humidity, housekeeping, Rome.

18-107**GENERAL REMARKS ABOUT STORED PRODUCT PROTECTION AS AN INTEGRATED SYSTEM**

Ch. Reichmuth, C. Adler, M. Schöller

Federal Biological Research Centre for Agriculture and Forestry, Institute for Stored Product Protection, Berlin, Germany

In recent years pest control as a whole and stored product protection specifically is reconsidered under new priorities. Whereas efficacy held the most important position in the decision process as to which method of control or prevention should be applied, other aspects like workers' safety, chemical residues in treated products, pollution, and total energy consumption gain more and more importance. Moreover, due to massive memory capacities of computers and cheap accessibility for people, plenty of various information concerning the behaviour and development of pests, depending on type of product, the dosage of chemicals for control and their residue building can be kept ready in huge data banks around the world connected via internet or world wide web. Expert systems can be expected to cover plenty of cases and situations of pest infestations and their control. These new developments require a detailed concept of how to proceed in a specific situation and how to standardise the methods. The problem analysis has to include a broad investigation and a thorough search for the best combined solution amongst physical, biological, chemical, and technological procedures.

18-109**INERT DUSTS - REVIVAL OF AN AGENT AGAINST PEST INSECTS IN STORAGE**

Ch. Reichmuth, M. Schöller, B. Trewin, W. Rassmann

Federal Biological Research Centre for Agriculture and Forestry, Institute for Stored Product Protection, Berlin, Germany

Fine inert dusts have the property to kill insects within a rather short time. This knowledge dates back into history being applied in ancient cultures when mixing ashes and sand with stored agricultural products against pest insects. The application of silica was presumably interrupted when worker safety regulations forced a limited use to prevent health risks. Lately, new products were introduced with amorphous and calcinated diatomaceous earth. These compounds could help to partially replace residue building chemical insecticides. In Australia these dusts are effectively used since some years. Experiments in the laboratory under Central European climate and with grain revealed that the efficacy of the earths is strongly linked to the relative humidity in the store. Difficulties with complete control exist with the granary weevil *Sitophilus granarius*. Other pest insects like the warehouse moth *Ephesia elutella*, the saw-toothed grain beetle *Oryzaephilus surinamensis* and the confused flour beetle *Tribolium confusum* die a few days after exposure. Possibilities to use these dusts for empty room treatment and for sanitation of crevices with hiding pest insects are discussed.

18-108**A SIMPLE AND CHEAP ACOUSTIC DEVICE TO DETECT IMMATURE STAGES OF THE INTERNAL FEEDERS *SITOPHILUS GRANARIUS* AND *SITOTROGA CEREALELLA* IN GRAIN**

Ch. Reichmuth, H. Welp, H. Bentert, Ch. Bentert, A. Wudtke

Federal Biological Research Centre for Agriculture and Forestry, Institute for Stored Product Protection, Berlin, Germany

National and international grain trade suffers from the fact, that produce infested with internal feeding stages of insects like the granary weevil *Sitophilus granarius* and the Angoumois grain moth *Sitotroga cerealella* are delivered into the market as insect free. The receiver of the goods faces expensive control measures like fumigation of the whole bulk on emergence of these insect pests some weeks after loading.

Sieving of aliquot samples prior to loading is the standard method for inspection leaving behind the described uncertainty.

An apparatus is presented which is capable to detect feeding larvae inside infested grain kernels by their frass activity by use of a very sensitive microphone. The sensitivity is sufficient for one larva in 10 kg of grain or in other words one larva in a distance of about 20 cm. The low cost instrument should be used without too much background noise from the environment for instance in a bureau of a silo or flour mill.

18-110**BIOLOGY AND BEHAVIOUR OF THE TOBACCO BEETLE *LASIODERMA SERRICORNE* (FABRICIUS) (COLEOPTERA: ANOBIIDAE)**

Ch. Ulrichs, Ch. Reichmuth, M. Schöller

Federal Biological Research Centre for Agriculture and Forestry, Institute for Stored Product Protection, Berlin, Germany

The tobacco or cigarette beetle *Lasioderma serricorne* creates world wide great losses in stored tobacco, drugs and spices. On the leaves, the feeding activity of the larvae results in holes of 2 mm diameter, which spoil cigars of high value.

Tobacco, tobacco paper, bran and a mixture of bran and tobacco were tested as suitable breeding substrates for the beetle. Abiotic factors like temperature and humidity were varied. The developmental time was registered depending on sex. It was shown that the females preferably deposited their eggs in the area of the central vein of the tobacco leave. At this site the larvae also preferred feeding. The length of the males (2.4 ± 0.2 mm) differed significantly from the corresponding size of the females (3.0 ± 0.3 mm).

18-111

AN EASY APPLICABLE METHOD TO EVALUATE NATURAL AND SYNTHETIC REPELLENTS AGAINST STORED PRODUCT PEST COLEOPTERA AND LEPIDOPTERA.

A.-C. Sá-Fischer, M. Pöschko and M. Schöller

Federal Biological Research Centre for Agriculture and Forestry, Institute for Stored Product Protection, Berlin, Germany

The use of plant products as repellents, deterrents or natural insecticides is one alternative method in stored product protection which is currently under investigation. Frequently, natural compounds which are promising in laboratory studies show low efficacy under practical conditions. To overcome this problem, a method was evaluated to study the long term effect of natural compounds on oviposition site selection and feeding behaviour of both lepidoptera and coleoptera infesting stored products. A box containing two glass vessels with feeding substrate were placed inside an experimental room under controlled temperature and humidity conditions (fumigation chamber, glass cube or wire cage). The vessels were arranged upside down with the rim on the top of spacers to enabeling the test insects to enter underneath, feed and oviposite on the test substrate. In one vessel a dispenser saturated with the test compound hung above the substrate. In this two-choice situation, the insects were released outside the vessels. After several days the number of insects on the feeding substrate were counted. Moreover, the substrate was incubated to determine the development of progeny produced by the insects. In experiments conducted with pyralid lepidoptera, dermestid coleoptera and various essential oils, always a lower number of insects was found on the feeding substrate compared with the controls, but the number of progeny produced was not significantly different. The correlation of substrate selection, oviposition site selection and the number of progeny deposited are discussed.

18-113

RECENT COLLECTED MITE PESTS OF FOOD PRODUCTS (ACARI: ACARIFORMES AND PARASITIFORMES)

R. L. Smiley, J. Barron²

Systematic Entomology Laboratory, Agricultural Research Service, USDA, Beltsville, MD, USA - 2 Food and Drug Administration, Public Health Service, Department of Health and Human Services, Baltimore, MD, USA

Twenty-six families representing two orders and four suborders of mites infesting stored food products are reported. The identified species, country origin, date collected, and infested foods are presented in a table.

Some of these mites collected or closely related species have great medical significance and are important to public health, causing contact dermatitis and other allergic reactions. Ways and means in which these mites are transmitted causing infestations are discussed.

18-112

DISTRIBUTION OF DELTAMETHRIN FORMULATIONS IN VARIOUS SOILS WHEN APPLIED FOR SUBTERRANEAN TERMITE CONTROL
S. T. Kamble, R. W. Davis
Water Center/Environmental Programs and Department of Entomology, University of Nebraska, Lincoln, NE 68583 USA

Deltamethrin emulsifiable concentrate (EC) and soluble concentrate (SC) diluted in water at 0.1% active ingredient (AI) were applied to loamy sand and silty clay soils at 1.52 liter per application point under 206.89 kPa pressure. Each formulation had 4 treatments and each treatment was replicated three times. An experimental unit for each treatment was a plywood box (1.22 m X 1.22 m X 0.61 m) filled with loamy sand or silty clay loam soil and covered with a 7.6 cm concrete slab. A 1.3 cm hole at the center of each concrete slab was made to apply deltamethrin. The insecticide was applied using a sub-slab injector equipped with a 10.2 cm single bore straight tip. Four soil cores measuring 0.61 m in length and 2.54 cm in diameter were removed from each unit with cores 1, 2, 3 and 4 located 2.5, 15.2, 30.4 and 45.6 cm below the bottom of the concrete slab, respectively. Each core was divided into 4 soil samples (15.2 cm interval). Deltamethrin from soil samples was extracted using methanol and analyzed by high performance liquid chromatography (HPLC). Data were analyzed by Proc GLM:Repeated Measures Analysis, ANOVA. The results indicated that neither the formulations nor the combinations of soils and formulations yielded significant differences in vertical or lateral distribution of deltamethrin. In terms of vertical penetration, maximum amounts of deltamethrin (70.7-169.3 µg/g of soil) were detected directly below the injection point regardless of soil type or formulation. Relative to lateral distribution, the highest amounts of deltamethrin (2.7-72.2 µg/g of soil) were found only at 2.5 cm depth combined with a horizontal distance of 15.2-30.4 cm from the injection point.

18-114

ARBOREAL AND LEAF LITTER SPECIES OF N. AMERICAN HARVESTMEN AS NOCTURNAL PREDATORS IN ROADSIDE AND URBANIZED ENVIRONMENTS (ARACHNIDA: OPILIONES).

G. Klee

Dept. of Biological Sciences, Kent State Univ.- Stark Campus, Canton, OHIO USA

During a research study of nocturnal field predation by Opiliones on various arthropods, several species were found to be quite numerous in previously unreported and novel habitats. One unusual type of habitat was the bases of lighted interstate highway signs; 3 harvestmen species were collected in significant numbers in this "habitat" during regular nocturnal collections in Northeastern Ohio from July through September 1990, and in other collections in following years. The harvestmen were apparently drawn to these areas by the many insects attracted to the lighted signs, which were 50 meters or more from typical mesic hardwood forest habitats from which the most frequently collected species, Leiobunum vittatum, has been previously reported. A laboratory maintenance technique for L. vittatum and another opilionid species, Hadrobunus maculosus, will also be described.

18-115

SPERM NUMBERS AND REPRODUCTIVE BEHAVIOUR IN MUTANT AND IRRADIATED MOTHS *EPHESTIA KUEHNIELLA* (LEPIDOPTERA: PYRALIDAE)J. Koudelová, P.A. Cook¹

Institute of Entomology, České Budějovice, Czech Republic

¹Department of Environmental and Evolutionary Biology, University of Liverpool, Liverpool, England

Quality of sperm transfer plays an important role in efficiency of genetic methods for suppression of Lepidoptera populations. We have examined competitiveness of mutant and/or irradiated males of *Ephestia kuehniella* by counting sperm transferred to female via spermatophore. BL-2 males, trans-heterozygous for two sex-linked recessive lethal mutations, *sl-2* and *sl-15*, produced 50% fewer eupyrene (fertile) and apyrene (non-fertile) sperm per spermatophore in comparison with wild-type males. However, the ratio of apyrene to eupyrene sperm was the same in both groups (9,5:1).

In the second experiment, late pupae heterozygous for one of the mutation, either *sl-2* or *sl-15*, were treated with different doses of gamma rays: 150, 175, 200, 250 and 350 Gy. Irradiation significantly decreased percentage of the pupal emergence at doses higher 175 Gy. Mating success of males was reduced at all doses excepting 200 Gy by about 50%. After irradiation with the dose of 175 Gy, the mean number of both eupyrene and apyrene sperm increased, even exceeding those in untreated wild-type males. At higher doses used, the numbers of both sperm decreased significantly to the maximal reduction of about 25% at 350 Gy.

The mean time required for copulation increased with the increasing dose. There was a tendency in the relationship between the number of sperm transferred and copula duration: the lower the sperm number the longer the copulation.

18-117

THE ANALYSIS OF REFUGE POPULATIONS OF *ORYZAEPHILUS SURINAMENSIS* IN MODEL GRAIN BINSR.J. Brown, C.A. Malcolm, R.A. Nichols and P. L. Mason*¹

School of Biological Sciences, Queen Mary and Westfield College, University of London, UK.

¹ Central Science Laboratory, Ministry of Agriculture, Fisheries and Food, Slough, UK

Oryzaephilus surinamensis is an important stored product pest. DNA based markers have been identified and used in conjunction with model grain bins to facilitate analysis of the structure and dynamics of heterozygous insecticide resistant populations within grain stores, in the presence of insecticide. The model grain bins were designed to mimic features of real grain stores, notably, the varying levels and surface areas of insecticide treatments and the presence of refuges. This work has shown that the presence of untreated refugia allow *O. surinamensis* individuals to survive treatment and reproduce to maintain long term residual populations. The data from the genetic markers showed that some insect refuges contained subpopulations, demonstrating that even the short migrations necessary to move into different refugia did not take place at a rate sufficient to ensure mixing of the whole bin population. This study is the first to combine the interaction of refugia and incomplete application of insecticide with the evolution of insecticide resistance over generations, on a scale that is large enough to mimic those in a true grain store. Contrary to theoretical models and laboratory studies the grain bin population that survived in this study had a higher level of resistance than the source population. The level of insecticide resistance in the grain bin populations rose in just one generation. These residual populations, despite being in insecticide free areas, harbour resistant individuals, and can therefore provide a focus for continual reinfestation of grain supplies.

ESSAYS AT APPLICATION OF THE MATHEMATICAL MODELING - THE EFFECT OF DIFFERENT AIR TEMPERATURES ON THE DURATION OF DEVELOPMENT AND THE INVASIVE ACTIVITY OF COMMON BEAN WEEVIL *ACANTHOSCELIDES OBTECTUS* SAY (COLEOPTERA, BRUCHIDAE)

D. Zimakowska-Gnoinska

Institute of Ecology, Polish Academy of Sciences Dziekanow Lesny n/Warsaw, 05-092 Lomianki, Poland

A temperature is one of the most essential factors influencing the energy flow and distribution in animal body.

In case of coleopterous common bean weevil (*Acanthoscelides obtectus* Say) the temperature change from 28°C (optimal temperature) to 20°C causes the seven times drop of female fertility and twice as longer the larvae development time.

Also the larvae invasive activity (successful settlements in bean seeds) decreases considerably.

Presented mathematical model is based on own experiments.

18-118

MITES AND INSECTS IN URBAN PIGEON'S NEST

A. Magnani, S. Proserpio¹, G.C. Lozzia, F. Ottoboni¹Istituto di Entomologia agraria, Università degli Studi, Milano, Italy ¹Lofarma Allergeni, Milano

The pigeon (*Columba livia domestica*) is one of the gregarious species which has settled in remarkable proportions in our cities. Pigeons build their nests in the garrets of buildings, monuments and ruins. These nests constitute an ideal habitat for many insects and other arthropods.

The objective of this work was to make a census of the arthropod fauna present in the nests of domestic pigeons, which live in the bell towers and attics in the city of Como (Northern Italy), in order to evaluate eventual risks for the health of man, linked to the presence of these hosts.

The arthropod fauna found resulted very varied: 11 orders of insects have been identified. Most of the samples taken were in the larval stage and their classification did not go any further than order. Just as numerous were the arachnids (aranea, pseudoscorpions and mites). Furthermore, crustacean isopods were seen in great numbers, especially in heaps of guano.

Among the insects there did not seem to be any harmful to man.

The mites identified are not regarded as being among those potentially pathogenic to man by literature, with the exception of the pigeon tick, which causes allergies in many individuals, sometimes lethal.

18-119

A method for the detection of mites in house-dust samples

M. Gentili, F. Ottoboni, G. Mistrello, P. L. Antoniotti and P. Falagiani

Reparto Ricerche Lofarma Allergeni, Milano, Italy

House dust mites exposure is an important risk factor in the development of allergic syndrome. The development of methods for detection of mites in domestical environments would be helpful in planning more proper anti-mites measures. Aim of this study is to develop simple, specific and rapid test for the evaluation of mites allergens in house-dust samples.

It is based on a nitrocellulose dipstick spotted with specific anti-mite allergens antibodies (capture matrix). Such antibodies, when conjugated with colloidal dye particle acts, as detecting reagent. The assay is one-step configuration, spotted dipstick being added in a tube containing detecting reagent and house-dust sample. No instrumentation is required, the response being visible at the naked eye as a colored spot after an hour of incubation. By analysis of several HDM samples, this method seems to be more specific than commercial guanine determination test even if less sensitive than Der p I Elisa.

18-121

SENSITIVITY OF *Anagasta kühniella* (Zeller, 1879) (LEPIDOPTERA, PYRALIDAE) AND ITS NATURAL ECTOPARASITE, *Habrobracon hebetor* (Say, 1836) (HYMENOPTERA, BRACONIDAE) TO MICROWAVES (2450 Mhz)

M.E.M. Habib & G.G.Fagundes

Dept. Zoology, Inst. Biology, State Univ. Campinas (UNICAMP), Campinas, SP, 13081-970, Brazil.

The Mediterranean flour moth, *Anagasta kühniella*, a cosmopolitan pyralid, is well known as one of the most important pests of stored products. Its larvae are naturally parasitized by *Habrobracon hebetor*, a very effective ectoparasite. Some physical control methods, including radio-frequencies, as microwaves, are being evaluated aiming to establish IPM programmes. The present work, therefore, was undertaken to determine the comparative effect of microwaves (2450 Mhz) on *A. kühniella* adults and larvae, as well as on *H. hebetor* adults.

Different microwave exposure times (ranging from 5 up to 34 seconds) were established. For *A. kühniella* bioassays, 100 individuals per treatment were utilized, while for the case of *H. hebetor*, 48 individuals per treatment were used. Median Lethal Exposure Time (LE50) criterium was applied; and the LE50 values were calculated 2, 12 and 18 hours after exposure. Concerning *A. kühniella*, the adults (with LE50 varied between 8 and 9 seconds) showed to be more sensitive than the larvae (with LE50 varied between 9 and 18 seconds), among the three evaluation periods. Moreover, larvae within the diet (LE50 varied between 9 and 11 seconds) revealed higher sensitivity than those directly exposed to radiation (LE50 varied between 14 and 18 seconds). *H. hebetor* adults showed to be significantly less sensitive than *A. kühniella* adults and larvae. The highest mortality (20.8 %) observed among treated braconid wasps was obtained 18 hours after an exposure time of 34 seconds. These results stimulate future investigations to verify the compatibility degree between these two mortality factors (biotic and abiotic) in IPM programmes for the control of this insect pest.

18-120

POTENTIALITIES OF MALATHION-BIFENTHRIN MIXTURES TO PROTECT STORED PRODUCE FROM PESTS

C. Beratlief, H. Iliescu

Research Institute for Plant Protection, Bucharest, Romania

The most common storage pests in Romania are *Sitophilus oryzae*, *S. granarius*, *Rhizopertha dominica*, *Oryzaephilus surinamensis*, *Tribolium confusum*, *Cryptolestes* sp. and *Plodia interpunctella*. In more humid areas mites are also sometimes troublesome. Psocids are often present in stores throughout the country. *Acanthoscelides obtectus* is widespread in stored haricot beans.

It was found that insect pests can reproduce within a time span extending from mid May through mid October in southern zone, while in early June-early October in the North. Winter low temperatures have little influence on storage insects and mites.

Opportunities to protect grain and beans in storage with malathion-bifenthrin mixtures (20:1) have been investigated in commercial grain silo bins, flat stores and empty storage premises. Suitable results have been obtained with rates of 6.0+0.3 mg/kg applied as protectants, and 500+25 mg/sq m. when spraying storage premises prior to grain introduction.

Malathion-bifenthrin mixture applied at a rate of 500-25 mg/sq m. was also efficient in controlling full-grown *P. interpunctella* larvae crawling on top of a grain bulk seeking for pupation sites. It is thought that UL formulations are adequate for applications in commercial stores, while EC sprays are convenient to household or on-farm storage of smaller amounts of produce.

18-122

INSECTICIDAL ACTIVITY OF PLANT ORIGIN PREPARATUS AGAINST STORED PRODUCT INSECTS

I. Kalinović¹, J. Martinčić¹, V. Ilić¹, V. Guberac¹¹University of Josip Juraj Strossmayer, Faculty of Agriculture, Osijek, Croatia

Plants dust and oil extract of *Rosmarinus officinalis*, *Laurus nobilis*, *Thymus vulgaris*, *Origanum vulgare*, *Lavandula officinalis* were evaluated for the control of infestations *Acanthoscelides obtectus* Say. and *Sitophilus granarius* (L.) imago in laboratory conditions. All investigated plants species have insecticidal influence on *A. obtectus* and *S. granarius*.

For the control of *A. obtectus* the most effective was oil of *L. officinalis*, with dose of 0.1 ml per kg *Phaseolus vulgaris* L. (total mortality per 24 h). Less effective was dust (*L. officinalis*, *O. vulgare*) with dose of 1g per kg bean with total mortality of *A. obtectus* during 48 and 72 h exposition. Dust of *L. nobilis*, *T. vulgare* and *R. officinalis* had lower efficacy (total mortality of *A. obtectus* was attained after 15 days).

For the control of *S. granarius* in wheat - *Triticum vulgare* the most effective was dust of *L. nobilis* with dose of 1g per 1kg (total mortality during 26 days), and less effective with dust of *R. officinalis*, *T. vulgare* and *L. officinalis* during 28 and 30 days of exposition.

By the investigation in store house conditions with dust and oil extract of *R. officinalis*, *L. nobilis*, *Th. vulgaris* and *L. officinalis* against *S. granarius* in mercantile wheat, the most effective was dust of *R. officinalis* with dose of 37 g per 5 kg (total mortality per 48 h).

In seed wheat the most effective was oil extract of *L. nobilis* in dose of 3.7 ml per 5kg (total mortality after 72 h).

All investigated plant origin preparatus had not negative influence on the seed wheat germination.

18-123

EXPANSION OF SYNANTROPIC COCKROACHES SPECIES IN RUSSIA

N.A. Alesho

Institute for Preventive Toxicology and Disinfection State Committee of Russia for Sanitary-Epidemiological Supervision, Moscow, Russia

Of 60 species of cockroaches (*Blattoptera* order) living in the fauna of Russia only six species are synantropic ones. In general two species of synantropic cockroaches, namely *Blattella germanica* and *Blatta orientalis* are constantly registered in urban sites of the country. Nowadays fauna of synantropic cockroaches in Russia has been significantly widened due to the species delivered by various transport communication. Since 1970 some foci of *Periplaneta americana* have been registered in a number of big cities. The colonies of *Nauphoeta cinerea*, *Periplaneta australasiae*, *Leucophaeta maderae*, *Supella longipalpa* occur in the buildings of the Zoo, green houses and living places. Some cases of *Blaberus* and *Panchlora* species appearance have been fixed as well. A dynamic process of urban ecosystems settling by new species of cockroaches is being observed now. The monitoring and mapping of the insects localization in various regions of the country is carried out.

18-125

ECOTYPES OF *TRIBOLIUM* UNDER DIFFERENT FOOD CONDITIONS

T. Prus, M. Prus

Laboratory of Ecophysiology of Invertebrates, Institute of Ecology, Polish Academy of Sciences, Dziekanów Leśny (near Warsaw), Poland

Investigations were made of the effect of altered habitat, when the animals were kept in wheat flour deprived yeast, on phenotypic differentiation in *Tribolium* strains. Fecundity, hatchability, survival and reproduction were assessed under the effect of this factor.

In *Tribolium castaneum* a considerable lowering of fecundity was observed in altered medium, whereas in *T. confusum* this factor had no effect. The altered medium did not cause changes in fecundity of ecotypes of *T. confusum* whereas in *T. castaneum* it caused lowering the fecundity almost by half. No significant effect was observed in hatchability.

Reduction of numbers was largest in the egg stage, and smallest in the pupal stage. In *T. castaneum* this reduction was smaller than in *T. confusum* and 6-instar ecotypes showed the best survival.

In the standard medium the reproductive effort was higher in *T. castaneum* than in *T. confusum*. It was also higher in 6-instar than in 7-instar ecotypes. In altered medium reproductive effort was relatively lower, especially in *T. castaneum*.

18-124

EFFECT OF TRICALCIUM PHOSPHATE ON REPRODUCTION IN *TRIBOLIUM*

M. Prus

Laboratory of Ecophysiology of Invertebrates, Institute of Ecology, Polish Academy of Sciences, Dziekanów Leśny (near Warsaw), Poland

The investigations involved the influence of Tricalcium phosphate (TCP) on reproductive efficiency in two species of *Tribolium* and two ecotypes distinguished in these species. Three concentrations of TCP were used, namely 0.5%; 1.0% and 1.5%. Reproductive effort was calculated with data on fecundity, individual weight of an adult and calorific value of pupae and adults.

Increasing concentration of TCP in the culture medium caused diminishing of the body weight of adults, however not in direct proportionality.

A clear decrease in fecundity under TCP effect was observed for *T. castaneum*, and in *T. confusum* decrease is significant only at 1.0% concentration. Such decrease is lower in 7-instar than in 6-instar ecotypes.

Calorific value decreases with increasing concentration of TCP in all development stages examined, more in *T. castaneum*. No differences were observed in calorific value among ecotypes.

The reproductive effort was compared with that in control series. This index decreased in the two species, much more in *T. castaneum* than in *T. confusum*.

18-126

ADJUSTEMENT OF PHOSPHINE DOSAGES FOR CONTROL OF IMMATURE STAGES OF RESISTANT STRAINS OF *SITOPHILUS ORYZAE*

M. R. Sartori, S. Bolonhezi and D.C. de Paula

Instituto de Tecnologia de Alimentos - ITAL, Campinas, SP, Brazil

The most important factor in order to achieve a successful fumigation with phosphine is the recognition that there exists a great difference in the tolerance to the gas among the several developmental stages of insects. To obtain information that could be used as guidelines for the adjustment of phosphine dosages to control insect resistant populations of stored products, all developmental stages of two strains of *Sitophilus oryzae* with a high frequency of resistance (as detected by the FAO discriminating dose test method n° 16), collected during a survey on resistance that covered 8 states of Brazil, were treated with doses of 1.5 and 3.5 g PH_3/m^3 and exposure periods that ranged from 72 to 336 hours, in glass dissection chambers kept in controlled environment chambers at $26 \pm 1^\circ\text{C}$ and $75 \pm 5\%$ R.H.

For both strains and doses, exposures periods of 72 hours were not sufficient to achieve complete control, with emergence occurring as early as the second week after fumigation in cultures containing old larvae and pupae, and in the fourth week, in cultures containing eggs and young larvae. A single emergency, corresponding to a mortality rate of 99.96% in relation to the control, was observed at a CTP of $168\text{gh}/\text{m}^3$ for 120 hours exposure in the strain with the highest level of resistance (108.4 at LC 99.9). However, in a second bioassay with this strain, under the same conditions, 100% mortality was achieved within 96 hours.

Results obtained indicate that it is necessary to change label recommendations of 72 hours exposure period in commercial phosphine products sold in Brazil. However, it is unlikely that a good control would be achieved unless a considerable improvement is also introduced in current sealing practices.

18-127

COMPARATIVE EFFICACY OF DIFFERENT FORMULATIONS OF PIRIMIPHOS-METHYL AND ETRIMFOS, WHEN ADMIXED WITH WHEAT, AGAINST SUSCEPTIBLE STORAGE INSECT PESTS

D. A. Collins, T. J. Binns and D. A. Cook
Central Science Laboratory, Slough, U. K.

The efficacy of emulsifiable concentrate (e.c.) and dust formulations of pirimiphos-methyl and etrimfos were compared, when admixed with wheat at 0.5, 1, 2 and 4 mg kg⁻¹, against susceptible strains of *Tribolium castaneum* (Herbst), *Oryzaephilus surinamensis* (L.), *Sitophilus granarius* (L.) and *Rhyzopertha dominica* (F.). Immediately after treatment and then at 4 weekly intervals for a period of 36 weeks, samples were taken for pesticide residue analysis and insect bioassays. Insect mortality was assessed after 1, 7, 14, 21 and 28 days exposure. The results indicated that complete mortality of *T. castaneum*, *O. surinamensis* and *S. granarius* was achieved for 36 weeks, when exposed for at least 7 days, to recovered pesticide residues of approximately 1 mg kg⁻¹ pirimiphos-methyl e.c., 1.3 mg kg⁻¹ etrimfos e.c., 2 mg kg⁻¹ pirimiphos-methyl dust and 1.6 mg kg⁻¹ etrimfos dust. The e.c. of pirimiphos-methyl was the most effective treatment against these species. Higher mortalities were recorded at equivalent doses, and longer periods of protection were provided, with shorter exposure periods required for complete mortality. Against *R. dominica*, the dust formulation of etrimfos appeared the most effective treatment, however, complete mortality was only achieved up to 4 weeks storage. There appeared to be little degradation of pesticide residues over the experimental period although loss of bioactivity was observed.

18-129

DISPERSAL AND CONTROL OF *Aedes aegypti* (L.) IN URBAN AREAS: STUDIES WITH A RUBIDIUM MARK-RELEASE TECHNIQUE

P. Reiter, M. Amador, R. Anderson¹, L. Velez² and G. Clark
Dengue Branch, Division of Vector-borne Infectious Diseases, NCID, Centers for Disease Control and Prevention (CDC), San Juan, Puerto Rico
- ¹ Department of Entomology, University of Manitoba, Winnipeg, Manitoba, Canada - ² National Malaria Eradication Service, Guayaquil, Ecuador

The mosquito *Aedes aegypti* (L.) is the principal urban vector of Chikungunya, dengue and yellow fever, viral diseases that can spread rapidly in explosive epidemics. We have developed a method for marking the eggs of this species with rubidium (Rb), a relatively rare alkali metal. A solution of 0.045M RbCl in pig's blood yields 8-14 ppb rubidium per egg laid on the first day of oviposition; eggs laid on subsequent days contain less rubidium, but are still detectable by atomic emission spectroscopy. We have used our method to monitor dispersal and to evaluate the impact of intra-domiciliary insecticide treatments. Our results provide direct evidence that oviposition activity can last several days in the field, and that eggs are distributed over an area at least 840 m in diameter. We believe that dispersal may be affected by the availability of oviposition sites. Our results indicate that the common practice for the control of *Ae. aegypti*-borne disease by "focal" treatments with insecticidal space sprays, centered on the homes of presumed or confirmed cases, are unlikely to be effective. Furthermore, attempts to reduce adult mosquito populations by eliminating larval habitats may enhance dissemination of virus by promoting wider dispersal of the vector. Our studies also confirm that intra-domiciliary treatments with insecticidal aerosols are more effective than treatments made from aircraft or road vehicles.

18-128

MONITORING OF DIFFERENT STORED-PRODUCT PESTS USING SYNTHETIC SEX PHEROMONE

P. Pereira, O. Carvalho, A. Mexia¹

¹ Centro de Estudos de Fitossanidade do Armazenamento, Instituto de Investigação Científica Tropical, Lisboa, Portugal

Different sex pheromone trap designs, were used to monitor the occurrence and intensity of *Lasioderma serricorne* Fabricius (Coleoptera: Anobiidae), *Ephestia cautella* (Wlk.), *E. kuehniella* Zell. and *Plodia interpunctella* (Hb) (Lepidoptera: Pyralidae), common stored-product pests.

Field trials were carried out in four different warehouses: tobacco for *L. serricorne* and almond kernel, carob and seed-corn stores for *E. cautella*, *E. kuehniella* and *P. interpunctella*.

The potential of such pest monitoring studies was evaluated as a assessment technique in order to use them, in the future, as a decision tool for pest control in stored-products.

18-130

FEEDING DETERRENT ACTIVITY OF SOME SYNTHETIC TERPENE LACTONES

Z. Winięcki¹, E. Paruch², T. Olejniczak², J. Nawrot¹,
C. Wawrzeńczyk²

¹ Institute for Plant Protection, Poznań, Poland

² Institute of Fundamental Chemistry, Agricultural University, Wrocław, Poland

Terpene and sesquiterpene lactones isolated from plants usually exhibit specific biological activity. Many of them showed the antifeeding activity against insects.

Continuing our studies on the synthesis of compounds which can be used for insect pest population control we have obtained mono- and bicyclic terpene and bishomoterpene lactones. Some of them were synthesized in both enantiomeric forms.

The antifeeding activity of these lactones was tested on three storage pest insects: granary weevil (*Sitophilus granarius* L., adults), confused flour beetle (*Tribolium confusum* Duv., adults and larvae) and the khapra beetle (*Trogoderma granarium* Ev., larvae). Some of lactones tested showed interesting activity.

18-131

THE POPULATION DYNAMICS OF STORED PRODUCT LEPIDOPTERA INSECTS IN REPUBLIC OF GEORGIA

G.Aleksidze, C.Chkhubianishvili,¹ M.Andronikashvili²

Department of Applied Entomology, Kanchaveli Georgian Research Institute of Plant Protection (KGRI), Tbilisi, Republic of Georgia - 1 Laboratory of Microbiological Control (KGRI), - 2 Department of Microbiology & Virology, Djavachishvili Tbilisi State University, Republic of Georgia

The complex of Lepidoptera insects: Nemapogon granellus L. (Tineidae), Sitotroga cerealella Oliv. (Gelechiidae), Plodia interpunctella Hb., Pyrallis farinalis L., Ephestia kühniella Zll. (Pyralidae) cause great damage to cereals in granaries. In connection with the changes in grain storage technology in Georgia during the last years, the pests are found mainly on the primary processing products - flour and groats. Bacterial and virus diseases, at a high density of larvae, both occur in mill and laboratory conditions. The study illustrates the importance of natural enemies, which determinates of the growth of population rates of several kinds of stored product Lepidoptera insects.

18-132

EVALUATION OF INSECT GROWTH REGULATORS AND THEIR MIXTURES FOR SUPPRESSION OF SYNANTROPIC COCKROACHES POPULATION

N.A. Alesho

Institute for Preventive Toxicology and Disinfection State Committee of Russia for Sanitary-Epidemiological Supervision, Moscow, Russia

In urban conditions sex and age composition of synantropic cockroaches can be greatly varied. That's why elaboration of alimental toxic baits for synantropic cockroaches (TBC) is of great importance.

A number of a new TBC recipes have been prepared on the basis of a mixture of insect growth regulators containing juvenil-hormon analogue (hydropren), chitin synthesis inhibitor (dimihlin) and permithrin. The efficiency of the preparations was evaluated on *Blatella germanica* and *Periplaneta americana* species by free group feeding in laboratory conditions. On the first stage a gradual death of juvenile larvae of *Blatella germanica* species was observed during ten-thirty days period that was attributed to a toxic action of dimihlin. Then an increase of the amount of chimeric insects has been observed up to 90% by the end of 30 days exposition. Feeding of the baits containing permethrin and hydropren has led to the death of all *Blatella germanica* and *Periplaneta americana* imago by the 7-th and 20-th days respectively. More than 60% of the larvae of both species were killed by the insecticides. Anomalous growth of the survived larvae has been observed by the end of 30 days period. The efficiency of the preparations was also evaluated on a number of Moscow objects occupied by *Blatella germanica* species. Suppression of the insect population was observed during 2-3 months period. A very low toxicity level for a human was also demonstrated.

Section 19

Ecology of Pesticides,
Resistance and Toxicology

19-002

Patterns of evolution and spread of mosquito resistance suggested from comparative analysis of the EST α 2/EST β 2 and EST β 1 amplicons.

J.Hemingway, A.Vaughan, S.H.P.Karunaratne, G.Small, Department of Pure and Applied Biology, University of Wales, Cardiff, P.O.Box 915, Cardiff, CF1 3TL.

The major insecticide resistance mechanism in *Culex quinquefasciatus* mosquitoes involves two amplified esterases. More than 90% of resistant field populations have a single amplicon on which two esterases, Est α 2 and Est β 2 occur. At a molecular level these esterases are identical in field populations from different sources. In contrast the remainder of the resistant populations, with one exception, contain two esterases, Est β 1 and Est α 3. These esterases are, however, on separate amplicons. At a molecular level the Est β 1 genes differ between the 3 populations analysed.

The gene sequence and structure of the Esterases suggests that the Est α s and Est β s arose originally from gene duplication. They also remain tightly linked in susceptible insects.

This paper will discuss the origin of the different amplicons. Evidence will also be presented to suggest that the fitness of individuals carrying the Est α 2/Est β 2 amplicon may be profoundly influenced by the presence of a third non-esterase gene within the amplicon. This may explain why this amplicon has spread so rapidly, despite the lack of an obvious fitness advantage of the Est α 2 and Est β 2 over the other esterases with regard to resistance confirmation.

19-001

EVOLUTION OF INSECTICIDE RESISTANCE IN THE
MOSQUITO *CULEX PIPPIENS*

M. Raymond, T. Guillemaud, N. Pasteur

Laboratoire Génétique et Environnement, URA 327, CC 065,
Université de Montpellier II, 34095 Montpellier, France.

The evolution of insecticide resistance in the mosquito *Culex pipiens* can be studied at the gene level, due to the recent progress of molecular tools. Esterase overproduction is a common resistance mechanism to organophosphate insecticides, and two esterase genes are involved: *esterase A* and *esterase B*. Using extensive population data (from five continents, from treated and untreated areas), analyzed for both loci at the protein and DNA level (RFLP, sequence), it is concluded that mutation conferring resistance have occurred only few times at these loci, but have spread worldwide since their first occurrence. This limitation of mutation and the importance of migration are discussed.

19-003

WHAT DO WE KNOW ABOUT THE ORIGIN OF
AMPLIFIED ESTERASE GENES IN *MYZUS PERSICAE*?

Linda M. Field and Alan L. Devonshire

IACR-Rothamsted, Harpenden, Herts, AL5 2JQ, UK.

Insecticide resistance in the aphids, *Myzus persicae* and *Myzus nicotianae* is conferred by the presence in both species of amplified E4 or FE4 genes encoding two closely related insecticide-detoxifying esterases. The FE4 gene is amplified in aphids of normal karyotype, and E4 in aphids with an A1,3 chromosomal translocation. The two forms of amplified gene are very similar, with the same exon/intron arrangement, only 20bp differences in their cDNA and a high nucleotide conservation within intron sequences. So what is the origin of these amplified genes?

Although data from restriction mapping of the esterase amplicons is consistent with single origins of each amplification (one for E4 and one for FE4) as has been suggested in *Culex* mosquitoes, this cannot be confirmed by mapping of susceptible aphid DNA. However, spread between populations is clearly occurring since both *M. persicae* and its tobacco-feeding form, *M. nicotianae*, from around the world have the same amplified genes. Sequencing of esterase genes has shown that E4, FE4 and at least two other closely related sequences are present in all individuals although only E4 or FE4 is amplified, and *in situ* hybridisation shows that the amplified genes can occur at several loci (even within the same aphid). This all points to *M. persicae* having a family of esterase genes, two of which have amplified once or more and then spread both around the aphid genome and throughout aphid populations worldwide.

19-004

ORIGIN AND SPREAD OF CYCLODIENE INSECTICIDE RESISTANCE ASSOCIATED WITH POINT MUTATIONS IN A GABA RECEPTOR GENE

R.H. ffrench-Constant, N.M. Anthony, D. Andreev, K. Aronstein
Department of Entomology, University of Wisconsin-Madison,
Madison, Wisconsin, USA

The number of independent origins of insecticide resistance alleles is currently the subject of intense debate. Support for the importance of a single point of origin and spread of resistance through insect populations comes from studies of amplified esterases and insensitive acetylcholinesterase in *Culex* mosquitoes. Here we argue that it is difficult to determine precisely the number of origins of resistance alleles due to the complexity of the two mechanisms studied in *Culex*. The repeated replacement of the same amino acid in the *Resistance to dieldrin (Rdl)* gene, conferring resistance to cyclodiene insecticides, offers a model system within which to examine the diversity and origins of resistance alleles. By comparing *Rdl* alleles in two *Drosophila* species, two beetle species and the *Bemisia tabaci* whitefly complex we present repeated evidence for multiple independent origins of resistance. Evidence for independent origins comes not only from the finding of different replacements of this same amino acid but also flanking sequence data supporting multiple origins of the same amino acid replacement. Further, we emphasize that the life history of the insect under consideration can play a major role in determining the likely origin and spread of different resistance alleles.

19-006

ESTERASE ALLOZYME AS ELECTROPHORETIC MARKER FOR RESISTANT MECHANISM OF *Plutella xylostella* (L.) (LEPIDOPTERA:PLUTELLIDAE)

Can-Jen Willian Maa

Institute of Zoology, Academia Sinica, Nankang, Taipei, Taiwan, ROC.

Thirteen esterase loci were estimated from the PAGE zymogram of *Plutella xylostella* (L.) (DBM) of Taiwan. Two loci, *Est 8* and *Est 9*, were easily coded in the 17 local DBM populations. *Est 8* has four alleles: *a*, *b*, *c*, *null*, and *Est 9* has three alleles: *a*, *b*, and *null*. All these allozymes were susceptible to 10^{-6} M paraoxon except *Est 9^b*. Two strains were established from the population of Sheh-Tze(ST), Taipei, through more than 6 generations of sib-mating. The malathion-resistant strain, ST10, selected through single female-male pairing method with malathion as selection force was bestowed with high frequencies of *Est 8^b* and *Est 9^b*. The susceptible strain, ST12 was bestowed with high frequencies of *Est 8^a* and *Est 9^a*. The ST10 insect had higher enzymatic activities of monooxygenase, glutathione-S-transferase, and acetylcholinesterases than that of ST12. Besides, acetylcholinesterases of ST10 was more tolerant to 10^{-4} M eserine than that of ST12.

Est 9^a of ST12 was stable and would not disappear from the zymogram of the larva during the investigation of consequent 6-generation sib-mating, and *Est 9^b* of ST10 was unstable and would disappear during the sibmating experiment, especially when malathion was applied as a selected pressure to the DBM; these phenomena hinted that regulatory factor for esterase allozymes was possibly associated with the resistance mechanism.

19-005

MULTIPLE SITES OF THE AMPLIFIED ESTERASE GENES THAT CONFER RESISTANCE TO INSECTICIDES IN *MYZUS PERSICAE* (SULZER) (HOMOPTERA: APHIDIDAE) REVEALED BY FLUORESCENCE *IN SITU* HYBRIDISATION

R.L. Blackman, J.M. Spence, L.M. Field¹, A.L. Devonshire¹
Department of Entomology, The Natural History Museum, London SW7 5BD, UK ¹Biological and Ecological Chemistry Department, IACR-Rothamsted, Harpenden, Herts AL5 2JQ, UK

Myzus persicae combats organophosphorus and carbamate insecticides by overproducing insecticide-degrading esterases, encoded by amplified genes. Resistant aphids have one of two alternative amplified esterase genes, E4 or FE4, depending on their karyotype. Aphids with an autosomal 1,3 translocation have E4 genes, whereas those without this translocation have FE4. We have used fluorescence *in situ* hybridisation (FISH) to locate the amplified esterase genes in mitotic and meiotic chromosomes of resistant aphids. Specific binding to amplified E4 and FE4 sites was achieved with a genomic probe encompassing most of the esterase gene. Chromosomal locations were confirmed by inheritance studies and by pairing relationships in male meiosis I, and the esterase type of each clone was diagnosed by Southern blotting. Whereas E4-producing clones usually have all their E4 sequences at a single site closely linked to the A1,3 translocation, FE4-producing clones can have several loci which bind to the probe on autosomes 1, 2 and/or 3, and can be either heterozygous or homozygous for amplified FE4. Overall, amplified E4 and/or FE4 sequences were found on 4 of the 5 autosome pairs of *M. persicae*. The evolution of both E4- and FE4-based resistance, including the role of the translocation and possible origins of the multiple loci, will be discussed.

19-007

ANALYSIS OF SODIUM CHANNEL GENE SEQUENCES IN KDR & SUPER-KDR HOUSEFLIES (*MUSCA DOMESTICA*)

D. Martinez-Torres, M.S. Williamson, C.A. Hick, A.L. Devonshire
IACR-Rothamsted, Harpenden, Herts, AL5 2JQ, UK

The pyrethroids are a major class of synthetic insecticides with widespread uses in the control of agricultural and human health insect pests. Their intensive use over the last 20 years has, however, led to the development of resistance in many insect species, and this represents a significant and increasing threat to their continued effective use. An important mechanism of resistance to pyrethroids, known as knockdown resistance or *kdr*, confers nerve insensitivity to these compounds and is thought to result from a modification of their primary target site, the voltage-sensitive sodium channel. This type of resistance has been best characterised in the housefly where several *kdr* alleles, including the more potent *super-kdr* factor, have been identified.

To investigate the molecular basis of the *kdr* mechanism, we have cloned the full 6.3kb coding sequence of the *para*-type sodium channel gene from a susceptible housefly strain. The cDNAs predict a polypeptide of 2108 amino acids with close sequence homology (92% identity) to the *Drosophila para* sodium channel, and around 50% homology to vertebrate sodium channels. Comparative sequence analysis of a range of housefly strains carrying *kdr* and *super-kdr* resistance factors has revealed two amino acid mutations that correlate with the resistance phenotypes. Both mutations are located in a region of the sodium channel known to be important for channel inactivation.

19-008

SEQUENCING OF DNA STRUCTURES OF THE PARA-TYPE SODIUM CHANNEL GENES FROM KDR-RESISTANT *BLATTELLA GERMANICA* AND *MUSCA DOMESTICA*

Fumio Matsumura, M. Miyazaki, K. Ohyama
Departments of Environmental Toxicology and Entomology, University of California, Davis, California 95616, USA

Using reverse transcription polymerase chain reactions (RT-PCR), the DNA sequence for the main membrane spanning region (IS3, through 20 bases beyond IVS6) of the gene encoding the α -subunit of the para-sodium channel of the German cockroach, *Blattella germanica* has been identified. The overall structure of this open reading frame region of the *Blattella germanica* gene is very similar to the para gene of *Drosophila melanogaster*, and that of the partially sequenced para gene of *Musca domestica*. On the other hand, it is distinctly different from that of the DSC gene (*Drosophila* sodium channel). As a result of a side-by-side comparison for the para gene sequences of the susceptible CSMA strain against the *kdr* resistant VT strain of *B. germanica*, one mutation (TTG to TTC) at the approximate center of the IIS6 membrane spanning region was found to result in an amino acid shift from L to F. While functional meaning of this mutation on the operation of the para-sodium channel remains to be studied in the future, it has been noted that this region is very conserved among all sodium channels identified so far in many species and is the most hydrophobic area of the entire α -subunit. For comparison, we have studied the same region of the para-sodium channel of both *kdr* and susceptible houseflies, *M. domestica*. We found the similar type of mutation, CTT to TTC, resulting in the same shift of amino acid L to F on this site. However, in the case of houseflies, both *kdr* and susceptible strain contained L and F.

19-010

NONSTEROIDAL ECDYSTEROID AGONISTS AS INSECT CONTROL AGENTS

Glenn R. Carlson

Rohm and Haas Research Laboratories, Spring House, Pennsylvania, USA.

The diacylhydrazine ecdysteroid agonists were first discovered by Rohm and Haas scientists over ten years ago. Extensive research in this area has so far yielded one commercial insecticide, tebufenozide, and two promising compounds in the pre-commercialization phase, RH-2485 and RH-0345.

Tebufenozide (MIMIC™, RH-5992) is a safe, effective, and highly selective caterpillar control agent for use in a wide range of vegetable, orchard, and agronomic crops. Because of its extraordinary safety to a wide range of predatory and parasitic arthropods, it has proven to be an effective tool for integrated pest management.

RH-2485 is a second generation caterpillar control agent. It is significantly more potent than tebufenozide at both the target site and the whole insect level. It has a broader caterpillar control spectrum.

RH-0345, currently under joint development in the US with American Cyanamid Corporation, is a highly effective soil/foliar applied control agent for grubs and caterpillars in turf.

The history, mode of action, and insecticidal properties of these compounds will be discussed.

19-009

SPINOSAD, THE FIRST MEMBER OF A NEW CLASS OF INSECT CONTROL PRODUCTS, THE NATURALYTES
L.L. Larson¹, T.C. Sparks¹, T.V. Worden¹, J.R. Winkle¹, G.D. Thompson¹, H.A. Kirst², J.S. Mynderse²

1 DowElanco Discovery Research, Indianapolis, Indiana.

2 Lilly Research Laboratories, Eli Lilly and Co. Indianapolis, Indiana.

Spinosad, the first product in the naturalyte class of insect management tools, is a mixture of two fermentation-derived products produced by *Saccharopolyspora spinosa*, a new species of Actinomycete discovered in a Virgin Islands rum still. This material exhibits such a favorable environmental and mammalian toxicity profile that it has been designated a reduced risk pesticide by the United States EPA. Spinosad is rapidly degraded in light, but is stabilized on leaf surfaces. Its rainfastness as a suspension concentrate is comparable to commercial standards, and its activity is unaffected over a wide range of pH's. Spinosad is selectively active on insects in the Orders: Lepidoptera, Diptera, Thysanoptera, and some Coleoptera and Hymenoptera. Targeted crops are cotton, vegetables, tree fruits, and nuts at use rates of from 50-180 grams AI/Ha. Spinosad, with its unique characteristics, does indeed fit a class of its own, and will offer an exciting pest management alternative for the future. No other naturally sourced material has its' combination of excellent contact and residual efficacy on target pests and safety to beneficials, aquatic organisms, and mammals. It will fit very well into Insect Pest Management Systems.

19-011

PYRROLE INSECTICIDES: DISCOVERY, PHARMACODYNAMICS AND BIOLOGICAL ACTIVITY

M.F. Treacy

Insecticide Discovery, American Cyanamid Co., Princeton, NJ USA

Following isolation and characterization of dioxapyrrolomycin (an actinomycete fermentation product), chemical synthesis work was started at American Cyanamid to obtain a highly active insecticide of novel structure and action mechanism. *In vitro* mitochondrial assays demonstrated that these synthetic pyrroles exert their insecticidal impact via uncoupling of oxidative phosphorylation. Structure-bioactivity relationships indicated that pesticidal properties of this chemical series could be optimized via differential pyrrole ring substitutions (e.g., electron withdrawing groups). Analogs possessing a balance of molecular acidity and lipophilicity in a pKa range of 7.0 - 7.8 and logP of approx 5.0 demonstrated greatest insecticidal activity. An N-substituted 2-arylpyrrole, CL 303,630, is known to be a prodrug and possesses excellent insecticidal and acaricidal activity (it is currently in a global registration and development program).

19-012

PYMETROZINE, AN EFFICIENT SYNTHETIC FEEDING INHIBITOR SPECIFIC TO HOMOPTEROUS PESTS, IS TRANSLOCATED IN BOTH PLANT XYLEM AND PHLOEM.

M. Bolsinger and P. Wyss
Ciba-Geigy AG, Insect Control, Crop Protection Division
CH-4002 Basel, Switzerland

Pyrimethrin (CGA 215'944) is a highly selective insecticide against plant sucking pests, provoking an immediate feeding stop and a subsequent starvation of affected insects to death. High efficacy against target pests is achieved after both drench and foliar application on plants.

Acropetal translocation of the compound is evident with the protection of the shoot against aphids after drench application, and can be explained by xylem transport. Additionally, systemic effects were also observed after foliar application. With a sequence of bioassays it could be shown that activity resulted not only from an acropetal but also from a basipetal translocation of the compound. This translocation is typical for photoassimilates, which move from source (mainly expanded leaves) to sink (roots, growing points and emerging leaves) over the phloem. After foliar application, pyrimethrin translocation in the phloem may therefore contribute to the long term control of aphids and whiteflies, since it is imported from the leaves to the growing parts of the shoot. This translocation pattern of the compound in the plant, which has been inferred from bioassays, was confirmed by detection and visualizing of pyrimethrin using autoradiographic techniques.

19-014

NEONICOTINOIDS-RETROSPECT AND PROSPECT

I. Yamamoto

Department of Agricultural Chemistry
Tokyo University of Agriculture, Setagaya, Tokyo, Japan
Nithiazine was invented as the first nitromethylene insecticide, though not commercialized. However, introduction of the 3-pyridylmethyl group on nitromethylene heterocycles remarkably increased the insecticidal activity and further optimization resulted in the invention of imidacloprid. It was shown that nithiazine and imidacloprid are agonists to the nicotinic acetylcholine receptor (nAChR), and imidacloprid and nicotine shared the same structural moiety, structure-activity relationships and mode of action. Because of the invention of several analogs of imidacloprid, which have either nitromethylene, nitroimino or cyanoimino group, they can be collectively called neonicotinoids. However, there are distinct differences between neonicotinoids and neonicotinids. Nicotine is highly toxic to mammals and has limited insecticidal activities, while imidacloprid has the opposite properties. Nicotine should have a basic nitrogen atom, which is positively charged in the insect body and provides a site of interaction with the nAChR, while the corresponding nitrogen atom in imidacloprid is not ionized but bears a partial positive charge, which is enough to interact with the insect nAChR, but not enough with the vertebrate one. Novel neonicotinoids, nitenpyram and acetamiprid share the above characteristic, but differ from imidacloprid in stability and insecticidal spectrum, thus can be complementarily utilized. The hydrophobicity of the compounds is a key factor. These generalization provide a biorational basis for further development of this series.

19-013

NEW ANTI-INSECT EXTRACT FROM A FOLK PLANT IN SOUTH AMERICA (VALLESIA GLABRA-APOCYNACEA).
E. Wood and E. Zerba.
CIPEIN(CITEFA-CONICET), Villa Martelli, Buenos Aires, ARGENTINA.

Vallesia glabra is the latin name for Ancoche which is the vernacular name for a ten foot tall bush that belongs to the Apocynacea family. Ancoche can be found from Florida up to Argentina, overlapping the endemic area of Chagas' disease in the American continent. Triatoma infestans is the latin name for Vinchuca which is the major vector of Chagas' disease or American Trypanosomiasis in Argentina. The disease was first described by Carlos Chagas in 1909 and still remains endemic and incurable in 1996. Ancoche was first described in 1799 but has never been tested as a potential insect control agent. In pursuing the study of anti-triatoma properties of extracts prepared from indigenous plants in Argentina, it was assessed the in vivo activity of Ancoche in vinchucas. Films or topical application bioassays showed acute toxicity in nymphs and adults. In fact, 5 ug of purified fraction per insect showed 100% mortality. The acetonic extracts did not show any repellency, but in survival females exposed to Ancoche extracts produced a significant decrease in laying eggs, and also a much lower ratio of hatched eggs. The purified fraction from Ancoche extracts showed anti-cholinesterase activity (IC₅₀=15 ug/ml) and also inhibition of glutathione S-transferase from T. infestans (IC₅₀=50 ug/ml). This preliminary study is the first concerning a botanical material active against the major vector of Chagas' disease in South America.

19-015

Imidacloprid: Discovery and Development

Shinzo Kagabu*

Department of Chemistry, Faculty of Education

Gifu University, Gifu 501-11, Japan

Imidacloprid, [1-(6-chloronicotinyl)]-2-nitroiminoimidazolidine, is a new type of insecticide possessing potential activity and novel modes of action. It controls resistant insects, has a broad spectrum of activity especially against sucking pests, excellent systemic properties and high residual activity. Imidacloprid was the end product of about 2000 compounds prepared during the synthetic study started by modifying the structure of the lead compound, nithiazin. The key step to the development of the new pesticide class was finding of a latent activator, 6-chloronicotinyl group. By introducing this group to the skeletons of the leading molecules the original insecticidal activities were increased enormously by a factor of several hundreds, and the target insect sorts were remarkably broadened. There remained dozens of equally active candidates for commercial use at the laboratory test levels. Imidacloprid was selected among them, principally owing to its superior properties under practical conditions. It is rather hydrophobic among the generally hydrophilic compounds in this class, is stable under acidic and neutral conditions, and resists air-oxidation. The definitive advantage of imidacloprid over the nitromethylene analogues like nithiazin is its photostability. The nitromethylene compounds decompose rapidly under the sunlight because of the chromophore of longer wavelengths than 290 nm.

19-016

FIPRONIL, AS A NEW BROAD SPECTRUM INSECTICIDE WHICH ACTS ON THE GABA REGULATED CHLORIDE CHANNEL.

D.F. Bushey, A.E. Chalmers, D.B. Gant, M.A. Wolff, and H.B. Hoffman.
Rhône-Poulenc Ag Co., Research Triangle Park, North Carolina, USA

The new insecticide, fipronil, represents a new class of chemistry with significant broad spectrum insect activity. The initial lead to this class of chemistry was discovered at the Rhône Poulenc Agro Sector research facilities at Ongar, England and was further developed into a commercial product at the R&D center at the Research Triangle Park, US. The initial compound was tested as a herbicide lead which turned out to have weak insecticide activity. This hint of activity was then the focus of a multi-year synthesis program that eventually led to the definition of the class of chemistry presently referred to as phenylpyrazoles.

These phenylpyrazoles, exemplified by fipronil, have been shown to act primarily on the GABA regulated chloride channel located in the central nervous system of the insect. This is supported by binding data on housefly tissue and by *Xenopus* oocyte data generated on a homomultimer of an insect GABA gene known as Rdl. There is also evidence that the inhibition of the GABA receptor is somewhat selective when one compares binding in vertebrate versus invertebrate tissue. Expression of the *Drosophila* Rdl in whole insect cells also gives a functional receptor that has pharmacological properties similar to that of the natural receptor that is presumed to be heteromeric.

Fipronil has been shown to be very much a broad spectrum product with especially good activity on certain insects, such as housefly, locust, and mole cricket. The biological activity is a mixture of topical and ingestion depending on the insect and the method of application. Field data has been consistent and has led to the registration of the active ingredient in a number of countries and crops around the world.

19-018

NOVALURON (MCW-275), A NOVEL BENZOYLPHENYL UREA, SUPPRESSING DEVELOPING STAGES OF LEPIDOPTERAN, WHITEFLY AND AGROMYZID LEAFMINER PESTS.

I. Ishaaya, S. Yablonski, Z. Mendelson, Y. Mansour and A.R. Horowitz
Department of Entomology, Agricultural Research Organization, The Volcani Center, Bet Dagan 50250, Israel

Novaluron, 1-[3-chloro-4-(1,1,2-trifluoro-2-trifluoro-methoxyethoxy)phenyl]-3-(2,6-difluorobenzoyl) urea, a novel benzoylphenyl urea, acts by inhibiting chitin formation, thereby causing abnormal endocuticular deposition and abortive molting. While most of benzoylphenyl ureas act mainly by ingestion, Novaluron seems to act by both ingestion and contact. As such it is a powerful suppresser of lepidopteran larvae such as *Spodoptera littoralis* and *Helicoverpa armigera* (by ingestion) and of the cotton whitefly larvae, *Bemisia tabaci* (by contact). The compound is now under advanced development by Makhteshim Chemicals.

The LC₅₀ value of Novaluron on 3rd-instar *S. littoralis* fed on castor bean leaves treated with the compound is ~ 0.1 mg (AI)/liter. This value resembles that of chlorfluazuron and is about 10-fold lower than that of teflubenzuron. An application of 250 g (AI)/ha in cotton fields resulted in 100% mortality of both *Spodoptera* and *Helicoverpa* larvae up to day 8 after application and about 60 and 30% mortality, respectively at day 15.

Novaluron affects, to a much higher extent, eggs and larvae of *Bemisia tabaci* than chlorfluazuron and teflubenzuron. Suppression of 100% egg hatch was obtained at a dipping concentration of 0.5 mg (AI)/liter and of 1st and 2nd instars at a concentration of 1 mg (AI)/liter.

Novaluron is far more active in suppressing developing stages of the leafminer *Liriomyza huidobrensis* than teflubenzuron and chlorfluazuron. Suppression of over 80% adult formation was obtained at a concentration of 0.8 mg(AI)/liter and a similar suppression of pupation and mine formation at a concentration of 20 mg (AI)/liter. Addition of 0.1% surfactant to Novaluron solution, increased considerably its potency, resulting in 80% and 100% suppression of pupation and adult formation, respectively, at a concentration of 0.8 mg (AI)/liter.

Our results indicate that Novaluron is a potential compound for controlling Lepidopteran pests, whiteflies and agromyzid leafminers in field crops, vegetables and ornamentals.

19-017

MOLECULAR MODELING OF OCTOPAMINERGIC AGONISTS

A.Hirashima, H.Hirakawa¹, S.Kuhara¹, E.Taniguchi, M.Eto²

Department of Agricultural Chemistry, Kyushu University, Fukuoka 812-81, Japan - 1 Laboratory of Molecular Gene Technics, Kyushu University, Fukuoka 812-81, Japan -2 Miyakonojo National College of Technology, Miyakonojo 885, Japan

Crowding, cold shock, and heat stress, which did not affect octopamine (OA) titers, as well as juvenile hormone (JH)-esterase inhibitor delayed pupation of *Tribolium freemani* larvae, reducing JH-esterase activity. Isolation, light irradiation, vibration, which stimulated OA titers, and OA agonists as well as precocene accelerated the pupation, increasing JH esterase activity. Thus OA agonists may be useful as insect growth regulators.

The quantitative relationship between the structure of 2-(substituted benzylamino)-2-thiazolines (SBTs) and their OA-agonist activities against the nervous tissue of American cockroach *Periplaneta americana* was studied by using reported physicochemical parameters and regression analysis. The electronic feature of a substituent was important: the more electron-donating the substituent, the greater the activity against *P. americana*.

Molecules were built by using the BIOSYM package of programs. Molecular geometries of elonidine, (R)-OA, and the formamidic insecticide, chlordimeform, were obtained from available X-ray crystallographic data and were used as the starting point for subsequent calculations. Each structure was energy-minimized by using MOPAC program (6.0) running on the Cray super computer system (Y-MP2E/264) and then reoriented to compare the superimposition of the phenyl group and side-chain N atom of each structure: these features were postulated to be important for OA activity. Based on the comparison of OA and known OA agonists, it was proposed that new compounds could be synthesized which possess similar structural features to OA and OA agonists.

19-019

LOCUST CONTROL TREATMENT CONDITIONS USING FIPRONIL : EXPERIMENTAL RESULTS.

J.-F. Duranton, M.H. Launois-Luong

CIRAD-GERDAT-PRIFAS, BP 5035, 34032 Montpellier Cedex 1, France

Fipronil, a phenyl-pyrazol pesticide, was developed by Rhône-Poulenc research scientists in 1981. This pesticide compound acts by inhibiting the GABA system involved in nerve signal transmission in insects.

Vegetable oil-based treatment formulations were prepared and meet acaricide specification criteria. The LD₅₀ and LD₉₀ of the product were determined through laboratory tests against several acridians, i.e. *Schistocerca gregaria* (Forskål, 1775), *Locusta migratoria* (L., 1758) and *Locustana pardalina* (Walker, 1870). The means of contamination and immediate and delayed effects were specified for 4 and 8 g a.i./ha doses under seminatural conditions (field cages) with Desert Locusts and Migratory Locusts. In operational conditions (total coverage), tests were carried out to perfect practical aspects of fipronil control treatments against Desert Locusts and various grasshoppers, and to assess fipronil effects on some non-target fauna.

The results showed that fipronil is an efficient acaricide at very low doses (4-8 g a.i./ha). It acts on contact (knockdown effect) and ingestion (delayed effect), which additively leads to very high locust mortality (>98%) within a few days. When tested at 11 g a.i./ha, fipronil remained toxic to locusts for 3-4 weeks. It could therefore be used in barrier treatments, essential for preventive locust control, especially against Desert Locusts.

19-020

EFFECTS OF A NONSTEROIDAL MIMIC OF 20-HYDROXY-ECDYSONE ON SURVIVAL AND DEVELOPMENT OF THE DIAMONDBACK MOTH, *PLUTELLA XYLOSTELLA* (L.)

Roger F. Hou and Ling-Lan Cheng

Department of Entomology, National Chung Hsing University, Taichung, Taiwan, ROC

Effects of a 20-hydroxyecdysone mimic, viz., RH-5992, on various stages of the diamondback moth, *Plutella xylostella* (L.), were investigated by feeding larvae on the kale leaves dipped into different concentrations of the mimic. This compound was effective to cause larval mortality only when treated various instars with the concentrations over 400 ppm. Although almost 100% cumulative mortality was obtained by treating 1st through 3rd instars with 400 ppm, the 4th instar was slightly lowered down to 87.5% with 400 ppm but maintained 97.5% with 800 ppm. The LC₅₀ values were 96.3, 95.3, and 105.8 ppm for 1st, 2nd, and 3rd instars, respectively. The LT₅₀ of 4th instar was ranged from 3.4 to 1.7 days at 100 to 800 ppm while it was ranged from 2.3 to 12.3 days for the other instars. The leaf consumption per larva was lower in the treatments with 100 ppm or above than the untreated control. The pupal weight, percent emergence, adult longevity and fecundity were affected when newly hatched larvae were continuously reared on the leaves treated with different concentrations of RH5992.

19-021

REDUCTION IN SPRAY VOLUMES AND PESTICIDE APPLICATION RATES IN POME FRUITS THROUGH IMPROVEMENTS IN SPRAY TECHNOLOGY.

R.J. Hardy

Specialist Agricultural Services Pty Ltd
Sorell, Tasmania, Australia.

The control of pests and diseases of pome fruits has commonly depended on high volume (1000-2000 litres per hectare) spraying. A large scale trial conducted in four Tasmanian apple orchards over two seasons demonstrated spray volumes can be successfully reduced to as little as 55 litres per hectare by optimising droplet diameter to 100 microns using Micon X1 spinning disks fitted to standard airblast sprayers.

Pesticide rates as low as 25% of the label rate achieved commercially acceptable control even under high levels of pest and disease pressure. The trials demonstrated the cost of spray application could be reduced by about 50%, largely due to time savings, which had the benefit of also achieving greater timeliness of application when the periods for spraying were limited by adverse weather. The commercial acceptance of even 25% of the label rates suggests integrated pest management programs that reduce insect, mite and disease pressure in apples to low levels prior to periods that favour pest outbreaks will allow the use of considerably less than label rates in many instances.

Very low volume applications were also successful in hops and glasshouse crops.

This investigation adds to the growing weight of evidence that suggests legislative restrictions that disallow the use of less than label rates and/or very low volumes are unnecessarily inhibiting the desire to reduce the use of pesticides and reduce the costs of pest management.

19-022

ACTION OF A NOVEL NONSTEROIDAL ECDYSTEROID AGONIST TEBUFENOZIDE IN *CYDIA POMONELLA* LARVAE IS RELATED TO PREMATURE MOULTING AND ARREST OF FEEDING: AN ULTRASTRUCTURAL ANALYSISE. Viñuela¹, G. Smagghe², F. Budia¹, J. Avilla³, D. Degheele²

¹ Unidad de Protección de Cultivos, E.T.S.I. Agrónomos, Madrid, Spain - ² Laboratory of Agrozoology, Faculty of Agricultural and Applied Biological Sciences, University Gent, Gent, Belgium - ³ Centre UdL-IRTA de R+D, Lleida, Spain

Toxicity assays indicated the substituted dibenzoylhydrazine tebufenozide (RH-5992) to be a potent agonist of 20-OH ecdysone, the natural insect moulting hormone, when tested on third-instar larvae of the codling moth, *Cydia pomonella* (L.). Upon ingestion, larvae showed characteristic effects of precocious larval moulting within 12 h of treatment, leading to head capsule apolysis and cessation of feeding. Shortly afterwards, intoxicated larvae died in a double cuticle. Phenotypic and structural changes of the integument related to new cuticle formation, and of muscle structure and attachment were studied by light, scanning and transmission electron microscopic analysis of control and treated preparations. This compound appears to act specifically on the ecdysteroid receptor of the epidermal cells and is suitable for use in crop protection due to its novel chemistry and mode of action and high selective toxicity for Lepidoptera.

19-023

COMPARATIVE TOXICITY OF FOLIAR AND SYSTEMIC APPLICATIONS OF TWO NICOTINYL INSECTICIDES (IMIDACLOPRID AND ACETMIPRID) AGAINST THE WHITEFLY *BEMISIA TABACI*
A.R. Horowitz¹, Z. Mendelson¹ and I. Ishaaya¹
Department of Entomology, Agricultural Research Organization, Gilat Experiment Station, Israel - ¹ The Volcani Center, Bet Dagan, Israel

Comparative bioassays of two nicotinyl insecticides, imidacloprid and acetmiprid, against the whitefly *Bemisia tabaci* (Gennadius), using foliar and systemic applications, were conducted under controlled room conditions, and field trials using foliar applications against aphids and whiteflies were done in a cotton field. Under controlled conditions, the ovicidal activity of foliar applications of acetmiprid on cotton seedlings was much higher than that of imidacloprid. According to LC₅₀ and LC₉₀ values, acetmiprid was 11- and 19-fold more potent than imidacloprid. Both compounds were effective when applied to soil against whitefly adults, however the potency of imidacloprid was somewhat higher than that of acetmiprid resulting in a LC₅₀ value of 3.6 mg (AI)/liter as compared with 10.4 mg (AI)/liter for acetmiprid. In an experimental cotton field, set in random blocks with 4 replicates, the efficacy of foliar applications of 60 g (AI)/ha acetmiprid and 210 g (AI)/ha imidacloprid was compared. Acetmiprid was very effective against *Aphis gossypii* Glover populations for 24 d after treatment, while imidacloprid was somewhat less effective. Residual activity of acetmiprid on whitefly adults lasted for approximately 10 d and of imidacloprid for only 3 d. Our results indicate that both nicotinyls are potential compounds for controlling whiteflies and aphids either by foliar or systemic application in field crops, vegetables and ornaments.

RH-0345, A NOVEL INSECT GROWTH REGULATOR: IMPACT OF SOIL TYPE, IRRIGATION, APPLICATION TIMING, AND APPLICATION RATE ON EFFICACY AGAINST JAPANESE BEETLE, *POPILLIA JAPONICA* NEWMAN (COLEOPTERA: SCARABEIDAE) GRUBS³
H. Oloumi¹, J. Thomas², D. Loughner³
¹ & ² American Cyanamid Co., Princeton, NJ USA;
³ Rohm and Haas Co., Spring House, PA USA
RH-0345 mimics the action of a natural insect hormone which induces the mortality and metamorphosis process in insects. This compound possesses systemic activity which could be used to simultaneously control both root-feeding and foliar-feeding pests of crops such as turfgrass. The results of laboratory, greenhouse, and field experiments studying the influence of soil type, time of insecticide application, irrigation and rainfall, and application rate on the control of several turfgrass insect pests including the Japanese beetle grubs will be discussed.

19-024

PHOTOINSECTICIDES, A NOVEL CLASS OF ENVIRONMENTALLY FRIENDLY AGENTS AGAINST *BACTROCERA OLEAE* AND *CERATITIS CAPITATA*

T. BEN AMOR¹ M. TRONCHIN¹ L. BRUNI¹ AND G. JORI^{1A}
V. GIROLAMI² ¹ DIPARTIMENTO DI BIOLOGIA UNIVERSITA DI PADOVA
² DIPARTIMENTO DI ENTOMOLOGIA UNIVERSITA DI PADOVA
We tested the potential of porphyrin -type photoactivatable compounds (photosensitizers) to promote the lethality of fruits flies upon exposure of the photosensitizer fed insects to sunlight .To ward this aim ,the following problems need to be addressed :
1) Choice of the photosensitizer .
2) Choice of light source
3) Definition of the minimal efficient amount of the photosensitizer
4) Definition of the optimal time of exposure to sunlight
5) Definition of most efficient light dose
For the second point we choose a halogen lamp whose emission spectrum covers the near UV/ visible range wave length and is very similar with the emission spectrum of sun
As regard the choice of the sensitizers the following parametrs were considered :
* The sensitizer must absorb spectrum with a high efficiency the largest possible portion of visible
* The sensitizer must generate toxic species such as radicals and singlet oxygen , with a high efficiency
To establish an efficient concentration of photosensitizers we adopted two methods :
a) The test of accumulation : the flies were fed with a mixture of water ,sugar and different concentrations of photosensitizer, a different concentration was used for ech group of flies
Subsequently we proceeded to the extraction of the photosensitizers from flies and to the determination of the extracted amount by emission fluorescence techniques
b) Different groups of flies that received no photosensitizer or were fed with increasing amounts of photosensitizer were irradiated under identical experimental conditions
The percent survival of flies yields the efficiency of the given photosensitizer concentration.
Analogously the efficiency of the exposure time and light power can be deduced from the percent survival .
Irradiation with natural sunlight confirms our results obtained with the artificial light source .

PRECOCIOUS METAMORPHOSIS-INDUCING ACTIVITY OF 1-SUBSTITUTED IMIDAZOLES

E. Kuwano, K. Shimazu, M. Shimizu, M. Sakaguchi, E. Taniguchi, K. Suzuki¹
Department of Agricultural Chemistry, Kyushu University, Fukuoka 812, Japan - ¹ Faculty of Agriculture, Iwate University, Morioka 020, Japan

We have already reported that a large number of 1,5-disubstituted imidazoles induce precocious metamorphosis in larvae of the silkworm, *Bombyx mori*. Recently we have found that various 1-substituted imidazoles induce precocious metamorphosis as well. 1-dodecylimidazole, 1-[3-(4-propylphenoxy)propyl]imidazole (**1**) and 1-[7-(4-ethylphenoxy)heptyl]imidazole (**2**) showed considerably higher activity than the other analogs containing variations in the carbon chain. Precocious metamorphosis induced by 1,5-disubstituted imidazoles, 1-dodecylimidazole and compound **1** was completely prevented by a simultaneous application of a small amount of tebufenozide, an ecdysteroid agonist, while the activity of compound **2** could not be counteracted by tebufenozide, indicating that the mode of action of compound **3** is different from that of other imidazoles.

FIELD EFFICACY TEST OF NEW INSECTICIDES AS TERMITICIDES

K. Nakayama¹, Y. Katsuda¹, Yun-qin Sun²

Research Laboratory, Dainihon Jochugiku Co Ltd
11-1, 1-chome Daikoku-cho Toyonaka, Osaka 561
Japan-1 Institute of Zoology, Academia Sinica
19 Zhongguancun Lu Haitien, Beijing China-2

In the course of our studies on termiticides Effects of molybdenum and tungsten compounds on termites were investigated.

These compounds possess the following characteristics (i) very slow acting and (ii) non repellent. Properties of Mo / W compound that make it suitable for use in bait block type termiticide.

We also have developed a useful method of forming waterinsoluble molybdenum and tungsten compounds. Baits prepared according to this method were applied in semi-field test in Japan and field test in Guangdong China.

The results of semifield and field tests are discussed.

PYMETROZINE: A CASE OF PERFECT SELECTIVITY

B. Sechser, B. Reber
Ciba-Geigy AG, Insect Control, Basel, Switzerland

Pymetrozine is the first representative of a new chemical class, the pyridine azomethines. It is active against sucking pests, where there is an urgent need for new compounds due to serious resistance problems. Another desirable feature is a high degree of selectivity. In three laboratory tests pymetrozine proved to be fully selective against the ladybeetle *Coccinella septempunctata*, the flower bugs *Orius majusculus* and *O. insidiosus*, and the green lacewing *Chrysoperla carnea*. In another trial, pymetrozine did not affect the parasitization capacity of *Encarsia formosa* against its host, the whitefly *Trialeurodes vaporariorum*, on tomatoes in a glasshouse when it was applied a single time.

Field selectivity trials were done on cotton, vegetables, pome fruit trees and glasshouse crops. A single spray on cotton in Egypt demonstrated excellent survival rates of the relevant predator groups (*Orius*, *Coccinella*, *Scymnus*, *Paederus*, *Chrysoperla*, spiders), comparable to the untreated control. A single spray against aphids on okra in Egypt resulted in perfect control of these pests, and surviving predators (*Orius*, *Chrysoperla*, *Coccinella*, syrphids) inhibited a reappearance of the aphid population. When pymetrozine was sprayed on a commercial tomato crop in a glasshouse in Switzerland for the control of aphids and whiteflies, it gave perfect control of both pest groups and allowed a complete parasitization of surviving pest specimens. Therefore pymetrozine can be considered as a unique case of combining both excellent pest control and outstanding selectivity.

19-028

NEW INSECTICIDE CHEMISTRY FOR CONTROL OF AUSTRALIAN PLAGUE LOCUST *CHORTOICETES TERMINIFERA* (WALKER) AND SPUR-THROATED LOCUST *AUSTRACRIS GUTTULOSA* (WALKER) IN AUSTRALIAN AGRICULTURE.R.M. Bull, G.H.S. Hooper¹

Rhone-Poulenc Rural (Australia) Pty Ltd, Brisbane, Australia - ¹ Australian Plague Locust Commission, Canberra, Australia.

A new phenyl pyrazole insecticide, Fipronil® was shown in field trials and a laboratory topical application assay to have high activity at very low doses against two of the major Australian locust species, *C. terminifera* and *A. guttulosa*.

Optimum field application rate was 7.5-10g active ingredient (AI) per hectare which achieved 80-100 percent mortality of both adult and juvenile stages in 1-3 days and was significantly ($P < 0.05$) better than the commercial standard, fenitrothion at 450g AI per hectare.

Serial introduction of fresh locusts into cages in treatment plots demonstrated good residual activity of Fipronil on rangeland herbage for up to 9 days after treatment while the intended commercial rate of Fipronil of 7.5-10g AI per hectare produced higher mortality and longer residual than fenitrothion.

PYMETROZINE: A NOVEL APHICIDE WITH A NEW MODE OF ACTION

D. Fuog, R. Senn, M. Bolsinger
Ciba-Geigy AG, Insect Control, Basel, Switzerland

Pymetrozine is the first representative of a new chemical class, the pyridine azomethines. The mode of action is different from all known mechanisms: an immediate feeding stop is followed later by death through starvation. Pymetrozine is active against aphids, whiteflies and hoppers in a large range of crops. Favourable toxicity and ecotoxicity profiles and its selectivity towards beneficial arthropods all contribute to an excellent fit into Integrated Pest Management programmes. Pymetrozine is highly effective in reducing the vectoring ability of virus-transmitting aphids.

The following aspects are covered in more detail:

- * Pymetrozine is not affected by cross resistance with established aphicides. This makes it a promising tool for resistance management.
- * Pymetrozine can be successfully applied through drip irrigation to control aphids in vegetables and in citrus. Pymetrozine is highly selective even with foliar application, however, application via the drip irrigation has several major advantages for the farmer. Workload is considerably reduced, and duration of control is increased. A longer duration of activity was observed with developing as opposed to fully developed plants.
- * Clear visual symptoms have been identified allowing to recognise the feeding stop before actual death of the pests.
- * The selectivity against bumble bees has been confirmed in a number of large scale trials. Pymetrozine applied to various crops in the glasshouse did not influence the activity of the bumble bees nor their pollination efficacy.

CONTROL OF CODLING MOTH (*CYDIA POMONELLA*) WITH SIRENE® CM, A NOVEL ATTRACT & KILL FORMULATIOND. Hofer¹, P. Charmillot², M. Angst¹

1) Ciba - Geigy AG., Crop Protection Division, CH - 4002 Basle, Switzerland; 2) Federal Agriculture Research Station, CH - 1260 Nyon, Switzerland

SIRENE® CM is a novel product for the control of codling moth (*Cydia pomonella*) in apple using the attract & kill concept to interrupt the life cycle at the adult moth stage.

The viscous slow release formulation based on a UV-absorber contains 6% of a contact insecticide and 0.16% of the pheromone codlemone as attractant. 150 or 300 g/ha of the formulation is applied in the form of 50 µl or 100 µl drops respectively. Application onto the leaves or branches is carried out by hand with a specially developed application system.

In 1995, registration trials were implemented in Switzerland after several years of successful testing SIRENE® CM.

SIRENE® fits very well into apple IPM programs due to its efficacy, selectivity and targeted application of low amounts of insecticide.

SIRENE®: Ciba - Geigy registered trade mark

19-033

MOLECULAR CLONING OF THE cDNA ENCODING THE PRO-PHENOLOXIDASE OF *HYPHANTRIA CUNEA* (LEPIDOPTERA: ARCTIIDAE)H.Y.Park, D.S.Park, S.S.Park, S.W.Shin, M.K.Kim, W.J.Lee¹, P.T.Brey¹

Insect Resources Laboratory, Korea Research Institute of Bioscience & Biotechnology, KIST, Taejeon, Korea -1 Unit of Ecology, Institut Pasteur, Paris, France

A cDNA clone encoding pro-phenoloxidase [pro-PO; zymogen of phenoloxidase (monophenol, L-dopa: oxydoreductase, EC 1.14.18.1)] was isolated from a Uni-ZAP XR library originated from the fall webworm, *Hyphantria cunea* larvae. This clone obtained with a 3.1kb insert that contained 5' initiation region and poly A signal.

The amino acid sequence was deduced from the respective cDNA. A hydrophobic NH₂-terminal sequence for a signal peptide is absent. The potential copper-binding sites shows high sequence similarity to POs especially *Bombyx mori* pro-PO P₁ and hemocyanins of arthropods. The overall cDNA sequence homology between fall webworm and other insect pro-POs ranged about 55-65%.

This clone was characterized by northern hybridization, southern hybridization and gene expression in insect cells.

19-032

PLANT MEDIATED EFFECT ON THE EFFICACY OF PYMETROZINE AGAINST APHIDS.

P. Wyss and M. Bolsinger

Ciba-Geigy Ltd, Insect Control, Crop Protection Division CH-4002 Basel, Switzerland

Pymetrozine (CGA 215'944) is a selective insecticide against plant sucking pests. It acts as a feeding inhibitor with a subsequent starvation to death. Highest efficacy is observed after food intake and much less after topical contact. Hence, in order to obtain a good efficacy the compound should reach the feeding site of the insect. Fortunately, pymetrozine is taken up by plants and translocated within the vascular system, the phloem and xylem. Thus, the compound is distributed over the whole plant and occurs at the same time at the main feeding site of aphids, the phloem. In such systems, plants as intermediate are known to be a determining factor for a high activity and persistence. In the case of pymetrozine most of the plant parameters tested, such as physiological development stage, age, shoot penetration, metabolism rate and soil type had no influence on the efficacy. In contrast plant species dependent efficacy was observed: against *Myzus persicae* a 40 time higher activity has been found on tomato than on sugar beet plants. This may be a consequence of local distribution of pymetrozine within leaf tissues. In fact, one third of extractable compound was found in the intercellular washing fluids of tomato leaves as opposed to only 5% in sugar beet leaves. Thus, a considerable amount of penetrated pymetrozine is localized in the intercellular space of tomato plants, but not in sugar beet. However, this distribution pattern alone does not account for all differences in activity observed, specially in cases where the efficacy of pymetrozine on two plant species is similar against one aphid species and very different against a second aphid species, as seen on pea seedling and sugar beet plants against *Aphis craccivora* and *M. persicae*. Such variations in efficacy may be explained by plant species dependent feeding behaviour of the aphids.

19-034

PRECOCIOUS METAMORPHOSIS-INDUCING ACTIVITY OF A NOVEL SERIES OF 3-PYRIDYL ETHERS

M. Shimizu, E. Kuwano, E. Taniguchi, K. Suzuki¹

Department of Agricultural Chemistry, Kyushu University, Fukuoka 812, Japan - 1 Faculty of Agriculture, Iwate University, Morioka 020, Japan

We have recently found that a new series of 3-pyridyl ethers induce precocious metamorphosis in larvae of the silkworm, *Bombyx mori*. Both 2- and 4-pyridyl ethers were completely inactive, indicating that 3-pyridine moiety was essential for the activity. Octyl, dodecyl, and farnesyl 3-pyridyl ethers had no activity. Among the compounds tested so far, 5-(4-propylphenoxy)pentyl 3-pyridyl ether showed the highest activity. The activity fell off with increasing or decreasing length of the carbon chain between two oxygen atoms. Introduction of a methyl group at the 6 position of the pyridine ring completely eliminated the activity. Precocious metamorphosis induced by 3-pyridyl ethers was counteracted by a simultaneous application of a small amount of tebufenozide, an ecdysteroid agonist, suggesting that 3-pyridyl ethers caused ecdysteroid deficiency in the larval hemolymph to induce precocious metamorphosis.

SPINOSAD: AN OVERVIEW OF THE INSECTICIDAL ACTIVITY OF THIS NOVEL BIOLOGICALLY-DERIVED COMPOUND

A. Adán, P. Del Estal, E. Viñuela

Protección de Cultivos. E.T.S.I.Agrónomos.
Universidad Politécnica. Madrid. Spain.

Spinosad belongs to a novel class of macrocyclic lactones produced by the soil actinomycete *Saccharopolyspora spinosa*, recently discovered by DowElanco. The compound is a complex of several natural metabolites, being spinosyns A and D, the two most active factors identified up to day.

Spinosad acts both as contact and stomach poison on the nervous system in a new manner, but the actual molecular mode of action is still unknown.

Furthermore, this new insect control agent has a very low mammalian toxicity.

In a variety of laboratory tests, the compound has been tested against 7 species of 5 orders, and the best results have been achieved against dipterans and lepidopterans.

19-037

[6-CHLORO-3-PYRIDYLMETHYL-³H]NEONICOTINOIDS: HIGH AFFINITY RADIOLIGANDS FOR THE NICOTINIC ACETYLCHOLINE RECEPTOR

B. Latli, M.-Y. Liu, M. Tomizawa, and J. E. Casida
Environmental Chemistry and Toxicology Laboratory, Department of Environmental Science, Policy, and Management, University of California, Berkeley, California 94720-3112

Neonicotinoids, acting at the nicotine binding site of the nicotinic acetylcholine receptor (nAChR), are one of the most important new classes of insecticides. Imidacloprid, the first commercial member of this new class, was synthesized in radioactive form with a specific activity of 25 Ci/mmol¹ and provided an outstanding radioligand that undergoes high affinity specific binding to the nAChR in house fly head membranes.² Since then several neonicotinoids have been prepared at high specific activities by methods applicable to neonicotinoids in general.³ These tritium-labelled compounds have helped greatly in mode of action research on the insect nAChR.⁴⁻⁷

INTERNATIONAL STUDIES OF THE NEWEST ACRIDICIDE : THE FUTURE OF FIPRONIL

Alexandre V. Latchininsky¹

All-Russian Research Institute for Plant Protection (VIZR), Saint-Petersburg - Pushkin, Russia

¹Current address: Department of Plant, Soil and Insect Sciences, University of Wyoming, Laramie, WY USA

Fipronil is an insecticide developed by Rhône-Poulenc Company. It belongs to a new family of phenyl-pyrazoles. Fipronil acts by blocking the GABA-regulated channels in the synaptic transmissions of the insect nervous system. It possesses a systemic action, being toxic both by ingestion and contact. Applied at very low rates (about 10 g of active ingredient per hectare), it causes the wholesale mortality in locust or grasshopper populations within a few days after treatment. The field tests of Fipronil were conducted in 1995 in Lake Baikal Region (East Siberia, Russia), to control temperate non-swarving grasshoppers. The community of grasshoppers exposed to treatments included 10 species, predominantly of Gomphocerinae subfamily. Age varied from first-instar hoppers to adults, the average grasshopper density was 28.8 individuals/m². Applied at the rate of 7.2 g a.i./ha, Fipronil caused 81-87% mortality of grasshoppers 24 h after treatment. Tests conducted in 1994-1995 in Mauritania by CIRAD-PRIFAS (France) established the rates of Fipronil efficient to control the Desert locust: 6.25 g/ha for total area treatments and 12.5 g/ha for barrier treatments. In these tests, the mortality of hoppers close to 100% was achieved 2-3 days after treatments.

Very high efficacy at extremely low dosages, good soil and foliar persistence, limited soil mobility, systemic action and formulation / application flexibility allow to consider the Fipronil as an outstanding acridicide, possibly a candidate to substitute the Dieldrin in locust and grasshopper control. It is virtually non-toxic for plants and mammals and low toxic for fish and birds. However, being highly toxic for many arthropods, further investigations are needed to evaluate the effects of the Fipronil on non-target arthropod fauna.

19-038

TOXICITY OF LARVIN® BRAND THIODICARB AND THREE OTHER INSECTICIDES TO SUSCEPTIBLE AND RESISTANT STRAINS OF TOBACCO BUDWORM *HELIOTHIS VIRESCENS* COLLECTED FROM DIFFERENT SITES IN THE USA. COTTON BELT

H.M. Ayad, R. G. Blenk, S. P. Schmidt and J. B. van Kretschmar.
Rhône-Poulenc Ag Co., Research Triangle Park, North Carolina, USA.

The results we accumulated over the last six years illustrated the consistence performance of Larvin® against susceptible and resistant populations of tobacco budworm collected from different sites in the cotton belt. These data are in agreement with our laboratory data that showed subjecting tobacco budworm larvae or eggs to the selection pressure of Larvin did not cause significant increase in the level of resistance to this compound. Another reason for Larvin consistence performance is our findings that small difference exists between its toxicity to the eggs collected from susceptible and resistant populations.

A careful examination of resistance ratios indicated that larvae collected from sites in the mid-south and south-west possessed high level of resistance to synthetic pyrethroid insecticides. Our biochemical studies show no significant difference between the penetration rate of Larvin in susceptible and resistant larvae. Also, Larvin was almost equitoxic to the acetyl cholinesterase enzymes separated from the heads of susceptible and resistant larvae.

19-039

SPATIAL DISTRIBUTION OF TEFLUBENZURON RESISTANCE BY PEAR PSYLLA IN WESTERN SWITZERLAND

L. Schaub and B. Bloesch, RAC Changins, Nyon, Switzerland

In recent years, pear producers in the region of Lake Léman observed an efficacy reduction of teflubenzuron against pear psylla (*Cacopsylla pyri* L.). Thus, in 1994 and 1995, we conducted experiments in the laboratory to confirm the efficacy reduction and to study the spatial distribution of the resistance in western Switzerland.

After application of a registered dose of teflubenzuron, all eight samples from orchards of the region of Lake Léman showed low mortality rates whereas the nine samples from the Valais showed normally high mortality rates. The estimation of the dose-mortality response of psylla from one orchard of each region confirmed these observations.

We conclude that the psylla of the Lake Léman region were resistant to teflubenzuron. Also, psylla from an organic orchard without any teflubenzuron treatment were resistant. This indicates that movement played an important role in psylla resistance development.

19-041

INHIBITION OF PYRETHROID RESISTANCE ESTERASES BY PIPERONYL BUTOXIDE IN AUSTRALIAN *HELICOVERPA ARMIGERA* (HÜBNER) (LEPIDOPTERA: NOCTUIDAE).

R. V. Gunning, G. D. Moores¹ and A. L. Devonshire¹
NSW Agriculture, The Tamworth Centre for Crop Improvement, Tamworth, Australia - ¹ Department of Biological and Ecological Chemistry, IACR-Rothamsted, Harpenden, UK.

The cotton bollworm *Helicoverpa armigera* (Hübner) is a serious pest of cotton and other summer crops in Australia, where it has a long history of insecticide resistance, (DDT, pyrethroids, carbamates, organophosphates and endosulfan). Chemical insecticides are currently essential for the control of *H. armigera* on cotton and are likely to remain an important component of control strategies for the foreseeable future.

Despite some pyrethroid synergism by piperonyl butoxide (Pbo), esterase mediated detoxification of pyrethroids has been found to be a major mechanism of resistance in *H. armigera*. This is due to the overproduction of esterase isoenzymes which sequester and hydrolyse pyrethroids.

Data presented in this paper shows that piperonyl butoxide is an effective inhibitor of esterase mediated hydrolysis of 1-naphthyl acetate in *H. armigera*. Up to 50% of enzyme activity, in the pyrethroid resistance related esterase, could be inhibited by piperonyl butoxide. Concentrations of Pbo which produced this effect, are similar to the internal concentrations of Pbo which synergise pyrethroids against *H. armigera*. We suggest that this esterase inhibition, is at least partially responsible for pyrethroid synergism by Pbo in Australian *H. armigera*.

19-040

DEVELOPMENT OF RESISTANCE TO MULTIPLE CLASSES OF INSECTICIDES IN *HELIOTHIS VIRESCENS* (F.) (LEPIDOPTERA: NOCTUIDAE) POPULATIONS IN THE U.S. MID-SOUTH

G. W. Elzen

USDA, ARS, Southern Insect Management Laboratory, Stoneville, MS USA

The tobacco budworm, *Heliothis virescens* (F.), an important pest of cotton in the United States, has developed resistance to nearly every class of insecticide used in cotton. Effective management of resistance depends in part upon a knowledge of insecticide resistance levels. Several different bioassays have been used during the past decade to characterize resistance in this pest. This paper summarizes findings of these studies and presents results of recent evaluations of resistance levels and cross-resistance patterns.

Resistance to pyrethroid insecticides was first detected in the 1985 and 1986 cotton growing seasons in West Texas, Louisiana, and Mississippi. Increased tolerance to carbamates and the cyclodiene endosulfan was first detected in 1989 and 1990, respectively, in Mississippi. Resistance to carbamates and organophosphorus insecticides was confirmed in Louisiana and Mississippi in 1990. Resistance to endosulfan was confirmed in a tobacco budworm strain collected in Mississippi in 1992. Through 1995, resistance levels remained higher to pyrethroids than to carbamates. The organophosphorus insecticides, with low levels of resistance, remained the more effective materials. No cross-resistance was found between different classes of insecticides with the exception of carbamates and organophosphorus insecticides. Currently, the number of alternative insecticides is limited.

19-042

ESTABLISHING INSECTICIDE SUSCEPTIBILITY BASE-LINES FOR *HELIOTHINE* CATERPILLARS, USING IRAC BIOASSAY METHOD NO 7

J J Osborn, A R McCaffery, R M Perrin¹

School of Animal and Microbial Sciences, University of Reading, Reading, RG6 2AJ, UK - ¹ ZENECA Agrochemicals, Fernhurst, Haslemere, GU27 3JE, UK

In order to monitor resistance levels in arthropod pests, it is important to establish reliable dose-responses and LD₅₀'s in known susceptible strains, against which field-collected populations can be compared and resistance factors or ratios calculated. This IRAC-funded study has generated base-line dose responses in four strains of *Heliothine* caterpillars against seven compounds representing the major product chemistries used for control of cotton bollworms. Discriminating doses based on these data will be validated in field studies in 1996/97.

IRAC Method No 7 was used throughout, as this is being promoted as a convenient and versatile bioassay procedure for leaf-feeding pests. Some strengths and weaknesses of the method are presented. A full report of the study is available from the authors.

19-043

RAPID SELECTION OF MALATHION RESISTANCE IN THE CAT FLEA *CTENOCEPHALIDES FELIS* (BOUCHE) (SIPHONAPTERA: PULICIDAE)
E. W. Moyses, A. Buchy, Ciba-Geigy, Animal Health, Basel, Switzerland.

Cat fleas were bred in the laboratory with the aid of an artificial feeding system. Susceptibility was measured by 24 hour exposure of unfed adults to insecticide deposits on filter paper. The LC_{50} of a field strain from Greensboro, NC, USA was 93 mg malathion/ m^2 . The corresponding "baseline" strain value was 63 mg. The Resistance Ratio (RR) was therefore 1.5. At the LC_{90} level the values were 400 and 140, respectively (RR = 2.8). A small fraction of the field strain population (3%) was not killed at 800 mg malathion/ m^2 .

Malathion selection pressure was applied, using the same methodology, first with 400 mg/ m^2 then in further generations with: 800 mg/ m^2 (F_1 to F_{11}) and 1,600 mg/ m^2 (F_{12} to F_{17}). Malathion resistance developed rapidly. The mortalities due to the selection process were: generation F_0 - 91%; F_1 - 45%; F_2 to F_{11} - average 17%; F_{12} to F_{17} - average 11%. Bioassays were made in F_2 , F_{14} and F_{16} with various concentrations of malathion. At the highest concentration tested (12,800 mg/ m^2) the highest mortality was 30% in F_{16} (RR = 260). Generations F_{18} and F_{19} were selected with 12,800 mg malathion/ m^2 . The resultant mortalities were 23% and 42%, respectively.

Higher mortalities could be obtained with topical application of very high dosages. A mortality of 95% (after 48 hours) was reached in F_{19} with a dosage of 20,000 ng malathion/insect. The corresponding value for the baseline strain was 29 ng. The RR at LD_{95} was therefore 690. This is, as far as we know, by far the highest resistance ratio recorded in the cat flea. The RR for malaoxon, in a similar comparison was only 18. These results are discussed.

19-045

ASPECTS OF INSECTICIDE RESISTANCE AND REPRODUCTIVE BIOLOGY OF *APHIS GOSSYPYII* GLOVER ON SEED POTATOES

D. Rongai, C. Cerato, R. Martelli
Istituto Sperimentale per le Colture Industriali, Bologna, Italy

For several years the aphid population patterns and the incidence of the main potato virus diseases have been monitored in Italian potato-growing areas. Starting from 1992, an increase in *Aphis gossypii*, as compared to *Myzus persicae*, *Macrosiphum euphorbiae* and *Aphis fabae*, was observed on seed potato fields in the north of Italy.

Laboratory tests revealed that *A. gossypii* was insensitive to the pesticide Pirimicarb, even at the maximum dose tested (2400 $\mu\text{g.ml}^{-1}$). Moreover, in the presence of Pirimicarb the reproductive capacity increased up to 28% as compared to the control and the new-born aphids began to appear 2 days earlier in the treated group. *M. persicae*, on the other hand, was controlled at a lower dose (300 $\mu\text{g.ml}^{-1}$). Lambda-Cyhalothrin (Karate) and Imidacloprid (Confidor) were very effective against both aphids.

19-044

GEOGRAPHIC VARIATION IN TOLERANCE OF THE RICE YELLOW STEM BORER (LEPIDOPTERA: PYRALIDAE) TO *BACILLUS THURINGIENSIS* TOXINS

R.M. Aguda¹, L.M. Criseno², F.L. Gould³, M.B. Cohen¹

¹Entomology and Plant Pathology Division and ²Biometrics Unit, International Rice Research Institute, Philippines;

³Department of Entomology, North Carolina State University, USA.

The yellow stem borer (YSB), *Scirpophaga incertulas*, is a major pest of rice in Asia and one of the principal targets of genetic engineering of rice with toxins from *Bacillus thuringiensis* (Bt). We examined geographic variation in tolerance of YSB to three Bt toxins, CryIA(c), CryIC, and CryIIA, that are highly toxic to YSB in the Philippines. Among populations collected on Luzon Island, Philippines, LC_{50} values did not differ among collection sites within towns or among towns within provinces. However, we detected small but significant differences in LC_{50} s for all three toxins among populations from three provinces.

YSB from China and Vietnam were more tolerant of all three toxins than were YSB from the Philippines. The LC_{50} of CryIC and CryIIA was up to 200-fold and 70-fold higher, respectively, in YSB from China than from the Philippines. Bt plants genetically engineered with CryIA(c), CryIC, or CryIIA should perform similarly well across the area of the Philippines that we studied. However, plants with CryIC and CryIIA may not perform as well in China, unless levels of toxin production are high enough to account for the possible higher tolerance of local YSB populations.

Acetylcholinesterase and P450 genes and insecticide resistance in *Heliothis virescens*.

Thomas M. Brown, Christopher L. Evans, Satish Pimprale, Patricia K. Bryson.

Department of Entomology, Clemson University, Clemson, South Carolina 29634-0365, USA;

e-mail: tbrown@clemson.edu

Heliothis virescens is a pest of cotton and tobacco in South Carolina. Resistance to methyl parathion was detected in 1978. Most cotton growers have changed to synthetic pyrethroid insecticides. After 18 years of application of synthetic pyrethroids, resistance to this class has been detected in South Carolina.

A portion of the acetylcholinesterase gene of *H. virescens* was amplified by the polymerase chain reaction (PCR) using degenerate primers designed from known sequences of other insects and employed in a nested procedure with RNA as template. The resistant form of this enzyme confers 20-fold resistance to methyl parathion. Also, PCR primers were designed to amplify the CYP9 gene of *H. virescens* from genomic DNA as template and a putative mutation in this gene will be described. Progress in linkage mapping of resistance genes and marker genes in this species will be reported.

19-047

ANTIFEEDANT-EFFECT, BIOLOGICAL EFFICACY AND HIGH AFFINITY BINDING OF IMIDACLOPRID TO ACETYLCHOLINE RECEPTORS IN TOBACCO ASSOCIATED *MYZUS PERSICAE* (SULZER) AND *MYZUS NICOTIANAE* BLACKMAN (HOMOPTERA: APHIDIDAE)

R. Nauen, H. Grothe, B. Tollo, K. Tietjen, A. Elbert

Bayer AG, Agrochemicals Division, Research Insecticides, Leverkusen, Germany

Myzus persicae (Sulzer) and *Myzus nicotianae* Blackman are two closely related homopteran pests and resistance to carbamates, organophosphates, and pyrethroids due to elevated levels of carboxylesterases and insensitive acetylcholinesterase is now widespread in both species.

Imidacloprid, a chloronicotinyl insecticide acting agonistically on nicotinic acetylcholine receptors, controls resistant aphid strains of both species due to its lack of any bonds susceptible to degradation by esterases. Nevertheless earlier studies as well as this study showed that in particular tobacco associated forms of *M. persicae* and *M. nicotianae* seemed to be somewhat less susceptible (5- to 10-fold) to this insecticide than susceptible reference strains.

Furthermore *M. nicotianae* seems to be more tolerant to antifeedant effects evoked by sublethal concentrations of imidacloprid relative to a susceptible reference strain. Antifeedant effects were bioassayed using a floating-leaf choice test and by counting excreted honeydew droplets.

Receptor binding studies with [³H]-imidacloprid and [³H]-nicotine in homogenates of *M. nicotianae* and *M. persicae* revealed no differences between susceptible and tolerant strains. Thus indicating that target site insensitivity is apparently not the mechanism for a 5- to 10-fold imidacloprid tolerance in *Myzus nicotianae*.

19-049

RESISTANCE OF TETRANYCHUS URTICAE KOCH. (TETRANYCHIDAE) TO BISCLOFENTEZIN

T. Stamenković¹, S. Stamenković², D. Marčić¹, S. Milenković²

¹Institute for science application in agriculture, Yugoslavia - J. ARI, "Serbia", Fruit and Grape Research Centre, Čačak Yugoslavia - ².

Investigation were carried out in the "Dedinje" glasshouse for flower growing (carnation, rose, etc.) in Belgrade. Over the 1984-1989 period the population of *Tetranychus urticae* was high and it considerably endangered flower production in almost all glasshouses in Serbia. Over the above-mentioned period two treatments per year were applied (Bisclofentezin combined with Cihexatin), providing successful flower protection against acarinae. Bisclofentezin was therefore applied until 1992. However, since 1988 the effect of Bisclofentezin has been observed to be considerably lower, especially in the last few years. The objective of this paper was to determine the resistance degree of *T. urticae* after Bisclofentezin has been applied for ten years.

The results obtained in this study show high degree of resistance in the studied population after 10 years of permanent treatments with Bisclofentezin. It is necessary to use some other acaricides instead of Bisclofentezin in the glasshouses where Bisclofentezin has been permanently applied for many years.

19-048

The *in vivo* mechanisms of housefly resistance to permethrin Yoji Takada, Takao Ishiwatari, Makoto Hatakoshi and Masachika Hirano

Agricultural Chemicals Research Laboratory
Sumitomo Chemical Co., Ltd., 4-2-1 Takatsukasa, Takarazuka, 665 Japan

In order to know the mechanisms of resistance to pyrethroids, the houseflies (*Musca domestica*) collected at Akagi, Gunma prefecture (Akagi colony) in Japan were used in this study. Permethrin selected Akagi PP15 strain showed the high resistance to pyrethroids. An increased metabolism by microsomal cytochrome P-450 dependent monooxygenase (mfo) system was responsible, but esterase was not related to the resistance in the study using synergists. And the *in vivo* metabolism of permethrin was also studied using ¹⁴C labeled compound. But the difference of metabolic fate of permethrin between Akagi PP15 strain and insecticide susceptible strain was not observed up to two hours after topical application of the compound. The influence of penetration through cuticle was negligible by the study using ¹⁴C labeled compound. It was also clarified that this Akagi PP15 strain showed the low sensitivity to pyrethroids by the electrophysiological study *in vivo*. Furthermore, it was clear that the locus of the recessive resistance gene on the third chromosome was allelic to *kdr* gene already known. In conclusion, the main mechanisms of Akagi PP15 strain were the low sensitivity of the nervous system to pyrethroids and the increased metabolism by mfo.

TESTS FOR PYRETHROID RESISTANCE ON ANOPHELES POPULATIONS WHICH HAVE LONG BEEN EXPOSED TO IMPREGNATED BEDNETS

C.F. Curtis

London School of Hygiene and Tropical Medicine
Keppel Street, London WC1E 7HT, U.K.

The encouraging results from the use of pyrethroid impregnated bednets against malaria vectors is leading to rapid expansion of use of such nets. It is important to assess whether there is therefore an imminent threat of emergence of pyrethroid resistance.

Observation of the time for knockdown of the first, median and last mosquito when a sample is made to walk on an impregnated net has been found to be a sensitive means of distinguishing pyrethroid resistant and susceptible anophelines. This method, has been applied, together with conventional observations of % mortality after 1 hour's exposure to W.H.O. impregnated papers. Observations were made on malaria vectors in two areas where impregnated nets have been extensively and continuously used since 1987 - in Sichuan, China, and in the village of Mng'aza in north east Tanzania. In each case comparison was made with the same species in areas where there has been no known use of pyrethroids. No evidence was found for resistance.

Time for knockdown by pyrethroids is reduced in heat stressed and older mosquitoes and precautions to avoid misleading results from these causes are required.

19-051

GENETIC STUDY OF DELTAMETHRIN RESISTANCE IN *ANOPHELES STEPHENSI* LISTON, A MALARIA MOSQUITO.

N. J. Shetty and B. H. Rajashree
Centre for Applied Genetics
Bangalore University
Bangalore 560 056, INDIA.

An.stephensi is one of the important vectors of malaria in Indian sub continent. It is a member of the sub-genus *Cellia* and series *Neo cellia*. Mosquitoes have developed resistance to various types of insecticides including organochlorides and organophosphates. Deltamethrin has been extensively used in India because of its biodegradability and low mammalian toxicity to control *Anopheles* vectors including *An.stephensi*.

A diagnostic dosage of 0.004 ppm of Deltamethrin was used to separate the laboratory produced homozygous resistant, F_1 hybrids, and susceptible strains. The progeny of the backcrosses and F_2 generations were also treated with the above dosage. The data on resistance, susceptibility and time-mortality relationship shows that Deltamethrin resistance was incompletely dominant and autosomal. There is a remarkable variation in respect of the sex ratio, fecundity and egg hatchability between the resistant and susceptible strains.

Total as well as soluble protein content and general esterase activity in resistant strains has been found increased. The same was also compared using other insecticides such as malathion, Parathion and Fenthion, which have been studied in our laboratory.

19-053

A MECHANISM OF PERMETHRIN RESISTANCE IN THE SOUTHERN HOUSE MOSQUITO, *CULEX QUINQUEFASCIATUS* SAY, FROM SAUDI ARABIA

S. Kasai, I.S. Weerasinghe¹, T. Shono

Institute of Agricultural and Forestry, University of Tsukuba, Tsukuba, Ibaraki, 305, Japan -¹ Department of Entomology, Medical Research Institute, Colombo, Sri Lanka

Culex quinquefasciatus larvae from Saudi Arabia (JPal-per) showed high levels of resistance (2,500-fold) to permethrin. Cross resistance of this strain to other pyrethroid insecticides and DDT was also observed. The resistance ratio for different pyrethroids with and without α -cyano groups in the alcohol moiety, as compared to the susceptible(S) strain varied significantly from 5.6-fold to 4,200-fold. The pyrethroids lacking an α -cyano group but having a phenoxybenzyl group in their chemical structure showed the highest resistance ratio.

A major contribution of P450 oxidases in the degradation of pyrethroids in JPal-per strain was indicated by large differences in the synergistic effects of oxidase inhibitors such as PBO and TCPE (2-propynyl 2,3,6-trichlorophenyl ether) on permethrin toxicity between the JPal-per and S strains. The amounts of P450 and b5 were also observed to be 2.7 and 2.9-fold higher in the JPal-per strain as compared to the S strain.

Previous studies have shown that *in vitro* metabolism tests can't be carried out perfectly due to an unknown inhibitor in the larval body. In our study we found the inhibitor in the contents of the larval gut and this made it possible to measure the P450 monooxygenase activity by removing the contents from gut. The microsomal fraction of JPal-per strain showed NADPH dependent high activity of permethrin degradation as compared to the S strain. Furthermore, the activity of P450 monooxygenase was greatly inhibited by oxidase inhibitors, TCPE and PBO. Therefore it was concluded that cytochrome P450 monooxygenase plays a major role as a mechanism of permethrin resistance in JPal-per strain.

19-052

RESISTANCE MECHANISMS IN PYRACLOFOS-RESISTANT HOUSEFLIES

S. Lee, T. Shono

Institute of Agriculture and Forestry, University of Tsukuba, Tsukuba Ibaraki, Japan

Houseflies collected from Yumenoshima, a dumping island in Tokyo Bay, were selected with an organophosphorus insecticide, pyraclofos ((R,S)-[O-1-(4-chlorophenyl)pyrazol-4-yl O-ethyl S-n-propyl phosphorothioate], Boltage®) for 13 generations to obtain a strain resistant to the chemical. The selected housefly (YBOL) strain showed a high resistance ratio of about 650 times that of the susceptible reference (SRS) strain. Acetylcholinesterases (AChE) of the YBOL strain were 70 times less sensitive to inhibition by pyraclofos than the SRS strain. Piperonyl butoxide (PB), inhibitor of P450 monooxygenase, increased toxicity of pyraclofos in the SRS strain, but it decreased pyraclofos toxicity in the YBOL strain.

There were no differences in penetration rate in both strains. The metabolic rate of pyraclofos *in vivo* was almost the same in both strains. Major metabolites were, however, greatly different between the resistant and susceptible strains. The YBOL housefly mainly cleaved the P-O-aryl bond and made 1-(4-chlorophenyl)pyrazol-4-yl glucose and 1-(4-chlorophenyl)pyrazol-4-yl sulphate conjugates whereas the SRS housefly primarily cleaved P-S-n-propyl bond and produced 1-(4-chlorophenyl) pyrazol-4-yl O-ethyl hydrogen phosphorothioate. The enzyme concerned with cleavage of P-O-aryl bond is thought to play an important role in the mechanism of pyraclofos resistance.

19-054

MOLECULAR EVOLUTION OF E4 AND FE4 B CARBOXYLESTERASE GENES AS INDICATED BY SEQUENCE VARIATION IN *MYZUS ANTIRRHINII* AND *MYZUS CERTUS* (HOMOPTERA: APHIDIDAE)

Paul Ready¹, Johann Testa¹, Roger Blackman¹, Jenny Spence¹, Linda Field², Alan Devonshire²

¹Department of Entomology, The Natural History Museum, London, U.K. and ²Biological and Ecological Chemistry Department, IACR-Rothamsted, Harpenden, U.K.

Identification of the primary E4 and FE4 carboxylesterase loci in *Myzus persicae* is made difficult by the multiple and varied chromosomal sites occupied by the amplified genes in different biological clones of this species. Therefore, we complemented our work on *M. persicae* by investigating the molecular evolution of these genes in closely-related members of the *M. persicae* species group that do not display insecticide resistance, namely *M. antirrhinii* (a permanently parthenogenetic species) and *M. certus* (a species that can be holocyclic). The sequences of introns 6 and 7 differentiate the E4 and FE4 genes of *M. persicae*. Using synthetic oligonucleotide primers complementary to sequences conserved between E4 and FE4 exons flanking introns 6 and 7, we have successfully amplified by PCR homologous gene fragments from both *M. antirrhinii* and *M. certus*. Comparative sequence analysis of these amplified fragments demonstrated for the first time that both E4 and FE4 genes could occur together naturally in individual biological clones of the *M. persicae* species group. Southern hybridization and quantitative dot-blot experiments showed that each of these two species has 2 to 5 copies of E4/FE4 genes. Recombinant DNA clones containing 3' flanking regions of *M. antirrhinii* E4/FE4 genes were isolated from a genomic library made with bacteriophage lambda DASH II, and comparative analysis of the flanking sequences is being used to investigate the mechanisms of gene amplification and dispersal to different loci.

19-055

MONITORING FOR THE RESISTENCE OF DIAMONDBACK MOTH (*PLUTELLA MACULIPALPA*) IN THE FIELD

Shi-xiong WU

Institute for the Control of Agrochemicals, Ministry of Agriculture, Beijing 100026, CHINA

By the diagnostic tests, the resistance of *Plutella xylostella* (Lepidoptera: Plutellidae) in Wuhan areas has been tested to Cascade (flufenoxuron), Sumicidin (fenvalerate), Lannate (methomyl) and Phosmet with the LC_{50} of sensitive strain as the discriminating doses and employing the leaf impregnation method. The results revealed that the resistance of *P. xylostella* to Cascade had risen by 12-14-fold during the period of 1991-1994, 136-263-fold to Sumicidin, and 193-233-fold to Phosmet, but no significant rising has been found to Lannate. It is suggested that, in Wuhan areas, the employment of pyrethroid and organophosphate pesticides should be forbidden, monitoring the application of insect growth regulators as Cascade and Atabron (chlorfluazuron), and the alternative use of Lannate and other insecticides has been recommended.

19-057

DIFFERENT MECHANISMS IN THE *Culex pipiens* MOSQUITO LARVAE (DIPTERA: CULICIDAE) RESULT IN RESISTANCE TO *Bacillus sphaericus*

E. Pasquier^{1&4}, C. Nielsen-LcRoux², J-F. Charles², G. Sinagre³, B. Gaven³, & N. Pasteur¹.

1 Institut des Sciences de l'Évolution, USTL, Montpellier, France-
2 Institut Pasteur (Bactéries entomopathogènes), Paris, France-
3 Entente Interdépartementale pour la Démoustication, Montpellier, France- 4 Station de Zoologie Forestière, INRA, Olivet, France

Recently field *Culex pipiens pipiens* mosquitoes collected after a control failure with Spherimos, substitute of conventional insecticides, in southern France developed a very high resistance (> 10,000 fold) to *Bacillus sphaericus* (Bsp) crystal toxins after a few generations of laboratory selection. We show that this resistance is (a) encoded by a single major recessive gene localized on linkage group I at 22.1 units of recombination from the sex factor, (b) not associated with the presence of serine proteins like the over-produced esterases involved in organophosphorous resistance and (c) not associated with any loss of binding affinity between brush border membrane fractions (BBMFs) and the Bsp radiolabeled toxin, in contrast to the high Bsp resistance developed after laboratory selection in Californian *C. p. quinquefasciatus*.

It thus appears that at least two different mechanisms may confer high levels of resistance to *B. sphaericus* crystal toxin in mosquitoes of the *Culex pipiens* complex. These results are discussed in relation to mosquito control strategies and resistance mechanisms.

19-056

DEVELOPMENT OF INSECTICIDE RESISTANCE IN AN ESTABLISHED CELL LINE OF MEDITERRANEAN FRUIT FLY (*CERATITIS CAPITATA* Wied.) (DIPTERA: TEPHRITIDAE).

E. Rossi¹, G. Rainaldi¹ and A. Piras¹

Dipartimento C.D.S.L., Sez. Entomologia Agraria, Università degli Studi di Pisa, Pisa (Italy) - 1 Genetica e Biochimica, IMD, CNR - Pisa (Italy).

Insect species have shown a generalized capability to develop mechanisms for surviving to biocides. This capacity is not the same in all species. Populations of Med Fruit Fly artificially selected in the lab or exposed to chemical treatments in the field did not develop resistance to insecticides or they did only slightly. In this work we tested the established cell line CCE/CC128 of *Ceratitis capitata* for the ability to develop resistance to insecticides. The cells were challenged for several cycles with 90 µg/ml of Malathion, an organophosphorous insecticide largely used in the control of this species in the field. After each cycle of treatment the cells were counted and the inhibition of cell proliferation was calculated. The percentage of inhibition was initially high, thereafter a progressive reduction was observed. After a period of three months, the Malathion selected population was not susceptible any more to the dose of 90 µg/ml of the biocide. The kinetics of cell proliferation at different doses of Malathion confirmed the selection of a cell population resistant to this insecticide. With the aim of understanding the biochemical basis of this resistance, we started to examine the proteins for which we have *a priori* expectations of involvement with resistance. The main detoxifying enzymes such as esterases and glutathione S-transferase are actually under investigation. Afterwards, the structure and expression of involved genes will be characterized.

Similar experiments with different insecticides are in progress.

19-058

CLONING AND CHARACTERIZATION OF THE CARBOXYLESTERASE GENE FROM THE BROWN PLANTHOPPER, *Nilaparvata lugens* (Stål)

T. Hasegawa¹, K. Sakata², T. Miyata²

1 Department of Genetics and Breeding, National Institute of Sericultural and Entomological Science, Tsukuba, Japan

2 Department Applied Entomology and Nematology, Nagoya University, Chikusa-ku, Nagoya, Japan

The brown planthopper (BPH), *Nilaparvata lugens* (Stål) is one of the most serious pest insects of rice plant in Asian countries and it has developed resistant to some insecticides.

Carboxylesterases (CEs) are reported to be involved in resistance to certain OPs and pyrethroids in this species. To study the molecular genetic basis of resistance to OPs, we cloned and characterized the DNA fragments of the CE gene in BPH.

Several molecular forms of CEs are observed in this insect. We prepared polyclonal antisera to the three major forms of CEs by injection of respective forms into mice. These antisera crossreacted to the other forms of CE in BPH. The BPH lambda gt11 cDNA library was screened using antiserum against the most active form of CE.

More than ten positive clones were isolated and partial sequence analysis showed that all these clones were almost identical to each other. These sequences are closely related to CE of the small brown planthopper. However, the DNA sequences of CE from the BPH did not have high identity with those of the other known insect CEs.

19-059

MOLECULAR CHARACTERIZATION OF KNOCK-DOWN RESISTANCE (*Kdr*) TO PYRETHROID INSECTICIDES IN THE GERMAN COCKROACH

K. Dong

Department of Entomology, Michigan State University, East Lansing, MI 48824, USA

Knock-down resistance (*kdr*) to DDT and pyrethroid insecticides was reported in several important insect pest species, including the German cockroach. Genetic linkage analysis has shown that *kdr* resistance in the German cockroach, house fly, and tobacco budworm is linked to the *para*-homologous sodium channel gene, suggesting that a mutation(s) in the *para*-homologous sodium channel gene results in *kdr* resistance. *kdr* resistant strains are cross-resistant to several site 2 sodium channel neurotoxins.

para-homologous sodium channel genes of a pyrethroid susceptible strain and a *kdr*-type strain of the German cockroach have been cloned and sequenced. Comparison of amino acid sequences deduced from these cDNA clones revealed several differences between the two *para*-homologous sodium channel genes. In this poster, the amino acid sequence comparison results will be presented. The possible involvement of these amino acid changes in the *kdr* mechanism will be discussed.

19-061

INSECTICIDE RESISTANCE GENES IN *Culex pipiens* FROM SARDINIAE. Pili¹, G. Addis¹, M. Raymond², A. Marchi¹

¹Dipartimento di Biologia Sperimentale, Sezione di Genetica, Università di Cagliari, Cagliari, Italy - ²Institut des Sciences de l'Evolution, Laboratoire Génétique et Environnement, Université de Montpellier II, Montpellier, France

Populations of *Culex pipiens* from different parts of Sardinia were analyzed for susceptibility to organophosphorous insecticides (OP) and for the presence of overproduced nonspecific esterases and of insensitive acetylcholinesterase, two major mechanisms of OP and carbamate resistance in this species. Resistance was found to be positively correlated with the frequency of insensitive *Ache* genes. Several overproduced esterases of A and B type were found in the resistant populations. However their frequency was always too low to be primarily responsible of OP resistance, except for the associated esterases A4 and B4 which high frequency was correlated with high resistance levels. Esterase A1 and the associated esterases A2 and B2 were concentrated in the Southern part of the island and always linked to high frequency of A4-B4. Monitoring of populations under routine insecticide treatment was conducted over a five year period to detect changes in frequency of resistance genes. Gene amplification responsible of B esterase overproduction was confirmed by RFLP analysis using a 1.3 Kb B1 probe. Restriction patterns of the amplified B regions were identical to those of other Mediterranean populations and of reference strains, sustaining the hypothesis of a unique origin of the amplification event.

19-060

INSECTICIDE RESISTANCE IN ITALIAN *CULEX PIPPIENS* FIELD POPULATIONSV. Di Pardo¹, C. Severini¹, F. Silvestrini¹, M. Marinucci¹, G. Pierdominici¹, R. Romi¹, M. Raymond².

¹Laboratorio di Parassitologia, Istituto Superiore di Sanità, Roma, Italy; ²Laboratoire de Genetique et Enviroment, Université Montpellier II, Montpellier, France.

The most widespread mechanisms of organophosphate resistance (OP) in *Culex pipiens* L. mosquitoes are overproduction of detoxifying nonspecific esterases and selection for insensitive acetylcholinesterase (AChE). In *Cx. pipiens*, the nonspecific esterases are encoded by two closely linked loci, named A and B. Overproduction of the B esterases is due to gene amplification, resulting in the B1, B2, B4 and B5 alleles, which generally are in linkage disequilibrium with specific A alleles. In Italy, previous studies on OP resistance in *Cx. pipiens* were carried out in only few areas.

A comprehensive geographical survey in Italian *Cx. pipiens* field populations was undertaken in order to evaluate the current mechanisms of OP resistance. 11 samples from 8 Italian regions have been studied; OP resistance was determined using WHO bioassays test procedures. AChE assay was carried out using propoxur as inhibitor; the different highly active esterases in each mosquito were detected using starch gel electrophoresis and DNA Restriction Fragment Length Polymorphism analysis. We found that the samples collected in regularly treated areas show high correlation between OP resistance and overproduced esterases patterns; in some of these areas OP resistance was determined also by the presence of insensitive AChE.

19-062

MONITORING AND DETECTION OF INSECTICIDE RESISTANCE IN *APHIS FABAE* AND *MYZUS NICOTIANAE* (HOMOPTERA: APHIDIDAE) IN GREECE.

Ph. M. Ioannidis, G. E. Skoulakis

Plant Protection Service and Research, Hellenic Sugar Industry S.A., Platy Imathias 59032, Greece

During 1993-95, fourteen populations of *Aphis fabae* Scopoli and thirty four populations of *Myzus nicotianae* Blackman were collected from sugarbeet and tobacco fields, respectively, in Northern Greece. Laboratory bioassays were conducted to evaluate the LC₅₀s for some of the insecticides used by farmers such as pirimicarb, methamidophos, fenvalerate and carbosulfan, and the recently used triazamate and imidacloprid. Resistance was determined using the FAO Dip Test method, with mortality assesment after 24 hours. Results from all bioassays suggested that *Aphis fabae* had no detectable insecticide resistance, but the probit analysis indicated that some populations were heterogeneous with shallow regression lines and high variability, suggesting that rapid development of homozygous resistance will occur, if selection pressure is continued.

Comparisons made among populations of *Myzus nicotianae* from different regions showed differences in the susceptibility to insecticides. Pirimicarb resistance was estimated from 2.5 to 939-fold, with LC₅₀ for the most susceptible field strain 30.04 (95%CL 19-47) ppm (AI). Tamaron resistance was up to 18.5-fold. LC₅₀ for the most susceptible strain was 40.16 (23-69) ppm. Triazamate has been used very little in the commercial fields. Despite that, resistance was detected from 5 up to 20-fold, probably because cross resistance has been occurred. LC₅₀ for the most susceptible population was 13.51 (8-23) ppm. No significant differences were found among populations for fenvalerate and imidacloprid. The pooled LC₅₀s were 4.84 (2.3-10.1) and 9.26 (4.17-15.8) ppm (AI), respectively.

19-063

SUSCEPTIBILITY OF VECTORS OF LEISHMANIASES IN VENEZUELA TO SELECTED INSECTICIDES

M.B. Mazzarri¹, M.D. Feliciangeli² and M. Maroli³

¹Division de Control de Vectores, Direccion de Endemias Rurales. Ministerio de Sanidad y Asistencia Social, Maracay, Venezuela

²Universidad de Carabobo, Escuela de Malariologia y Saneamiento Ambiental, MSAS, Maracay, Venezuela

³Laboratorio di Parassitologia, Istituto Superiore di Sanità, Roma, Italia.

Cutaneous and visceral leishmaniasis are endemic in Venezuela, being *Lutzomyia longipalpis* and *L. ovallesi*, respectively, recognized as vectors of these diseases in the country. Both species enter the houses, therefore a control programme based on the use of insecticides, indoor spraying or impregnated curtains, might be applicable. In order to determine the susceptibility to different insecticides, a laboratory strain of *L. longipalpis* and a field strain of *L. ovallesi* were challenged to organochloride (DDT 2%), organophosphate (Malathion 2%, fenitrothion 1% and pirimiphos methyl 1%), carbamate (prothion 0.01%) and pyrethroid (deltamethrin 0.06%, lambda-cyhalothrin 0.06% and permethrin 0.2%). The results show that *L. longipalpis* is susceptible to organophosphate, carbamate and pyrethroid insecticides, being the lethal time (LT₉₅) less than 60 minutes (27-47 min), whereas for the DDT the LT₉₅ was up to 60 min. However, a field population needs to be tested.

Preliminary data observed for *L. ovallesi* indicated a higher susceptibility to pyrethroid, deltamethrin and lambda-cyhalothrin insecticides. The LT₉₅ was 15 and 8 minutes, respectively.

This work was supported by the PAHO Unit, Venezuela [Project No. 0096 (CR) 95] and by the CEC [Contract T*S3-CT93-0247]

19-065

THE STRUCTURE-ACTIVITY RELATIONSHIP OF PYRETHROIDS AGAINST PERMETHRIN-RESISTANT AND SUSCEPTIBLE STRAINS OF ANOPHELES STEPHENSI LARVAE AND ROLE OF MIXED-FUNCTION OXIDASES IN RESISTANCE PROFILE

H. Vatandoost, H. Townson

Liverpool School of Tropical Medicine, Pembroke Place, L3 5QA, Liverpool, UK.

Structure-activity relationship of pyrethroids (permethrin, deltamethrin, lambda-cyhalothrin, cypermethrin, cyfluthrin) against larvae of different geographical strains of *An. stephensi* revealed that α -cyano group of pyrethroids with dibromo substitutions are more toxic than the other classes to sensitive strains. The ranking order in toxicity of pyrethroids was different in resistant strains. Evidence of enhanced monooxygenase activity and the synergism shown by piperonyl butoxide suggests that each resistant strain possesses a monooxygenase-mediated resistance mechanism responsible, at least in part, for pyrethroid resistance.

19-064

REDUCED ACETYLCHOLINESTERASE SENSITIVITY IN DIAMONDBACK MOTH POPULATIONS IN SOUTH CHINA

Yun-qin Sun, Jia-gui Yuan, Jing Wang

Institute of Zoology, Academia Sinica, Beijing 100080, China
The diamondback moth, *Plutella xylostella* (L.) is an important pest of cruciferous vegetables in South China. In different regions the field populations of this moth have developed different levels of resistance to insecticides used. In recent years, farmers have expanded the cultivated area of vegetables, consequently there is a great need for developing some biochemical methods to detect and monitor the resistance in individual insect. It has been widely recognized and documented that in this moth acetylcholinesterase (AChE) insensitivity is the important mechanism of resistance. A method of dot-blot on nitrocellulose membrane for identification of insensitive AChE in single insect has created the opportunity for early detection and subsequent monitoring of resistance in field populations. The percentages of inhibition of AChE activity in resistant strain (GBR) and field population (DG) were 50.97% and 43.96% respectively in the presence of prothion, and were 43.76% and 35.87% respectively in the presence of paraoxon. The results showed that GBR and DG have higher degrees of AChE insensitivity to organophosphorus and carbamate than the susceptible strain.

19-066

HIGH RESISTANCE IN NATURAL POPULATIONS OF DROSOPHILA MELANOGASTER TO LUFENURON, A CHITIN SYNTHESIS INHIBITOR INSECTICIDE

T.G. Wilson

Department of Biology, Colorado State University, Fort Collins, CO USA

Chitin synthesis inhibitors are potent insecticides against certain insects, including *Drosophila melanogaster*. The benzoylphenyl urea compound lufenuron was tested against both laboratory and natural population strains of this insect. Lufenuron exposure results in lethality in all preadult stages of development. When fed to adult females, lufenuron sterilizes the females due to embryonic lethality of the oviposited eggs. Laboratory strains were highly susceptible to this compound, while natural population strains from two widely separated locations in the U.S. exhibited considerable (as much as 100-fold) resistance. The resistance is being genetically mapped and compared with resistance of these strains to several other insecticides. Since *D. melanogaster* is not under direct insecticide selection pressure, these results suggest that strong selection for insecticide resistance can occur in insects indirectly affected by an insecticide.

19-067

INSECTICIDE RESISTANCE IN DIAMONDBACK MOTH *PLUTELLA XYLOSTELLA* L. IN INDIA : DISCRIMINATING DOSE STUDIES

J. Chandrasekaran, A. Regupathy

Department of Entomology, Tamil Nadu Agricultural University, Coimbatore, India.

Discriminating doses for carbosulfan, cartap hydrochloride, fenvalerate, monocrotophos and quinalphos were fixed for different methods of bioassay viz., vial, leaf dip, larval dip, and spray tower. This involves : 1. Culturing the populations collected from fields less exposed to insecticide application for 25 generations without exposure to any insecticides, 2. Working out log-dose-probit-mortality lines (LDPM) for the above insecticides by vial, larval dip, spray tower and leaf disc bioassay methods using, third instar (1.83 ± 0.28 mg) larvae, 3. Extrapolation of discriminating dose (LD/LC₉₉).

The susceptibility of *P. xylostella* decreased considerably on rearing for 25 generations. The LC₅₀ of F₁ field collected population ranged from 56.1 to 64.0 for quinalphos, 32.0 to 32.4 for fenvalerate, 10.8 to 40.7 for carbosulfan, 50.1 to 74.7 for monocrotophos, 38.9 to 92.1 for cartap hydrochloride while the same for F₂₅ ranged from 0.5 to 3.4, 10.0 to 13.9, 0.7 to 3.1, 18.6 to 23.0 and 0.5 to 1.1 µg/ml respectively in different bioassay methods.

The extrapolated discriminating doses (LD/LC₉₉) based on the LDPM of F₂₅ population was 4.0, 5.0, 115.0, 140.0 and 3.0 µg/ml for carbosulfan, cartap hydrochloride, fenvalerate, monocrotophos and quinalphos respectively in vial assay. The same for spray tower assay was 20.0, 10.0, 170.0, 170.0 and 10.0 µg/ml while larval dip assay method gave 15.0, 10.0, 130.0, 150.0 and 10.0 µg/ml respectively for carbosulfan, cartap hydrochloride, fenvalerate, monocrotophos and quinalphos.

The assay methods adopted were comparable to each other, as the correlation among them was of high order, the coefficient being 0.99 in respect of vial to spray tower and vial to larval dip. The larval dip assay, though easier and economical, does not facilitate treatment in batches as the larvae get clumped up. Therefore, vial assay is suggested for adoption.

TISSUE-SPECIFIC ACCUMULATION PATTERNS OF PB, CD, CU, ZN, FE, AND MN IN WORKERS OF THREE ANT SPECIES (FORMICIDAE, HYMENOPTERA) FROM A METAL POLLUTED SITE

W. B. Rabitsch

Department of Ecophysiology, Institute of Zoology, University of Vienna, Vienna, Austria.

In any quantitative survey of heavy metal accumulation in terrestrial arthropods conducted so far, ants of the subfamily Formicinae showed very high metal body burdens. Metabolic requirements of essential metals and physiological strategies to manage excess of the available metal pool in contaminated environments cause a non-uniform distribution of the elements in the tissues. Because of the beneficial role ants play in terrestrial ecosystems, the welfare of such keystone species is of general importance.

The present study investigated the concentrations of Pb, Cd, Cu, Zn, Fe, and Mn in the tissues of *Formica pratensis* RETZ., *Formica rufa* L. and *Camponotus ligniperda* (LATR.). Ants were collected in the vicinity of a closed down lead/zinc smelter, which was in operation from 1495 to 1992 in Arnoldstein, Austria.

The highest metal levels were almost always found in the midgut, followed by the hindgut and the Malpighian tubules. The mandibles appeared as a target site of Zn accumulation. Levels of Pb, Cu and Fe in the ovarioles were very high in all species. A comparison of the metal concentrations among the investigated exocrine glands revealed highest metal levels in the Dufour gland and the labial gland.

Significant differences between the species and within the metals occur. However, the degree and the history of pollution at the sampling site is of major importance and should be considered. Finally, results were discussed in the light of ecotoxicological literature.

19-068

DISPOSAL OF WASTE PESTICIDES AND RECYCLING OF PESTICIDE CONTAINERS

C.E. Hoelscher, D. Nash¹

Department of Entomology, Texas Agricultural Extension Service, Texas A&M University, College Station, TX USA

¹Texas Natural Resource Conservation Commission, Austin TX USA.

A four-year project has been completed to dispose of 670 tons of waste agricultural pesticides. Collection days were held at 16 regional collection sites. Chemical disposal was conducted in the State of Arkansas by a commercial contractor in a high heat furnace. Ash residues were sealed in glass containers and placed in an approved landfill.

Educational materials were developed to inform the agricultural community about safety techniques for the collection, transportation and disposal of waste pesticide. A grant of \$5.3 million was used to support proper disposal activities. The objective of the program was to improve environmental conditions by reducing the burying and dumping of illegal waste. The Texas County Clean Up program has recycled 400,000 pounds of empty pesticide containers during the 1994 and 1995 crop seasons. The program also recycles tires, batteries, waste oil and filters.

The effects of Dorwant oil spraying on Pomegranate aphids and mites

by : S. A. Mirkarimi

High population of aphids and mites on young shoots, leaves, buds and small fruits cause considerable damage in pomegranate orchards.

In an attempt to investigate about none toxic chemical method for integrated control of these pests, 3 and 2 percent dormant oil was applied in mide march and late June respectively. Samples of aphids, mites as well as crops harvested in cheks and treated plots were compered and evaluated statistically. These investigations revealed that oil sprays reduce aphids and mites and increased fruit production up to 25 percents.

The population changes of aphids mites were investigated and the obtained data were statistically analysed and related histograms were drwan. The results indicated that, oil treatment decreased the population of mites and aphids and increased the fruit production.

19-071

SOLID PHASE EXTRACTION, MATRIX SOLID PHASE DISPERSION AND SOLID PHASE MICRO EXTRACTION TECHNIQUES FOR THE QUANTIFICATION OF ORGANOCHLORINE PESTICIDE RESIDUES IN BIOLOGICAL MATRICES.
J.J. Johnston and E.E. Petty., USDA/APHIS/ADC - Denver Wildlife Research Center, Bldg. 16 Denver Federal Center, Denver, CO 80225.

Quantification of organochlorine pesticide residues at parts per billion levels in animal matrices is routinely performed to monitor food supplies, monitor the effectiveness of environmental clean-up efforts and for numerous wildlife studies. Traditional approaches involve solvent extraction and quantification by gas chromatography with electron capture detection (GC-ECD). Unfortunately, this widely used approach generates large quantities of hazardous waste. Also, co-extracted lipids frequently have deleterious effects on chromatography. Reversed phase solid phase extraction and matrix solid phase dispersion were combined with GC-ECD and evaluated for the quantification of organochlorine residues in lipid rich animal matrices. When compared to solvent extraction, both methods gave a cleaner extract resulting in improved chromatography and increased sensitivity. The matrix solid phase dispersion technique resulted in extremely clean extracts, excellent precision and sub parts per billion limits of detection. Comparable results were achieved using solid phase micro extraction for the analyses of organochlorine pesticide residues in animal serum and urine samples. Furthermore, extraction and clean-up via solid phase matrix dispersion and solid phase micro extraction resulted in the generation of minimal quantities of hazardous waste.

19-073

FURTHER EXPERIMENTS ON THE BIOACTIVITY OF PLUMBAGINOIDS AGAINST THE COTTON STAINER; *DYSDERCUS KOENIGII* FABRICIUS (HETEROPTERA : PYRRHOCORIDAE)

G.T. Gujar and R.V. Satyanarayana Rao
 Division of Entomology, Indian Agricultural Research Institute, New Delhi, India

Further studies on the bioactivity of plumbagin and analogues, collectively termed, plumbaginoids, were carried out on the nymphs and adults of the cotton stainer, *Dysdercus koenigii* F. Plumbagin (2-methyl 5-hydroxy, 1,4-naphthoquinone) caused more mortality of young (0-day old) last instar nymphs than the 6 day old last instar ones. The lethal dose of plumbagin for 50 % nymphal mortality was about 20 µg for 0 day and >30 µg for 6 day old last instar nymphs. Besides, the inhibition of growth of the last instar nymph by plumbagin was dose dependent especially in younger nymphs. Plumbagin was more active than juglone (5-hydroxy 1,4-naphthoquinone) and lawsone (2-hydroxy 1,4-naphthoquinone), suggesting undesirability of hydrophilic substituents at 2 and 5 positions of 1,4-naphthoquinone ring. Little variation in the bioactivity of plumbagin from different sources was found when tested against 0 and 6 day old last instar nymphs. Only the highest dose of 50 µg of piperonyl butoxide synergized the activity of plumbagin (5 µg) against 0 day old last instar nymphs. Plumbagin adversely affected mating behaviour and fecundity of the adult females. The bioactivity of plumbagin is discussed in view of its reported action on neuroendocrines and integument.

The Investigation of Effect of some Insecticides on, Pomegranat - Scarabelds In Varamin In 1993-94.

Abstscat :

In some parts of the district of Varamin, some of Scarabeidae cause large damages and they play the important role of decrease in the yield rate. We took some pictures of those harms and damages. Their nutrient consists of : Sympodial roots, completely and also the skin of the main thick roots. These insects produce one generation, per-3 years.

In examining the ways to control of them, we found the effective usage in Diazinon G. 5% , 20 Kg/ha , Lindane wp 5.7% 5 Kg/ha , Sevine wp 85%, 4Kg/ha in the soil.

In 1993, by taking some samples of the different parts of the pomegranate gardens. Soil was tested for the movement of Scarabeide-larves in different depths and figures were illustrated.

In 1994, wetried out these kinds of insecticides. In an experimental of project, blocks located randomly, were applied with seven treatments and four series. Each inecticide was used at two different times, one; on 4 April, when worms came up to the surface of the earth, the other one, on 20 May, when they were in the stage of development into pupa.

The yield rate of pomegranate in each section, in fall, was so useful, in our calculation. of course, in taking samples and drawing the figure of it, we had also in mind for number of living larvae and pupae, a week after spraying; Because these things were justifying the results of the project.

The toxins experiment, were consirted of granul Diazinon 5%, Lindan 57% and sevin 85% powder forms in suspension; and we got the best results from the average of Diazinon, on 20 may.

In order to classify the average of insecticidal effects, we applied a way, called Duncan. The results of this project, in the planning of the integrated control along with the other controlling produres, will be employed.

19-074

BIOLOGICAL ACTIVITY AND RECEPTOR BINDING OF NONSTEROIDAL ECDYSTEROID AGONISTS IN COLORADO POTATO BEETLE LARVAE

G. Smagghe¹, E. Viñuela², F. Budia², D. Degheele¹

¹ Laboratory of Agrozoology, Faculty of Agricultural and Applied Biological Sciences, University Gent, Gent, Belgium - ² Unidad de Protección de Cultivos, E.T.S.I. Agrónomos, Madrid, Spain

Toxicity assays demonstrated a moderate susceptibility of last-instar larvae of the Colorado potato beetle, *Leptinotarsa decemlineata* Say, for the first nonsteroidal dibenzoylhydrazine-based ecdysteroid agonist, RH-5849, since LC₅₀ reached 1.8 mg/l; for tebufenozide, LC₅₀ was >100 mg/l. Intoxicated larvae showed external signs of premature moulting within 12 h of treatment leading to double head capsule formation. Shortly afterwards, larvae died in a double cuticle without signs of normal shedding of the old cuticle. Electron microscopic analysis of treated larvae revealed a forced, untimely synthesis of a new, however incomplete cuticle via epidermal cell activation. Furthermore, the receptor binding affinity of the natural insect moulting hormone, 20-OH ecdysone, and the nonsteroidal ecdysteroid agonists was tested on *in vitro* cultured mesothoracic imaginal wing discs of last-instar larvae. The current data suggest that the specific ecdysteroid-mimicking activity and insect selectivity of such dibenzoylhydrazine-based compounds is related to true, however selective, binding on the ecdysteroid receptors of the epidermal cells. As a consequence, the new chemistry and mode of action of such compounds open up new avenues in the control of various agriculturally important insect pests, even non-Lepidoptera.

19-075

Glutathione S-transferase (GST) isozymes were purified and isolated from larval midguts and fat bodies of the fall armyworm (*Spodoptera frugiperda*) using a 3-step procedure involving ammonium sulfate fractionation, followed by affinity chromatography on a GSH-agarose column and nondenaturing polyacrylamide gel electrophoresis. The midgut possessed 5 isozymes, namely, MG GST-1, MG GST-2, MG GST-3, MG GST-4 and MG GST-5, all of which were heterodimers with subunit molecular weights of 26,700 to 30,000. The pI values ranged from 4.6 to 6.0 among these isozymes. No qualitative difference in isozyme composition was observed during larval development. The fat body contained 3 isozymes, namely, FB GST-1, FB GST-2 and FB GST-3, all of which were believed to be homodimers with subunit molecular weights of 20,100 to 29,000. The pI values ranged from 4.4 to 6.5 among these isozymes. Using isozyme-specific antisera as probes, MG GST-2, MG GST-3, FB GST-2 and FB GST-3 were found to be immunologically related. MG GST-2 and MG GST-3 were also immunologically related to the GST from larval Malpighian tubules of fall armyworm. Among the corn earworm, tobacco budworm, beet armyworm and cabbage looper, MG GST-3 was immunologically related to GSTs from all of these species except the cabbage looper, whereas MG GST-2 was immunologically related only to the GST from the beet armyworm.

19-077

SUBLETHAL EFFECTS OF TWO PESTICIDES ON SURVIVAL AND REPRODUCTIVE BEHAVIOR OF THE CODLING MOTH, *CYDIA POMONELLA* L. (LEPIDOPTERA: TORTRICIDAE)

C. Abivardi, D. C. Weber¹, S. Dom²

Department of Geobotany, Swiss Federal Institute of Technology (SFIT), Zurichbergstr. 38, Zurich, Switzerland - 1 Agricultural Research Group, Lakeville, Massachusetts, USA - 2 Department of Plant Sciences (Applied Entomology), SFIT, Zurich, Switzerland

Sublethal effects of carbaryl, an insecticide and growth regulator, and cyhexatin, an acaricide, on survival and reproductive behavior of the codling moth adults, and the movement of neonate larvae, were studied under laboratory conditions. Depending on the concentration used, both pesticides resulted in high adult mortality. Exposure of the codling moth adults to most doses of carbaryl significantly reduced total oviposition. The females exposed to these concentrations, however, laid significantly more eggs during the first 24 h of exposure. While in all treatments ca. 50% of the eggs were laid on the side of the oviposition substrate, the spatial distribution of the eggs laid under the lid and on the floor was concentration dependent. Although exposure to cyhexatin, at the lower rates, increased the frequency of copulation, females exposed to all concentrations of carbaryl copulated less frequently than control. Similar effects were observed when the number of spermatophores per female were considered. In contrast to carbaryl, which exhibited a high ovicidal effect at all concentrations, the ovicidal activity of cyhexatin was low. A large number of the eggs exposed to this pesticide could complete their embryonic development, hatching at a high rate. While carbaryl killed the neonate larvae at all concentrations, cyhexatin acted as a larvicide at the highest two rates only.

DISLodgeABLE RESIDUES OF METHAMIDOPHOS IN TOMATO CROPS IN BRAZIL.

A. Evaristo¹, G. C. de Baptista¹

¹ Department of Entomology, ESALQ, University of São Paulo, Piracicaba-SP, Brazil.

The objective of this study was to evaluate the behavior of dislodgeable residues of methamidophos on leaves, fruits and soil of tutored tomato crops.

The experiment was conducted in a representative region in the State of São Paulo, Brazil. It consisted of four treatments (with four replicates): (1) one application of methamidophos (Tamaron BR) at single rate of 60 g a.i./100 l of water, (2) one application at double rate of 120 g a.i./100 l of water, (3) four applications at single rate, and (4) control. The leaf, fruit and soil samples were taken one day before the combined application, and then at 0, 1, 2, 3, 5, 7 and 14 days after that one.

Methamidophos dislodgeable residues were extracted with Surten aqueous solution (sodium dioctylsulfocinate - 70%); the extracts were partitioned in a mixture of 15% methanol in ethyl acetate and quantified by gas chromatography, using a flame photometric detector. Foliar dislodgeable residues of methamidophos in the treatments had degradation half-lives ranging from 0.7 to 2.4 days, and in the soil from 1.3 to 2.9 days, showing that residues in the soil are more persistent than those in the leaves.

Dislodgeable residues on fruits were detected only on 0 and 1-day old samples, and they decreased from 0.19 to 0.05 µg/cm², 0.27 to 0.06 µg/cm², and 0.11 to 0.05 µg/cm², respectively in the treatments with one application at single rate, one application at double rate, and four applications at single rate. These results show that dislodgeable residue degradation in fruit is relatively fast.

19-078

USE OF INSECTICID GRANAULE, AN INITIAL STEP TOWARD

INTEGRATED CONTROL OF CEREAL SUNN PEST *Eurygaster integriceps* PUT. (HET. SCUTELLERIDAE) IN IRAN.

M. ESMAILY, K. TALEBI, K. SEPEHR

Areal spray of about 800,000 hectare, per year against sunn pest causes numerous damages to living environment including complete destruction of beneficial arthropods both, insect pollinators, Parasitoids and Predators.

In a 4 years (1991-1995) attempts to reduce these hazards, on the basis on geotactic behavior of this pest, granular formulation of Fenitrothion 1kg.ai. and Diazinon 2kg a.i. Per hectare were applied effectively with significant reduction of honey bees and other pollinators mortality, and 50 to 70 per cent saving of scelionid and tachinid Parasitoids of sunn pest. Granule broad casting, enabled pilots to fly with higher elevation which increases working efficiency and reduces danger of fatal accidents.

19-079

FATE OF INSECTICIDES, FENITROTHION AND CARBARYL, IN FOREST SOIL AND THEIR DEGRADATION BY SOIL BACTERIA
Y. Sato

Forestry and Forest Products Research Institute, Tsukuba, Japan

Fenitrothion (MEP) and carbaryl (NAC) have been used widely in Japan to control Japanese pine sawyer *Monochamus alternatus* which is a vector of pine wilt disease-agents. The fate of these insecticides in forest soil after aerial application was investigated by gas chromatography (GC) analysis. A majority of MEP (ca. 80%) in the soil disappeared on 30 days after application, although MEP in soil was still detectable slightly on 240 days. Several species of bacteria were isolated from the forest soil and were assayed for their MEP-degraded ability. Two strains of *Bacillus* sp. degraded ca. 50 % and ca. 80% of MEP in the inorganic-salt liquid medium on 5 days and 25 days after inoculation, respectively. The GC-mass spectrometry (GC-MS) analysis revealed that its major degradation metabolite is amino-fenitrothion and other minor metabolites are acetyl-amino-fenitrothion and 3-methyl-4-nitrophenol.

Two strains of gram-negative and rod bacterium harbored the excellent NAC-degrading ability. The strains degraded completely and rapidly NAC in the liquid medium on 10 days after inoculation. As its main degradation metabolite, 1-naphthol was detectable with GC-MS analysis. These insecticides-degrading bacteria may be available to restore the environments contaminated with insecticides applied in forests.

19-081

EFFECTS OF THREE NEW JUVENILE HORMONE ANALOGUES ON *TENEbrio MOLITOR* L. PUPAE
A. Arzone, M. Dolci¹, P. Quagliotto²
Dipartimento di Entomologia e Zoologia applicate all'Ambiente "Carlo Vidano", Università di Torino, Torino, Italy - 1 Dipartimento di Valorizzazione e Protezione delle Risorse Agroforestali, Università di Torino, Torino, Italy - 2 Dipartimento di Chimica Generale ed Organica Applicata, Università di Torino, Torino, Italy

Since 1974 we have been engaged in researches on new juvenile hormone analogues (JHA) with the aim to search compounds dangerous for insects only and respectful for the environment.

6-[1-(2-phenoxyethoxy)ethoxy]-1,3-benzoxathiole (I) and three new derivatives of 6-hydroxy-1,3-benzoxathiole, differing from I for the introduction on the phenyl of a methoxy group in positions 2- (II), 3- (III), and 4- (IV), respectively, were synthesized and applied on 0-24 hours old *Tenebrio molitor* L. pupae to evaluate their juvenilizing activity.

The products were applied topically on the last three urosternites at the doses of 1, 10, and 100 µg contained in 1 µL of acetic solution. For each dose of each product, 4 groups of 10 pupae have been tested; pupae treated with 1 µL of acetone and pupae not treated were used as controls.

The results of the biological tests proved that, in comparison with I, the compound II is slightly less active, the compound IV is moderately more active, the compound III is much more active.

19-080

EVIDENCE FOR A SUBSTRATE-BORNE SEX PHEROMONE AND EFFECT OF INSECTICIDES ON MATE FINDING IN PARASITOID WASPS (*TRICHOGRAMMA BRASSICAE*)
F. Pompanon, B. de Schepper, J.-M. Delpuech
Laboratoire de Biométrie, Génétique et Biologie des Populations, CNRS ura 2055, Université Claude Bernard Lyon I, Villeurbanne, France.

While the use of chemical cues in host location is quite well known in parasitoid insects, little is known about their role in sexual interactions. In this work, the role of a sex pheromone was investigated in the egg parasitoid *Trichogramma brassicae*, and the evidence for a substrate-borne sex pheromone was demonstrated. Moreover, evidences that insecticides interact with communications using sex pheromone were obtained. Virgin females (<1 or 5 days old) deposited chemicals that were attractive for males whatever their mating status. Male response decreased over time but was always significant for the 8 min of video-tracking, even when male response was tested 15 min after the end of marking. Furthermore, the response of males surviving a LD30 of Chlorpyrifos (organophosphorus insecticide) was drastically decreased. Males surviving the LD30 spent only 66% of their moving time in the female-marked area vs 83% in controls. The difference was highly significant (p< 0.001) even when considering treated males with a total moving corresponding to that of controls. Then Chlorpyrifos decreases mating chances for virgin females searching for oviposition sites, and it also decreases mating chances on emergence sites. Adaptive issues of both the substrate-borne pheromone and its interaction with insecticides are discussed.

19-082

COMPARING INSECTICIDE-RESISTANT AND INDIGENOUS STRAINS OF THE PREDATORY MITE *AMBYSEIUS FALLACIS* FOR FIELD EFFECTIVENESS AGAINST *PANONYCHUS ULMI*, *ACULUS SCHLECHTENDALI* AND *TETRANYCHUS URTICAE* IN APPLE ORCHARDS
G. Chouinard, J. Brodeur¹
Service de Phytotechnie de St-Hyacinthe, Direction de la Recherche et du Développement en Agro-alimentaire, Ministère de l'Agriculture, des Pêcheries et de l'Alimentation du Québec, Saint-Hyacinthe, Canada - 1 Département de phytologie, Centre de recherche en horticulture, Université Laval, Québec, Canada

Two strains of the mite predator *Amylyseius fallacis* were released in 1994 and 1995 in two different apple orchards in Quebec, Canada, to compare their relative effectiveness and compatibility with chemical protection spray programs. At each site, both the organophosphate and pyrethroid resistant strain, and the indigenous strain were released (100 per tree) in six tree plots ca. one week before spider mite populations reached an average of five motile forms per leaf. Populations of *A. fallacis*, *Tetranychus urticae*, *Panonychus ulmi* and *A. schlechtendali* were monitored weekly on apple foliage from June to September. Two releases were needed both years in all plots. No significant differences were observed between populations of *A. schlechtendali* or *P. ulmi* developing in presence or absence of *A. fallacis*. *T. urticae* populations remained lower in treatment plots than in control plots. Predator populations were severely affected by most of the insecticides applied on trees during the observation period. No significant differences were either observed between the two strains regarding their effectiveness or their compatibility with pest management programs used.

TISSUE-SPECIFIC EXPRESSION OF GLUTATHIONE S-TRANSFERASE ISOZYMES IN FALL ARMYWORM LARVAE

S. J. Yu

Department of Entomology & Nematology,
University of Florida, Gainesville, FL,
USA

Glutathione S-transferase (GST) isozymes were purified and isolated from larval midguts and fat bodies of the fall armyworm (*Spodoptera frugiperda*) using a 3-step procedure involving ammonium sulfate fractionation, followed by affinity chromatography on a GSH-agarose column and nondenaturing polyacrylamide gel electrophoresis. The midgut possessed 5 isozymes, namely, MG GST-1, MG GST-2, MG GST-3, MG GST-4 and MG GST-5, all of which were heterodimers with subunit molecular weights of 26,700 to 30,000. The pI values ranged from 4.6 to 6.0 among these isozymes. No qualitative difference in isozyme composition was observed during larval development. The fat body contained 3 isozymes, namely, FB GST-1, FB GST-2 and FB GST-3, all of which were believed to be homodimers with subunit molecular weights of 20,100 to 29,000. The pI values ranged from 4.4 to 6.5 among these isozymes. Using isozyme-specific antisera as probes, MG GST-2, MG GST-3, FB GST-2 and FB GST-3 were found to be immunologically related. MG GST-2 and MG GST-3 were also immunologically related to the GST from larval Malpighian tubules of fall armyworm.

19-085

THE STUDY OF MICROSOMAL OXIDASES OF MIDGUT OF CORN EARWORM *HELIOverpa armigera* (LEPIDOPTERA: NOCTUIDAE)

E.L. Hsu and H.Y. Hsu

Department of Plant Pathology & Entomology
National Taiwan University, Taipei, Taiwan
R.O.C.

Corn earworm, *H. armigera* is a very important agricultural pest on corn, sorghum, ornamental flowers, tomato, pea and cucumber etc. in Taiwan. The extensive selection pressure from insecticide application the corn earworm would be expected to develop the insecticide resistant strain. The character of microsomal oxidases in corn earworm should be examined for the analysis of insecticide resistance mechanism and the strategy of insecticide application could be planned. The biochemical characteristics of microsomal oxidases between the specific activity and insecticide susceptibility and enzyme inducibility in corn earworm will be investigated in this study. The microsomal enzyme of the Tainan corn earworm midgut would be assayed in this experiment. The microsomal enzyme of the activity of aldrin epoxidase was the highest (4539.2 pmole/min/mg protein), among the others activities as Biphenyl hydroxylase, Cytochrome b5, N-demethylase, Cytochrome p-450, MR O-demethylase, ER O-deethylase.

19-084

CONTACT AND *PER OS* LETHAL CONCENTRATION VALUES OF DIFLUBENZURON ON *MELANOPLUS SANQUINIPES* (F.) (Orthoptera: Acrididae).B. W. Fuller, M. A. Boetel, L. Jech¹, T. Wang & R. N. Foster¹.Department of Plant Science, South Dakota State University,
Brookings, South Dakota, USA - ¹USDA, Animal and Plant
Health Inspection Service, Plant Protection and Quarantine,
Phoenix Plant Methods Center, Phoenix, Arizona, USA.

The migratory grasshopper, *Melanoplus sanguinipes* (F.) is a serious cropland pest, and some rangeland outbreaks may include this insect and closely related melanoplinae. We used this easily reared pest and believe its susceptibility to be a good indicator for extrapolating lethal concentrations for many of our rangeland grasshopper species. Our bioassays used 3rd instar *M. sanguinipes* (F.) that received diflubenzuron via both *per os* and topical applications. Treated discs of lettuce facilitated *per os* treatments while topical dosages were applied in 1 ml aliquots of acetone to the abdominal sternites. Corrected mortality rates were subjected to probit analysis using the POLO-PC software program.

No mortality was detected in the *per os* treatment until 120 h post exposure (feeding) at which the calculated LC₅₀ was 1656 ppm (range = 789-2447) (95% CI). Responses to topical applications at 120 h resulted in LC₅₀ calculations of 31 ppm (range = 22-40). The LC₅₀ topical dose was 53 times more effective than the same *per os* dosage. Implications for field use will be presented.

19-086

METAL CONCENTRATIONS IN VARIOUS DEVELOPMENTAL STAGES OF ENDANGERED *PARNASSIUS APOLLO* (LEP.: PAPILIONIDAE) IN PIENINY MOUNTAINS (SOUTHERN POLAND).

A. Kędzierski, M. Nakonieczny, E. Świerczek.

University of Silesia, Department of Human & Animal Physiology,
Bankowa 9, Katowice, Poland.

In last three decades rapid decline of *P. apollo* populations has been noted in Poland and some other European countries. Among the reasons of this decline there may be anthropogenic pollution. Fragmentary data so far obtained suggest, that food-plant of apollo larva - various orpine species (*Sedum spp.*) - strongly accumulate cadmium and some other metals. Observations of apollo developmental anomalies and high pupae mortality in semi-natural colony carried out in Pieniński National Park, suggested possible influence of metals also on ontogeny of this species.

So the aim of this study was to evaluate whether the insects of successive developmental stages are really exposed to excessive concentrations of various metals, particularly the highly toxic ones - cadmium and lead. Due to small number of free-living individuals the specimens for analyses came mostly from the colony. Concentrations of Cd, Pb, Zn, Fe and Cu were determined in dried samples of livelong orpine (*S. maximum*) leaves and the insects of various stages after complete wet digestion (HNO₃:HClO₄ - 4:1) by means of flame AAS.

Obtained results confirmed the suggestion, that some metals, particularly Cd and Pb, can be a stressing factor to apollo larvae and also to adults. *Sedum* leaves contained high concentrations of cadmium, lead and zinc. These metals came probably mainly from dust fallout. Cadmium cumulated in the body with the age of larva and its concentrations were higher than in food-plant. Due to the specific feeding habit the youngest larvae are particularly exposed to lead depositing on the leaves surface. Older instars could maintain relatively constant body burden of Pb. Adults that do not eat orpine leaves also contained high concentrations of the metals. It was interesting, that the „wild” insects were significantly more contaminated than the individuals from colony.

19-087

THE INFLUENCE OF CADMIUM AND SELENIUM ON DEVELOPMENTAL ACTIVITY PATTERN OF CARBOXYL-ESTERASES IN HEMIMETABOLOUS INSECTS.

M. Nakoneczny, A. Kędzierski, L. Świerczek, M. Grzesiak.

University of Silesia, Department of Human & Animal Physiology, Bankowa 9, Katowice, Poland.

Carboxylesterases (CarE) are widely distributed group of mainly cytosolic enzymes, that metabolise many endogenous as well as exogenous compounds. Hence, disturbances of their activities may severely affect detoxifying abilities of an organism. They are particularly important for developing individuals. Earlier studies have shown, that cadmium - one of the most toxic metals - stimulated or inhibited, depending on the dose, the enzymes activity in midgut tissues of last larval instar and adults of house cricket (*Acheta domesticus*), and young adult madagascar cockroach (*Gromphadorhina portentosa*). The aim of this study was to determine whether selenium ($0.01 \mu\text{mol Se} \cdot \text{g}^{-1}$ of dry weight feed), considered as a cadmium antagonist, would protect these insects from sublethal poisoning with Cd ($0.4 \mu\text{mol} \cdot \text{g}^{-1}$ of dry weight feed) during later stages of their ontogeny.

Female crickets were intoxicated from 20th day after hatching, at least for 2 weeks, and female cockroaches - for 7 - 9 weeks. CarE activities were measured in crude homogenates obtained from midgut using α -naphthyl acetate (α NA) as substrate in 1st, 7th and 50th day after final molt of *G. portentosa* larvae. The activity in crickets was measured in 1st, 5th and 9th day of last larval instar and from 1st to 30th day of adult stage with 5-days intervals.

In the given dose cadmium stimulated the activity of CarE in midgut of both species, but in cricket it occurred during the whole examined period, while in cockroach it appeared only in the last age-group. Selenium itself did not cause marked changes of the enzymes activities in these species but given simultaneously with cadmium significantly decreased its effects. However, the insects differed in their response to these elements. Protective action of Se against cadmium depended on the age in cockroach, while no such relation has been observed in crickets.

EFFECT ON THE MORTALITY OF THE OLIVE-TREE ENTOMOFAUNA CAUSED BY ADULTICIDAL AND LARVICIDAL TREATMENTS USED TO CONTROL THE OLIVE-FLY: *Bactrocera oleae* (Gmel.) (DIPTERA, TEPHRITIDAE). TESTS CARRIED OUT IN THE THREE-YEAR PERIOD OF 1991-93 IN THE OLIVE-GROWING ENVIRONMENT OF NORTHERN LAZIO (CENTRAL ITALY).C. Pucci¹, A.F. Spanedda¹, A. Forcina², A. Giovagnoli³¹Dipartimento di Protezione delle Piante, Università della Tuscia, Viterbo (Italy)-²Dipartimento di Statistica, Università degli Studi, Perugia (Italy) - ³Istituto di Statistica, Università degli Studi, Bologna (Italy)

A comparative test was carried out in the olive-growing area of Canino (Northern Lazio) on the mortality, with regard to the olive-tree entomofauna, determined by the adulticidal and larvicidal treatments normally used against the *Bactrocera oleae* (Gmel.).

The experiment was carried out and repeated for 3 consecutive years, in a 2 ha olive-grove, in which 20 homogeneous plants of the same age were selected from the Canino cultivar, subdivided into 5 thesis with 4 repetitions and distributed at random, taking care that the sample plants were not adjacent to one another.

The insecticides compared were:

Fenthion + proteinaceous lure (adulticidal), Deltamethrin + proteinaceous lure (adulticidal), Dimethoate (larvicidal).

The methodology adopted for detecting the data was that suggested by IOBC in "Standard methods to test the side-effects of pesticides on natural enemies of insect and mites".

Under the projection of the canopy of each plant 4 collectors were located to correspond with the four cardinal points.

The insects which were gathered, distinctly per plant and per collector, were counted and separated by Systematic Order.

With the statistical analysis of the data, based on the adaptation of several log-linear models, the different effect on the mortality produced by the larvicidal and adulticidal treatments on the elements of the different Systematic Orders was assessed, together with their relative density in distinct periods of the year.

AN INSECTICIDAL CYCLOPEPTIDE RESPONSIBLE FOR BRUCHID RESISTANCE IN A WILD MUNGBEAN *M. Ishimoto*¹, *F. Sugawara*², *K. Kitamura*¹¹ National Agriculture Research Center, Tsukuba, Ibaraki, Japan-2 The Institute of Chemical and Physical Research (RIKEN), Wako, Saitama, Japan

Seeds of grain legumes in the genus *Vigna*, such as cowpea (*Vigna unguiculata*), mungbean (*V. radiata*) and azuki bean (*V. angularis*) are staple foods in many countries. Post-harvest damage of the seeds by a group of bruchids (Coleoptera:Bruchidae) is quite extensive. Previously, a wild mungbean strain (TC1966) which possesses bruchid resistance was identified. This resistance is controlled by a single dominant locus; however, the principal factor for the resistance had never been characterized. Here we report on a cyclopeptide, named vignatic acid ($\text{C}_{30}\text{H}_{39}\text{N}_3\text{O}_7=553$), which has been identified as a principal factor conferring the bruchid resistance. This is the first example of a plant peptide which has insecticidal activity.

A STUDY ON THE MODE OF ACTION OF CARBOSULFAN BY ACTION OF CYTOCHROME P450 VIA BIOACTIVATION PROCESS. *J. H. HUR*, *D. S. HAN*, *K. W. YANG*¹, *S. J. LEE*. Department of Agricultural Chemistry, Kangwon National University, 200-701, Korea.

This study focused on understanding a proposed hypothesis that carbosulfan must be converted to a more potent anticholinesterase to show its toxicological properties in biological systems.

The bimolecular inhibition rate constants of carbosulfan to AChE and BuChE were approximately $10^3 \text{M}^{-1} \text{min}^{-1}$ which was low enough not to inhibit the ChEs effectively. The potency of carbosulfan as an inhibitor of AChE and BuChE was increased when carbosulfan and ChEs were incubated with microsomes fortified with NADPH compared to the microsome alone. Piperonyl Butoxide (PB), when added to these coupled systems, greatly reduced the inhibition of both enzymes by blocking a bioactivation process.

The I_{50} value of carbosulfan for *in vivo* mouse brain AChE was 14mg/kg, while this value was altered to 162mg/kg when PB was pretreated. Rat blood AChE and BuChE were similarly inhibited *in vivo* by carbosulfan administered i.p. at 130mg/kg. Maximum inhibition was observed at 8hr for AChE and 1hr for BuChE. When PB was pretreated, more inhibition was observed than that of the control.

These results showed that the bioactivation of carbosulfan is essential for showing its toxicological action and cytochrome P450 must be an important enzyme which possibly participated in the bioactivation process.

DOSE RESPONSE ANALYSIS OF FENTHION TOXICITY IN TWO BRAZILIAN POPULATIONS OF *Anastrepha fraterculus* (DIPTERA: TEPHRITIDAE)I.B.M. Da Cruz¹, E. Humeres², C. Bica¹, A.K. Oliveira¹

Departamento de Genética, Universidade Federal do Rio Grande do Sul, Porto Alegre, Brasil - Empresa de Pesquisa Agropecuária e Extensão Rural, São Joaquim, Brasil

Anastrepha fraterculus (Wiedemann), the South American fruit fly, highly polyphagous and known to attack dozens of cultivated and wild fruits (Malavasi et al. 1980; Norrbom & Kim 1988). In southern Brazil, it causes severe fruit damage in apple orchards. We estimated basic toxicity data for two *A. fraterculus* populations and general handling methods for contact and feeding bioassays in F1 of two south Brazilian field populations of the *A.* (N= 3.780). The slope are the same between males and females of populations studied. Contact bioassay was more effective ($LD_{50} = 1.11$ ppm) when compared to feeding bioassay ($LD_{50} = 20.51$ ppm). In these two different experiments males and females were similar in the responses. The results obtained could help the implementation of a rational *A. fraterculus* management integrated of pest (MIP) that is not yet made today and are related with biology, populational dinamic of South American fruit fly. Grants and Fellowships: CNPq, ABPM.

PHYSIOLOGICAL EFFECTS OF CHLORFLUAZURON ON THE REPRODUCTIVE ACTIVITY IN *SPODOPTERA LITURA*

T. Miyata, K. Yoshida

Laboratory of Applied Entomology, Faculty of Agricultural Sciences, Nagoya University, Chikusa, Nagoya, Japan

It is acknowledged that benzoylphenyl urea compounds inhibit chitin synthesis in insects and thus they disturb molting process and metamorphosis. Also benzoylphenyl urea compounds are known to affect the reproduction of insects. We investigated the reproductive effects of chlorfluazuron in *Spodoptera litura* topically applied at larval stage. When chlorfluazuron was applied to newly molted 5th instar larvae at a sublethal dose (LD_{10} , 31.2ng/larva), it was observed that the fecundity of the resulting adults as well as the hatching rate of their eggs was suppressed. The hatching rate of eggs oviposited by an untreated female copulated with a treated male was suppressed to the similar degree to that of eggs oviposited by a treated female copulated with a treated male. In males of *S. litura*, testes develop during the larval stage and attain complete differentiation in the pupal stage. Larval treatment of chlorfluazuron resulted in the reduction of the size of testes, the reduction of the number of sperm bundles, the delay of spermatogenesis, and the reduction of testes ecdysteroids. Thus, it was considered that the suppression of testis ecdysteroids titers by chlorfluazuron caused to decrease the number of sperm bundles and the sperm volume.

ACTIVITY OF AN ACETONIC EXTRACT OF *TRICHILIA HAVANENSIS* (MELIACEAE) ENDOSPERM ON *SPODOPTERA EXIGUA* LARVAEJ. Lopez-Olguin¹, M. C. de la Torre², E. Viñuela³, P. Castañera¹

1. Centro de Investigaciones Biológicas, CSIC, Madrid, Spain

2. Instituto de Química Orgánica, CSIC, Madrid, Spain.

3. Unidad Protección Cultivos, E.T.S.I. A, Madrid, Spain.

A bioassay-guided, silica gel column fractionation of an acetone endosperm extract of *Trichilia havanensis* Jacq. yielded seven fractions. Four of them were pure compounds, identified as the limonoids: azadirone, trichilenone acetate, 14,15-deoxyhavanensin-3,7-diacetate and 14,15-deoxyhavanensin-1,7-diacetate. Short-term choice and no-choice feeding bioassays of each fraction (at 1000 ppm) showed antifeedant activity against fifth instar larvae of *Spodoptera exigua* in the most polar fraction only.

Rechromatography of the active fraction resulted to be a mixture of two compounds. Both compounds were isolated and their structures, established by NMR, correspond to 14,15-deoxyhavanensin-1,7-diacetate and havanensin 1,7-diacetate (1:2 w/w). This mixture exhibited antifeedant activity (at 1000 ppm) in short-term choice and no-choice feeding bioassays. Interestingly, when both compounds were singly evaluated, havanensin 1,7-diacetate was the active one, though its activity was lower than that found in the mixture.

LABORATORY TOXICITY TEST OF SEVERAL NATURAL PESTICIDES ON *ALEURODICUS DISPERSUS* RUSSELL (HOM.: ALEYRODIDAE) THE SPIRALLING WHITEFLYI. Zoltan¹, E. Kiss Ferencné¹, I. Kajati², C. Budai¹, R. Torres³, M. Hernández-García³, E. Hernández-Suárez³, A. Carnero³.

(1) Csongrád Megyei Növényegységügyi és Talajvédelmi Allomás-Biológiai Védekezési Laboratórium. Hódmezővásárhely. Hungria. (2) Budapest Fővárosi Növényegységügyi Allomás. Budapest, Hungria. (3) Dpto. de Protección Vegetal, Instituto Canario de Investigaciones Agrarias, La Laguna, Tenerife. Islas Canarias, España.

The spiralling whitefly *Aleurodicus dispersus* was discovered in Canary Islands in 1964. However in the two last years it has been the first problem in the gardens of the coast areas of the Canaries.

The pesticides of Hungarian patent VEKTAFIG[®] A 1%, VEKTAFIG[®] R 1%, BIOSECT[®] 2% and TIOSOL[®] 1% were selected by their natural origin and the low toxicity on the beneficial insects and the human being.

The side effect of this natural pesticides on the pest *A. dispersus* were tested in laboratory going on the guidelines of the IOBC-Working Group of pesticides and beneficial Arthropods.

The best results were obtained with VEKTAFIG[®] A 1% and BIOSECT[®] 2% on the different development stages of the insect.

EVALUATION OF INSECTICIDE FOR *PIERIS BRASSICAE* (L) CONTROL ON CABBAGE IN MEGHALAYA, INDIA.

Prof. T.C.Deka, Department of Zoology, Gauhati University,
Guwahati - 781 014, Assam, India.

The recommendation of chemical for control of cabbage caterpillar eleven insecticides, malathion 50 Ec @ 1 kg. a. i/ha, chlorpyrifos 25 Ec @ 0.5 kg. /ha, monocrotophos 36 Ec @ 0.5kg./ha, fenvalerate 20 Ec @75 gm./ha, deltamethrin 2.8 Ec @ 12.5 gm/ha, cypermethrin 10 Ec @ 75 gm/ha, endosulphon 35 Ec @ 0.7 kg./ha, fenitrothion 50 Ec @ 0.8 kg./ha, quinalphos 25Ec @ 0.5 kg./ha, diflubenzuron 25 wp @ 75 gm/ha were tested in 3 replicated 2 trials on plots 3 x 2.5 m containing 20 plants at pre and post headed stage, when on them larval density was $14.67 - 23.67 = (\sqrt{x} + 0.5)$ in 1991-92.

The control status and yield data were analysed following DMRT (Duncan's multiple range test), the residual tolerance and cost benefit ratio (CBR) calculated. Evaluation showed 100% (99%) control by fenvalerate with 99% safety to natural enemies and mammal (LD 50,200-451), 97.73% (99%) by deltamethrine (LD 50, 128-138), 96.8% (98%) by cypermethrine (LD 50, 242-303), 85.2% (100%) by diflubenzuron (LD 50, 2150).

The CBR of fenvalerate yielded 172.13 q/ha with net gain of 96.8 q/ha (Rs. 29,558.00) CBR 1:43, deltamethrine and cypermethrine (Rs. 6,842.00 /ha) CBR 1:33, 1:32 and diflubenzuron (Rs. 10,481.00 /ha) CBR 1:44 . Therefore on economic gain, safety and environmental friendly reasons fenvalerate, deltamethrine, diflubenzuron and cypermethrine recommended to farmers.

TACTICS FOR MANAGEMENT OF INSECT RESISTANCE TO INSECTICIDES FROM PAST EXPERIMENTAL DATA

T.Saito
School of Agricultural Sciences, Nagoya
University, Furo-cho, Chikusa, Nagoya, JAPAN

Insect resistance to insecticides is very difficult matter for management of insect pest and meaning matter in the sciences include insect physiology, ecology, genetics, toxicology and biochemistry. Missing of excellent insecticides by occurring of resistance is very serious problem not only for industry also public sector and farmer. Because they can not establish insect control programme and can not recommend effective insecticides to their farmer.

We have many reports on the insecticide resistance from past experimental data. Regarding on origin of resistance, we believed that the insecticide acts to select those naturally possessing factors conferring resistance and that eventually the resistance progeny become dominant in the population. It is a kind of insect adaptation and revolution to insecticidal environment. Following suggestions could proposed tactics for management of insect resistance to insecticides.

1. Insecticide resistance monitoring in key insect pests.
2. Insecticide rotation use of no cross resistance insecticides.
3. The tactics of delaying of insect resistance to insecticides with pesticide management.

The studies on insecticide resistance in the diamondback moth, the brown planthopper and the citrus red mite have been conducted. Tactics for management of these insect pests resistance to insecticides and acaricides to be discussed.

19-096

THE TOXICITY OF CYROMAZINE TO *CHIRONOMUS ZEALANDICUS* AND *DELEATIDIUM* SP.

P.W. Robinson, R.R. Scott
Department of Entomology and Animal Ecology,
Lincoln University, Canterbury, New Zealand
Cyromazine and a commercial Formulation Vetrazin were tested against *Chironomus zealandicus* and *Deleatidium* sp. Under acute conditions, the LC50 values were comparable. For *C. zealandicus* they varied according to instar from 100-400 mg per litre for second and third instars to 1000-10000 mg per litre for old fourth instars. For the one size class of *Deleatidium* tested, the value was 300-400 mg per litre. In chronic whole-of-life tests with *C. zealandicus*, cyromazine was very toxic. A maximum acceptable toxicant concentration of 17.5 ug per litre was calculated. The implications of the difference between acute and chronic results for getting environmental exposure limits with compounds like cyromazine is discussed.

19-098

DETECTION AND MANAGEMENT OF RESISTANCE TO AZINPHOS-METHYL IN *CYDIA POMONELLA* (L.)

W. G. Thwaite
NSW Agriculture, Agricultural Research & Veterinary Centre, Orange,
N.S.W. Australia

Cydia pomonella (L.), codling moth, has long been a serious insect pest of apples and pears in south-east Australia. From 1950, following the loss of DDT through resistance, control in commercial orchards was largely based on carbamate and organophosphate insecticides. In the last 20 years, azinphos-methyl has provided the majority of the industry with cost-effective control.

Resistance to azinphos-methyl was first suspected in 1989 when a small number of apple growers in each of the three eastern mainland states of Australia experienced control failures which could not be attributed to pesticide application factors alone. Adult bioassays subsequently diagnosed resistance to azinphos-methyl up to 6.8 fold at the LC₅₀. Alternative insecticides for control were investigated but neither chlorpyrifos nor fenoxycarb were effective where resistance levels were highest. The range of chemical alternatives is limited because of increased reliance of the Australian apple and pear industry on integrated pest management practices.

A resistance management strategy was developed for the industry and is periodically reviewed. At present the strategy relies on growers decreasing the use of azinphos-methyl through improved timing using spray warning services and field monitoring. Orchard sanitation practices are recommended to reduce the carryover of *C. pomonella* between seasons. Mating disruption has been successful in limiting the use of insecticides for *C. pomonella* control in some orchards although used alone, mating disruption has not yet proved sufficiently robust under Australian conditions to become a major component of the strategy in orchards where resistance already occurs. Mating disruption in conjunction with a modified insecticide program is under investigation as part of the resistance management strategy.

EFFORTS TO REDUCE THE LEVELS OF CYROMAZINE RESISTANCE IN THE LEAFMINER, *LIRIOMYZA TRIFOLII*, POPULATIONS IN SOME TOMATO - PRODUCING AREAS OF SOUTH AFRICA

Desirée van Heerden

Roodeplaat Vegetable and Ornamental Plant Institute, Private Bag X293, PRETORIA, 0001, SOUTH AFRICA

One of the most important pests of tomatoes in certain areas in South Africa is the leafminer *Liriomyza trifolii* (Burgess) (Diptera: Agromyzidae) which was introduced to South Africa with chrysanthemum cuttings in 1983.
